U. S. DEPARTMENT OF AGRICULTURE.

Scientific Bureaus and Divisions.

WEATHER BUREAU—Willis L. Moore, *Chief*.
 BUREAU OF ANIMAL INDUSTRY—D. E. Salmon, *Chief*.
 BUREAU OF PLANT INDUSTRY—B. T. Galloway, *Chief*.
 BUREAU OF FORESTRY—Gifford Pinchot, *Forester*.
 BUREAU OF SOILS—M. Whitney, *Chief*.
 BUREAU OF CHEMISTRY—H. W. Wiley, *Chemist*.
 BUREAU OF STATISTICS—John Hyde, *Statistician*.
 DIVISION OF ENTOMOLOGY—L. O. Howard, *Entomologist*.
 DIVISION OF BIOLOGICAL SURVEY—C. Hart Merriam, *Chief*.
 DIVISION OF FOREIGN MARKETS—George K. Holmes, *Chief*.
 OFFICE OF PUBLIC ROAD INQUIRIES—Martin Dodge, *Director*.

OFFICE OF EXPERIMENT STATIONS—A. C. True, *Director*.

THE AGRICULTURAL EXPERIMENT STATIONS.

ALABAMA— College Station: <i>Auburn</i> ; J. F. Duggar. ^a Canebrake Station: <i>Uniontown</i> ; J. M. Richeson. ^a Tuskegee Station: <i>Tuskegee</i> ; G. W. Carver. ^a	MINNESOTA— <i>St. Anthony Park, St. Paul</i> ; W. M. Liggett. ^a MISSISSIPPI— <i>Agricultural College</i> ; W. L. Hutchin- son. ^a MISSOURI— College Station: <i>Columbia</i> ; H. J. Waters. ^a Fruit Station: <i>Mountain Grove</i> ; Paul Evans. ^a
ALASKA— <i>Sitka</i> ; C. C. Georgeson. ^b ARIZONA— <i>Tucson</i> ; R. H. Forbes. ^a ARKANSAS— <i>Fayetteville</i> ; W. G. Vincenheller. ^a CALIFORNIA— <i>Berkeley</i> ; E. W. Hilgard. ^a COLORADO— <i>Fort Collins</i> ; L. G. Carpenter. ^a CONNECTICUT— State Station: <i>New Haven</i> ; E. H. Jenkins. ^a Storrs Station: <i>Storrs</i> ; L. A. Clinton. ^a	MONTANA— <i>Bozeman</i> ; S. Fortier. ^a NEBRASKA— <i>Lincoln</i> ; E. A. Burnett. ^a NEVADA— <i>Reno</i> ; J. E. Stubbs. ^a NEW HAMPSHIRE— <i>Durham</i> ; F. W. Moore. ^d NEW JERSEY— <i>New Brunswick</i> ; E. B. Voorhees. ^a NEW MEXICO— <i>Mesilla Park</i> ; Luther Foster. ^a NEW YORK— State Station: <i>Geneva</i> ; W. H. Jordan. ^a Cornell Station: <i>Ithaca</i> ; I. P. Roberts. ^a
DELAWARE— <i>Newark</i> ; A. T. Neale. ^a FLORIDA— <i>Lake City</i> ; T. H. Talliaferro. ^a GEORGIA— <i>Experiment</i> ; R. J. Redding. ^a HAWAII— Federal Station: <i>Honolulu</i> ; J. G. Smith. ^b Sugar Planters' Station: <i>Honolulu</i> ; C. F. Eckart. ^a	NORTH CAROLINA— <i>Raleigh</i> ; R. W. Kilgore. ^a NORTH DAKOTA— <i>Agricultural College</i> ; J. H. Worst. ^a OHIO— <i>Wooster</i> ; C. E. Thorne. ^a OKLAHOMA— <i>Stillwater</i> ; J. Fields. ^a OREGON— <i>Corvallis</i> ; J. Withycombe. ^a PENNSYLVANIA— <i>State College</i> ; H. P. Armsby. ^a PORTO RICO— <i>Mayaguez</i> ; F. D. Gardner. ^b RHODE ISLAND— <i>Kingston</i> ; H. J. Wheeler. ^a SOUTH CAROLINA— <i>Clemson College</i> ; P. H. Mell. ^a SOUTH DAKOTA— <i>Brookings</i> ; James W. Wilson. ^a TENNESSEE— <i>Knoxville</i> ; A. M. Soule. ^a TEXAS— <i>College Station</i> ; W. B. Gibbs. ^a UTAH— <i>Logan</i> ; J. A. Widtsoe. ^a VERMONT— <i>Burlington</i> ; J. L. Hills. ^a VIRGINIA— <i>Blacksburg</i> ; J. M. McBryde. ^a WASHINGTON— <i>Pullman</i> ; E. A. Bryan. ^a WEST VIRGINIA— <i>Morgantown</i> ; J. H. Stewart. ^a WISCONSIN— <i>Madison</i> ; W. A. Henry. ^a WYOMING— <i>Laramie</i> ; B. C. Buffum. ^a

^a Director.

^b Special agent in charge.

^c Acting director.

^d Vice-director.

EXPERIMENT STATION RECORD.

Editor: E. W. ALLEN, Ph. D., *Assistant Director.*

EDITORIAL DEPARTMENTS.

Chemistry, Dairy Farming, and Dairying—The Editor and H. W. LAWSON.
 Meteorology, Fertilizers and Soils (including methods of analysis), and Agricultural
 Engineering—W. H. BEAL.
 Botany and Diseases of Plants—WALTER H. EVANS, Ph. D.
 Foods and Animal Production—C. F. LANGWORTHY, Ph. D.
 Field Crops—J. I. SCHULTE.
 Entomology and Veterinary Science—E. V. WILCOX, Ph. D.
 Horticulture—C. B. SMITH.
 With the cooperation of the scientific divisions of the Department.

EDITORIAL NOTES.

	Page.
Increased funds for station maintenance	1
Education of the American farmer	3
Royal Society's catalogue of scientific papers	4
Fiftieth anniversary of the first State experiment station	101
Prof. A. Petermann, founder of experiment station system of Belgium	103
Jacob Richards Dodge, agricultural statistician	104
Virchow's service to agriculture	105
Progress in plant breeding	205
Dr. Robert C. Kedzie, a pioneer in agricultural science	309
New yearbook of the Russian experiment stations	311
Overworking among experiment station men	413
Need of extending the scope of station operations	415
Some factors in research work	517
P. P. Dehérain, deceased	519
Agricultural experimentation in the Philippine Islands	621
The agricultural appropriation act, 1903-4	725
The Department publications	726
The soil survey in 1903	727
School garden at the Department of Agriculture	728
Need of experiments with horses	829
An index catalogue for agricultural libraries	830
An index of scientific periodicals	831
Memoir of the National Institute of Agriculture at Paris	832
Progress of secondary education in agriculture	933
The exhibit of the land-grant colleges and the experiment stations at St. Louis	1037
Conclusion of volume fourteen	1041

SPECIAL ARTICLES.

	Page.
Convention of Association of Official Agricultural Chemists, 1902, H. W. Lawson	107
International Conference on Plant Breeding and Hybridization, Walter H. Evans	208
Convention of Association of American Agricultural Colleges and Experiment Stations, D. J. Crosby	313
Agricultural Science at the American Association meeting.....	520
Values in science, W. H. Jordan	625
New buildings at the New Hampshire and Missouri agricultural colleges	729

STATION PUBLICATIONS ABSTRACTED.

ALABAMA COLLEGE STATION:

Bulletin 119, April, 1902	10
120, April, 1902	128
121, November, 1902	802
122, January, 1903	996
Fifteenth Annual Report, 1902	928

EXPERIMENT STATION RECORD.

VOL. XIV.

SEPTEMBER, 1902.

No. 1.

Although fine buildings do not insure an efficient and progressive experiment station, they contribute to this end, and they show the high regard in which the institution is held. They are indicative of the place which the station occupies as a State institution, and of its permanency; and, aside from furnishing superior facilities for investigation, they should stimulate to higher effort. The condition of the stations in this respect has been greatly improved within the past few years, as the result of specific State appropriations, a recognition on the part of the States which has been most gratifying, and has given encouragement to directors and workers alike.

But there is a danger that unless additional funds are given for general maintenance, these fine buildings may prove an embarrassment to the stations by increasing the expense of operation and the demands upon them. The increased laboratory and office facilities bring with them additional expenses for heat and light, janitor service, and incidental expenses, which are frequently not taken account of by those who appropriate the money. It is but reasonable to expect that such public buildings will be properly cared for and kept in good state of repair. A dirty, unkempt building reflects discredit upon the whole institution. Fortunately, such are not often found, although occasionally lack of means is plead in extenuation of a condition which is far from being a credit to a scientific institution.

Moreover, if the appropriation for the new building is not sufficient to cover the necessary equipment, as often happens, the departments occupying it may be seriously embarrassed for several years. New quarters invariably call for considerable additions to the movable equipment of the laboratories. The old fittings are rarely suited or adapted to the new rooms, and, at best, look out of place. More modern forms of apparatus and more permanent arrangements seem desirable in place of the former makeshifts. The result is that unless the appropriation makes provision for these, they are likely to be supplied out of the regular allotment for the several departments, diminishing the funds available for experiment and research. In a number of cases the efficiency of the departments has been temporarily reduced.

in consequence of this, and the investigations actually set back several years. And, finally, improvement in buildings and equipment unmistakably carries with it increased obligations. The public quite naturally expects more from a station which has been amply provided with quarters and equipment than one which has been compelled to run along from year to year without these improvements.

These considerations are not cited as reasons why the stations should not seek to obtain suitable accommodations for their work and adequate and thoroughly modern equipment for it. The improved facilities are one of the most encouraging signs of the times, as marking real progress. But the time is coming in most of the States, and is at hand in many of them, when increased funds for general maintenance are a more real and pressing need than additional buildings, or men even. The demands made upon the station for its services in a variety of directions have necessitated broadening and extending its work, until in many States it has reached the extreme limit which the present funds will allow. In not a few cases we have more departments than there are funds for, so that a part of them are stifled and held down to the sheerest necessities. Moreover, the character of the work of the stations is gradually undergoing a change. The simpler and more superficial problems in many lines of agriculture have been solved to a large extent, and demonstrated beyond doubt. The more complex and intricate investigations, involving deeper and more time-consuming research, will be the field more largely occupied by the leading stations in the future. Some have already entered it, and others are being stimulated and led on by their example. This means a more specialized station staff, assigned primarily to station work. There is a gradual tendency in that direction, and any movement in the direction of increasing the duties of station workers in elementary instruction is unmistakably to be regarded as a retrograde movement.

These conditions, as well as the more expensive plants of the stations, call for larger means for general maintenance; and this need is becoming imperative if the stations are to continue to advance in accordance with the demands which their popularity has brought about. Fortunately progress is being made in that direction, and State appropriations for special lines of investigation are increasing every year.

Every State has some leading branch of agriculture which would be especially benefited by the station's work, or some line in which special interest might be aroused which might be utilized in securing State appropriations. The stations have so abundantly demonstrated their usefulness and justified their cost that in most States organized interests can be incited to action if the needs are brought before them properly. It is a matter in which the interest is mutual. The success of every station helps all the others by example and precedent, and strengthens the whole cause.

It is a rather noteworthy fact that the Secretary of Agriculture should be invited to address such a body as the National Educational Association, upon a subject related to education in a special field, but it is significant of the position which the head of the National Department of Agriculture has attained within the past few years. Secretary Wilson's subject was, "The education of the American farmer," and the manner in which he treated it showed that he had bestowed much study on this branch of industrial education and its needs and requirements, and was thoroughly conversant with the latest progress and views regarding it. It was an earnest plea for the education of "the producers of wealth," to the end that they might not only become more intelligent and efficient in their craft, but might live on higher levels of comfort and happiness, and have more time to devote to intellectual, moral, and spiritual life.

Agricultural education was characterized as "the great field of applied science where the grower seeks the help of the scholar, of the experimenter, and of the observer." The breadth of the subject and its relations make it necessary that study "should begin with the primary school and continue through life. . . . The four-year college course does not begin soon enough nor continue long enough to meet the requirements of our day in this regard. Teachers are wanted in primary and secondary schools and in postgraduate work in the universities. They are wanted to do work that has not been done in all the ages—the discovery of truths underlying production, and their application to the farm."

Secretary Wilson commended very heartily the movement in a number of the States looking toward the introduction of the elements of agricultural science into common and secondary schools. The education of the teachers in these schools he believed to be the place to begin, and he advised that this should be provided at the expense of the State. "The faculty of the agricultural college of the State is the repository of this information, and the teachers should have their expenses paid while they are becoming possessed of it." The magnitude and character of this new departure should command the highest order of ability in working out the pedagogic scheme and in effecting the proper organization. "We want a man now to organize the education of half the people under our flag, who till the soil and furnish 65 per cent of our exports; who create the wealth of the country from materials found in earth, air, and water; we want organization from the primary schools to the university and beyond into fields, where things grow; into the stable and yard, through which crops go to the market; into the factory, where skill should add to value; into the pasture, where skill should direct form, feature, and development; into the cultivation, where science should defy drought and deluge; into fertilization, where observation and experience must be supplemented by education regarding soils and their composition."

The Secretary called attention to the growing need for education to assist not only the farmer himself, but all the agencies which are working in his interests, such as the National Department of Agriculture, the agricultural colleges, the State experiment stations, the high schools of agriculture, agricultural societies, the agricultural press, writers of books on agriculture, etc. All these agencies need more and better equipped men; and the best method of preparing them for their work is one of the unsolved problems in education. "Five thousand students attend agricultural colleges, but these colleges are feeling their way in the dark along untraveled paths. They are fitting and trying, as carpenters built barns in old times. They will at last forge out a system that will meet the requirements of producers and be entirely new and suitable to our conditions as a people." Summarizing the present status of agricultural education, he said in conclusion: "We find that progress is being made toward the education of the farmer; that belief is extending regarding its interest; that opposition is vanishing among educators whose studies did not include the science of the farm; that demand for instructors and organizers along these lines is growing; that, as a nation, our power for good at home and abroad depends upon the education of all our citizens; and that all classes, kindreds, tongues, and peoples look to you, the educators of America, to lift the whole up to higher intellectual and moral altitudes."

In 1867 the Royal Society of London commenced the publication of a Catalogue of Scientific Papers, to serve as an index to all important contributions to science contained in the transactions of societies, journals, and other periodical literature. The review began with publications of the year 1800, and the results of the compilation were issued from time to time in large quarto volumes of about 1,000 pages each. The eleventh volume, issued in 1895, brought the catalogue down to 1883; and a supplementary volume (volume 12) has just been issued, which is devoted to the more important papers omitted from the earlier volumes. This last volume embraces upwards of 350 serials, which were selected with care from a preliminary list of periodicals not previously catalogued.

The stupenduous nature of this undertaking is readily apparent, and the end is not yet, for the period from 1883 to 1900 remains to be compassed. The Royal Society purposes to complete the catalogue up to the close of the nineteenth century, at which point the work has already been taken up by an international organization.

The society announces that the Catalogue of Scientific Papers from 1883 to 1900 is now in hand, and that considerable progress has been made on a classified index to the twelve volumes already issued. As the arrangement is at present by authors only, the classified index will greatly enhance the value of the work and will make it an incomparable aid in looking up the literature upon a given subject.

RECENT WORK IN AGRICULTURAL SCIENCE.

CHEMISTRY.

Report of the Chemical laboratory of the Ploti Agricultural Experiment Station, B. M. VELBEL (*Sic. Rap. An. Sta. Expt. Agron. Ploti, 1900, pp. 73-111, 215-234*).—The work of this department of the station during the year included chemical studies of atmospheric precipitation, lysimeter water, products from the field experiments, and methods of analysis. It is a continuation of that of previous years (E. S. R., 12, p. 916) and has for its primary object a study of the evolution of the combinations and the annual balance of nitrogen in the soil. This involves the determination of the nitrogen brought down by precipitation, that lost in the drainage water, and that taken up by the products grown on the soil. The ammonia, nitrites, and nitrates in the atmospheric precipitation are reported. The lysimeters, having the same surface area as the rain gauges, viz, 500 sq. cm., were so placed as to collect drainage water to depths of 30 cm. (arable soil), 45 (arable and subarable soil), and 1 meter (subsoil). The relative solubility of the soil constituents, as shown by the analyses of the lysimeter waters, was (1) organic matter, (2) lime, (3) nitrates, (4) sodium chlorid, (5) silica, (6) magnesia, (7) iron oxid and alumina, (8) potassium chlorid, (9) phosphoric acid, and (10) sulphuric acid, i. e., organic substances and combinations of lime and nitric acid, probably $\text{Ca}(\text{NO}_3)_2$, predominated in the humus-calcareous soils experimented with. The effect of plant cover in reducing drainage losses was strikingly shown in these observations. The results show such a rapid removal of organic matter, nitrogen, and mineral matter from the arable layer (30 cm. deep) of the soil that impoverishment of the upper soil would soon result if the losses were not replaced. The amount of these constituents carried by the drainage water to a depth of 50 cm. was still quite large, but under the normal conditions obtaining in these observations the amount of drainage at 1 meter depth was very small (25 cc. during the year). From data showing the amount of combined nitrogen found in the drainage water during the year, it is estimated that one acre of the arable layer of the soil (to a depth of 30 cm.) yielded 21.125 lbs. of nitric nitrogen, of the arable and subarable layers (to a depth of 45 cm.) 37.72 lbs. of nitrogen. The rain, etc., which fell during the same period brought down 3.58 lbs. per acre of nitrifiable nitrogen. Deducting this, it appears that the arable layer produced 17.55 lbs. per acre of ammoniacal and nitric nitrogen, and the arable and subarable layers 34.14 lbs. per acre.

A comparison of the nitrogen required by the products grown on the soil with that brought down by rainfall, etc., shows the latter to be almost insignificant, and emphasizes the importance of adopting a system of culture and cropping, especially of green manuring, which will replace the losses which occur.

A method for determining small quantities of carbonates, A. D. HALL and E. J. RUSSELL (*Jour. Chem. Soc. [London], 81 (1902), No. 470, pp. 81-85, fig. 1*).—Methods employing Scheibler's apparatus are stated to be inaccurate for substances such as soils containing as little as 0.5 per cent of calcium carbonate, due to the solu-

bility of the carbon dioxide in the acid used in decomposing the carbonates. The method proposed by the authors is based upon the change in pressure produced when the unknown volume of gas, produced by the action in a partial or complete vacuum of dilute sulphuric acid upon the substance containing the carbonate, expands by a known volume which is measured by means of a glass bulb of known capacity and a manometer connected with the generating bulb. The apparatus used is described, the method of calculation of results is explained, and a number of determinations by the method are reported.

On the estimation of alkaline hydrate or bicarbonate in the presence of monocarbonate, B. NORTH (*Jour. Soc. Chem. Ind.*, 21 (1902), No. 5, pp. 322-325).

The detection of magnesia in ammonium oxalate precipitates of lime, A. TÄUBNER (*Chem. Ztg.*, 26 (1902), No. 23, p. 246).—It is stated that magnesium oxalate is sufficiently soluble in water to give a precipitate of silver oxalate when silver nitrate is added to the wash water of calcium oxalate precipitates.

The determination of caesium and rubidium as hydrosulphate and of potassium and sodium as pyrosulphate, P. E. BROWNING (*Ztschr. Anorgan. Chem.*, 29 (1901), No. 1, pp. 140-144).—Salts of caesium and rubidium with volatile acids give acid salts of the type $RHSO_4$ when treated with an excess of sulphuric acid and heated to constant weight at 250 to 270° C., and neutral salts of the type R_2SO_4 when heated to glowing. Under the same conditions potassium and sodium salts give pyrosulphates of the type $R_2S_2O_7$, which on heating are transformed into the neutral salts R_2SO_4 .

A contribution to the knowledge of metaphosphate, A. WIESLER (*Ztschr. Anorgan. Chem.*, 28 (1901), No. 3, pp. 177-209, figs. 3).

On calcium carbophosphate, A. BARILLÉ (*Répert. Pharm.*, 1901, p. 145; *abs. in Centbl. Agr. Chem.*, 31 (1902), No. 2, p. 136).—The author studied the solution of calcium phosphate in a water solution of carbon dioxide under pressure. He found that under these conditions a very unstable compound of biphosphate with carbon dioxide was formed, to which he gives the formula $P_2O_5 \cdot H_2Ca \cdot 2CO_2$. By the action of carbon dioxide on tricalcium phosphate there was formed first a biphosphate and calcium bicarbonate. The presence of the latter reduced the solubility of the biphosphates in water containing carbon dioxide to a very marked extent. Attempts to separate the calcium carbophosphate by cooling or adding alcohol failed, decomposition and evolution of carbon dioxide taking place under this treatment. No reaction took place when dry calcium biphosphate was treated with dry carbon dioxide.

Phospho-molybdenum compounds, F. MAWROW (*Ztschr. Anorgan. Chem.*, 28 (1901), No. 2, pp. 162-166; 29 (1901), No. 1, pp. 156-158).

The use of weak solvents in soil analysis, A. D. HALL and F. J. PLYMEN (*Jour. Southeast. Agr. Col.*, Wye, 1902, No. 11, pp. 90-99, figs. 3).—Comparative tests of citric, hydrochloric, acetic, and carbonic acids, and ammonium citrate as solvents for available phosphoric acid and potash in Rothamsted soils of known history are reported. The citric-acid method proposed by Dyer seemed to give results most in accord with what was known of the soils.

Report of the subcommittee on uniformity in analysis of materials for the Portland cement industry (*Jour. Soc. Chem. Ind.*, 21 (1902), No. 1, pp. 12-30).

The determination of nitrates in water by the indigo carmine method, S. R. TROTMAN and H. PETERS (*Jour. Soc. Chem. Ind.*, 21 (1902), No. 10, pp. 694, 695).—The method proposed is as follows: "From 5 to 20 cc. of the water under examination is mixed with 25 cc. of indigo carmine solution. To this is added concentrated sulphuric acid equal in amount to the united volumes of the water and indigo carmine solution. The whole is then heated on the sand bath for 15 minutes. At the end of this time, the excess of carmine solution is titrated with a standard solution of potassium permanganate. In a similar manner, and alongside the above, a blank estimation is done, replacing the water under observation by distilled water. The difference

between the two titrations is the amount used by the nitrates in the water. The permanganate solution is standardized by means of standard solution of potassium nitrate containing 0.0001 gm. of nitrogen per cubic centimeter."

The determination of nitrogen, E. DURAND (*Ann. Chim. Analyt.*, 7 (1902), pp. 17, 18; *abs. in Chem. Centbl.* 1902, I, No. 9, p. 541).—The author uses a copper digestion flask and employs copper sulphate or oxid instead of mercury.

Contribution to the determination of nitrogen, A. HEBBRAND (*Ztschr. Untersuch. Nahr. u. Genussmtl.*, 5 (1902), pp. 61, 62, figs. 2; *abs. in Chem. Centbl.*, 1902, I, No. 9, p. 541).—A description is given of an Erlenmeyer flask with a U-tube blown in its side which is recommended for the collection of the distillate in the Kjeldahl process.

A modified Argand burner for the first process in the Kjeldahl estimation of nitrogen, J. GOLDING (*Jour. Soc. Chem. Ind.*, 21 (1902), No. 10, p. 694, fig. 1).—"This is a simple device, consisting of a clip attached to a thin brass rod, the other end of which passes through a thicker rod, which screws into the foot of the Argand burner. The clip supports the neck of the flask, the weight of which rests on a pipeclay triangle; the rod is adjusted to the desired height by means of a screw in the end of the thicker rod. The advantages of using these burners are: (1) That a very low even heat can be obtained, thus enabling the determination of the nitrogen in liquids and solids which have a tendency to froth with the strong sulphuric acid; (2) that a strong heat can be produced without danger of the flasks breaking; (3) that the burners can be used for other purposes."

On the Kjeldahl method, C. NEUBERG (*Beitr. Chem. Physiol. u. Path. Ztschr. Biochem.*, 2 (1902), No. 4, p. 214).—The author proposes the use of sodium thiosulphate to break up mercury compounds before distillation.

Inorganic ferments, D. MCINTOSH (*Jour. Phys. Chem.*, 6 (1902), No. 1, pp. 15-44).—This is a study of the reducing action of colloidal silver and mercury on hydrogen peroxid.

Provisional methods for the analysis of foods adopted by the Association of Official Agricultural Chemists, November 14-16, 1901, edited by H. W. WILEY and W. D. BIGELOW (*U. S. Dept. Agr., Bureau of Chemistry Bul. 65*, pp. 169, figs. 7).—The bulletin is made up of the reports of the referee and his associates as amended and adopted provisionally by the association (*E. S. R.*, 13, p. 411). Methods are given for the examination of the following: Meat and meat products, by W. D. Bigelow; edible oils and fats, by L. M. Tolman; dairy products, by J. A. Le Clerc; infant and invalid foods, by H. W. Wiley; saccharine products, by A. E. Leach; canned vegetables, by L. S. Munson; spices, by A. L. Winton; vinegar, by W. Frear; flavoring extracts, by A. S. Mitchell; fruits and fruit products, by L. S. Munson and L. M. Tolman; fermented and distilled liquors, by W. D. Bigelow; baking powders and baking-powder chemicals, by A. L. Winton; food preservatives, by W. M. Allen, and coloring matter, by L. M. Tolman. Reference tables are added and an appendix gives suggestions from numerous analysts which, though not adopted by the association, were thought to be valuable and worthy of consideration.

Composition of nitrogen-free extract matter in potatoes, C. H. JONES and B. O. WHITE (*Vermont Sta. Rpt. 1901*, pp. 209-216).—Analyses of the nitrogen-free extract matter of 32 composite samples of potatoes of the crop of 1898 and 41 samples of the crop of 1899 are reported. Marketable and small potatoes of the White Star and Delaware varieties were examined in 1898, and of the Delaware variety in 1899. The potatoes were dug at different intervals during the growing season. The official methods of analysis, with some modifications noted, were employed. The aqueous extract was calculated as dextrin and soluble starch after allowing for the reducing sugars present. Starch was inverted by treating with 5 cc. hydrochloric acid for 45 minutes in a water bath at 90° C. Reducing sugars were present in small quantities and showed considerable variations among individual samples. Dextrin and soluble

starch were present in large quantities, which is considered as probably largely due to a change in the starch occurring during the preparation of the sample for analysis. It is recommended, therefore, that the analysis of the nitrogen-free extract matter should be made on the fresh undried sample. The starch contents varied indirectly with the amount of dextrin and soluble starch determined. The average composition of the marketable potatoes grown in 1899, calculated to the original substance, was as follows: Moisture 79.41 per cent, crude ash 1.26, crude protein 2.28, crude fiber 0.36, reducing sugars 0.09, dextrin and soluble starch 1.35, starch 14.51, ether extract 0.06, and undetermined 0.68 per cent.

Composition of nitrogen-free extract matter in artichokes, C. H. JONES and B. O. WHITE (*Vermont Sta. Rpt. 1901*, pp. 217-219).—Analyses of the nitrogen-free extract matter of 14 samples of artichokes obtained at different intervals during the season are reported. The average composition of 6 samples dug in November calculated to the original material was as follows: Moisture 79.59 per cent, crude ash 1.51, crude protein 2.12, crude fiber 0.74, reducing sugars (largely levulose) calculated as dextrose 0.70, sugars (levulin and a sugar resembling sucrose) calculated as sucrose 12.05, inulin 1.92, ether extract 0.08, and undetermined 1.29 per cent.

Concerning the sugars and organic acids in tropical fruits, A. BORNTREAGER (*Staz. Sper. Agr. Ital.*, 34 (1901), No. 10, pp. 975-992; *Ztschr. Untersuch. Nahr. u. Genussmit.*, 5 (1902), No. 4, pp. 145-155).—The fruits studied included *Diospyros lotus*, *D. virginiana*, *D. kaki*, *Sorbus domestica*, *Mespilus germanica*, *Arbutus unedo*, *Musa sapientum*, and *Eryobotrya japonica*.

The constituents of corn pith and elder pith and the occurrence of arabin and xylene together in plants, C. A. BROWNE, JR. (*Inaug. Diss., Göttingen, 1901*, pp. 51; *Ber. Deut. Chem. Gesell.*, 35 (1902), No. 8, pp. 1457-1467).—The author reports investigations carried out in the laboratory of Prof. B. Tollens. The composition of the two kinds of pith, as determined by the Weende method, was as follows:

Composition of corn pith and elder pith.

[Air-dry condition.]

Constituents.	Corn pith.	Elder pith.
	<i>Per ct.</i>	<i>Per ct.</i>
Water.....	9.81	11.28
Crude fiber.....	38.24	61.26
Ash.....	4.04	1.71
Fat.....	1.26	1.06
Protein.....	2.99	2.22
Nitrogen-free extract.....	43.66	22.47

The percentage of pentosans obtained by distillation with hydrochloric acid (1.06 sp. gr.) ranged from 24.45 to 27.04 per cent for corn pith, and was 18.81 per cent for elder pith. A mechanical separation was made of the fibrovascular bundles of corn pith from the fundamental tissue, and each examined separately. The latter constituted about three-fourths of the pith. Analysis showed practically no difference in the percentages of pentoses, fiber, and nitrogen-free extract in the two parts, but the fat and protein were somewhat higher in the fibrovascular bundles. Both kinds of pith were found to contain xylose in relatively large quantities and arabinose as well, from which the author is inclined to the belief that in very many cases, and perhaps in all, the mother substances of these pentoses occur together in nature.

The materials were hydrolized with dilute sulphuric acid and with acid sulphite of calcium, and various other experiments were made. Both kinds of pith were found to contain much cellulose which was not in free condition, but in combination with lignin substances, pentosans, galactan, etc. Pure cellulose was prepared by Cross and Bevan's chlorin method. This pure cellulose, although it gave none of

the reactions for pentosans, yielded considerable quantities of furfural when distilled with dilute hydrochloric acid—5.53 per cent from corn pith cellulose and 5.39 per cent from elder pith cellulose, which the author believes was derived from oxycelluloses which were either present in the original pith or more probably were formed during the oxidation.

The determination of pentoses and pentosans by means of distillation with hydrochloric acid and precipitation of the furfural by phloroglucin, E. KRÖBER and C. RIMBACH, reported by B. TOLLENS (*Ztschr. Angew. Chem.*, 15 (1902), No. 20, pp. 477-482).—The result of recent investigations of this method are summarized and quite minute directions given as to the distillation, the precipitation of the furfural, handling of the precipitate, etc. Hydrochloric acid of 1.08 and 1.1 sp. gr. was found to give somewhat higher results than that of 1.06 sp. gr., but the latter is adhered to as giving the more uniform result. The distillate is treated with an excess of phloroglucin, dissolved in 12 per cent hydrochloric acid, and allowed to stand for 12 to 14 hours, after which the precipitated furfural-phloroglucin is transferred to a porcelain Gooch crucible, washed with 150 cc. of water, and dried for 4 hours in a water bath at 97 to 98°. Kröber has found that it is immaterial whether the phloroglucin is absolutely pure or contains a little diorescin.

Kröber advises transferring the covered crucible to a stoppered weighing glass and placing this in a desiccator to cool, as by this means the hygroscopic phloroglucin is best protected from moisture. Drying for 4 hours is found to be sufficient, and allowing the open crucible to stand exposed to the air results in material increase in weight. The principal cause of lack of concordance in the results is the solubility of the phloroglucin in the 400 cc. of precipitant plus the 150 cc. of wash water. Rimbach found in special experiments that 0.005 gm. of phloroglucin was dissolved, and Kröber, on an average, 0.00518 gm. The use of a correction of 0.0052 gm. is suggested, and formulas are given on that basis. Kröber has prepared a table showing the amounts of pentoses and pentosans corresponding to different amounts of phloroglucin from 30 to 300 mg. This table is based upon special determinations made with all possible exactness. The results are generally somewhat lower than those previously given, but the close concordance between the data given by Rimbach and Kröber indicates the correctness of the new figures. A portion of the data are given in the following table:

Amounts of pentosans and pentoses corresponding to different amounts of phloroglucin.

Phloro-glucid.	Furfural.	Arabinose.	Araban.	Xylose.	Xylan.	Pentose.	Pentosan.
Gram.	Gram.	Gram.	Gram.	Gram.	Gram.	Gram.	Gram.
0.030	0.0182	0.0391	0.0344	0.0324	0.0285	0.0385	0.0315
.050	.0286	.0611	.0538	.0507	.0446	.0559	.0492
.074	.0411	.0875	.0770	.0726	.0639	.0801	.0700
.100	.0546	.1161	.1022	.0964	.0848	.1063	.0935
.169	.0904	.1919	.1688	.1592	.1401	.1756	.1546
.200	.1065	.2250	.1964	.1874	.1649	.2065	.1817
.300	.1581	.3335	.2935	.2784	.2450	.3060	.2693

Although the above factors represent the greatest exactness as yet obtained by this method, Professor Tollens states that it should be remembered that the present method for pentosan can not be regarded as an absolutely exact one, but only as a conventional method, which is the best we now have. In addition to the pentoses there are other materials, such as oxycellulose and glucuronic acid, which also yield furfural; and, furthermore, methyl-pentosans may occur, yielding methyl-furfural in the distillation, which in turn is precipitated as phloroglucin. These considerations, however, do not prevent the use of the pentosan method as a conventional method, and the employment of Kröber's method of weighing the phloroglucin and the use of his table will give more uniform results.

Employment of the pentosan determination in testing various vegetable materials and paper stock, E. KRÖBER and C. RIMBACH, reported by B. TOLLENS (*Ztschr. Angew. Chem.*, 15 (1902), No. 21, pp. 508-510).—The results of tests of various fiber substances are reported, indicating the applicability of the pentosan determination to the testing of paper stock for wood fiber, etc.

On the alleged reaction of brucin on nitrous acid, G. LUNGE (*Ztschr. Angew. Chem.*, 15 (1902), No. 1, pp. 1-3).—The author reports experiments which lead to the conclusion that brucin acts only on nitric acid and not on nitrous acid, and that if a brucin reaction is obtained in a nitrate solution free from nitric acid it is due to the formation of nitric acid from nitrous acid during the manipulation of the method.

On the behavior of nitric and nitrous acids toward brucin sulphuric acid, L. W. WINKLER (*Ztschr. Angew. Chem.*, 15 (1902), No. 8, pp. 170-172).—The author reports experiments which show that, contrary to the statement of G. Lunge, nitrous acid reacts more readily upon brucin than nitric acid.

The present status of the chemistry of albumin (*Ber. Deut. Chem. Gesell.*, 34 (1901), p. 3214; *abs. in Amer. Chem. Jour.*, 27 (1902), No. 2, pp. 147-154).—A summary of some of the more recent theories and experiments on the chemistry of albumin.

The effect of nascent chlorin upon proteids, R. EHRENFELD (*Ztschr. Physiol. Chem.*, 34 (1902), No. 5-6, pp. 556-579).

The coagulable material in the white of egg, L. LANGSTEIN (*Beitr. Chem. Physiol. u. Pathol. Ztschr. Biochem.*, 1 (1901), p. 83; *abs. in Hyg. Rundschau*, 12 (1902), No. 5, p. 239).—A chemical study.

The fluorin content of teeth and bones, I. JODLBAUER (*Ztschr. Biol.*, 41 (1901), No. 4, pp. 487-492).—Methods of estimating fluorin are critically discussed.

Miscellaneous analyses, C. H. JONES and B. O. WHITE (*Vermont Sta. Rpt. 1901*, pp. 223-226).—Analyses of 48 samples are reported, including nitrate of soda, dried blood, tankage, ground bone, bone dust, acid phosphate, muriate of potash, double manure salt, wood ashes, home-mixed fertilizers, muck, jadoo fiber, gluten meal, dried prepared squash, graham flour, and sugar feed.

New apparatus in water analysis, G. E. THOMAS and C. A. HALL (*Jour. Amer. Chem. Soc.*, 24 (1902), No. 6, pp. 535-539, figs. 4).—Apparatus for determining free and albuminoid ammonia, for collecting samples from reservoirs or rivers, for the determination of dissolved oxygen or carbon dioxide, and for filtering water for the determination of suspended matter are described.

New extraction apparatus, A. LANDSIEDL (*Chem. Ztg.*, 26 (1902), No. 25, pp. 274, 275, figs. 3).—Apparatus for use with solvents of high and low boiling points and for hot extraction are described.

A drying oven with circulation of air, W. GALLENKAMP (*Chem. Ztg.*, 26 (1902), No. 23, p. 249, fig. 1).

BOTANY.

The flora of the metamorphic region of Alabama, F. S. EARLE (*Alabama College Sta. Bul.* 119, pp. 43-120).—A list is given of the ferns and flowering plants of the metamorphic region of Alabama, based on the collections present in the herbarium of the Alabama Polytechnic Institute. This region is of botanical interest since it constitutes the southern extension of the Carolina life zone. A list is given of 1,146 species and varieties, 94 of which are new to the State.

Some changed conditions of our flora incident to the settlement of the State, L. H. PAMMEL (*Proc. Soc. Prom. Agr. Sci. 1901*, pp. 107-112).—Attention is called to some of the notable changes that have taken place in the flora of Iowa, which are attributed to the settlement and cultivation of the land. Data are given relating to the growth of a number of trees known to be 50 years old or less, including the height and circumference of individual trees. Changes brought about by

the construction of wind-breaks and hedges are mentioned, and the introduction of numerous classes of weeds is commented upon.

Review of the most useful plants of the family Leguminosæ, E. GOEZE (*Wiener Illus. Gart. Zig.*, 26 (1901), No. 1, pp. 15-28).—The leguminous plants cultivated for human food, forage, or other useful purpose, are catalogued for Europe, America, Asia, Africa, and Australia.

Notes on the northeastern Carices of the section Hyparrhenæ, M. L. FERNALD (*Proc. Amer. Acad. Arts and Sci.*, 37 (1902), No. 17, pp. 447-495, pls. 5).—A synopsis is given of the species of *Carex* occurring in the northeastern United States, as indicated in the above title.

The variations of some boreal Carices, M. L. FERNALD (*Proc. Amer. Acad. Arts and Sci.*, 37 (1902), No. 17, pp. 495-510).—Attention is called to the wide variation occurring in some of the species of *Carex* which frequent the higher latitudes of North America, Europe, and Asia.

The arrangement of the air canals in the stalks of Nymphæas, M. T. MASTERS (*Jour. Roy. Hort. Soc. [London]*, 26 (1902), No. 4, pp. 840-843, figs. 2).—The author claims that by a study of the transverse sections of the leaf and flower stalks of water lilies it is possible to present a scheme for classification of the different species. The air passages in the stems arrange themselves in definite orders, and a key is given for the determination of species based upon this character.

Behavior of mutilated seedlings, B. D. HALSTED (*Abs. in Science*, n. ser., 15 (1902), No. 376, pp. 407, 408).—The form of mutilation of seedlings reported upon is that of the removal of the plumule. In radish seedlings the first change noticed was a deeper green of the cotyledons, followed by a remarkable elongation of the petioles. The cotyledons became thicker than in normal plants, due to an increase in size of the cells which were filled with starch. A somewhat similar behavior was noted for the cotyledons of the morning-glory plants, while the hypocotyls became enlarged and served as repositories for a large accumulation of starch. In the Hubbard squash the cotyledons remained close to the earth and grew to a length of 4 or more inches, and remained green for more than 4 months. In experiments with eggplant the rigid upright cotyledons became quite fleshy and remained alive for several months. With sunflower the hypocotyl elongated until it attained a length of over 9 in., the primitive structure being retained. These experiments show that an organ normally designed to store food for the developing seedling may, in case of an emergency, persist and take on a greatly increased size for that purpose. Along with the other changes in the seed leaves, the hypocotyl becomes remarkably thickened and green in the morning-glory, and greatly elongated but slender in the sunflower.

The embryology and germination of the genus Peperomia, D. S. JOHNSON (*Abs. in Science*, n. ser., 15 (1902), No. 376, pp. 408, 409).—The ripe seed of this genus is about 0.5 mm. long, with a very small embryo surrounded by an endosperm 0.1 mm. in diameter. In germination the endosperm bursts out of the seed coat, but continues as a sort of jacket, 2 cells in thickness, to inclose the embryo until the latter, after reaching a size of 0.15 mm. as a globular mass of cells, at length develops 2 cotyledons and a root. The latter bursts through the endosperm and bending downward anchors in the soil. From the beginning of its development to the time when it drops, the endosperm seems never to serve for the storage of food material, but always as a digesting and absorbing organ for dissolving and passing to the embryo the starch contained in the perisperm. This is said to be the sole function of the endosperm in a number of other genera in which there is an abundant perisperm.

On kaki-shibu, a fruit juice in technical application in Japan, M. TSUKAMOTO (*Bul. Col. Agr. Imp. Univ. Tokyo*, 4 (1902), No. 5, pp. 329-335).—The name kaki-shibu is given in Japan to the juice of the unripe fruit of the Japanese persim-

mon or kaki tree (*Diospyros kaki*). This juice is used for the preservation of fish nets and lines, and as an application to packing papers, making them less penetrable to moisture, to tubs and wooden vessels, etc. There are two well-known varieties of kaki in Japan. In one the fruit becomes sweet when ripened, while the other remains astringent and is very rich in tannin, yielding a great quantity of the juice desirable for making kaki-shibu. When the fruit of this variety is fully grown, it is crushed and mixed with water, the mixture being allowed to remain 3 or 4 days in large tubs, when a kind of fermentation sets in, accompanied by the evolution of gas. The juice is generally prepared in August and may be applied fresh or after standing for 2 or 3 years. In contact with the air a film is formed over the surface, probably by oxidation. The solution leaves on evaporation an insoluble film that fills the pores of fibers and woods, diminishing their water-holding capacity and preventing the entrance of destructive fungi. The chemical properties of this material are described, the most characteristic constituent seeming to be a kind of tannin which has some abnormal properties. Tannin determinations have been made, and both gallotannic and quercitannic acids have been found present, constituting a large percentage of the dry matter. The industrial value of kaki-shibu, it is claimed, is due to the tannin, which differs from other tannins in being insoluble in water and alcohol, and soluble in dilute acids.

On the formation of asparagin in the metabolism of shoots, U. SUZUKI (*Bul. Col. Agr. Imp. Univ. Tokyo*, 4 (1902), No. 5, pp. 351-356).—While the various amido-compounds formed from protein during the germination process disappear gradually, with the further development of the shoots, the asparagin is said to increase to a certain phase, after which it also disappears. The amount of carbohydrates present in the seed seems to bear a direct relationship to the disappearance of the asparagin. With seeds rich in protein the accumulation of asparagin is greater. The author conducted a series of experiments with barley and soy-bean shoots which seem to confirm the previous observations of Palladin that asparagin must be considered as a synthetic product formed with the aid of an oxidation process, after partial destruction of the primary amido-compounds. In etiolated shoots the decomposition of protein continues in the absence of oxygen as well as in its presence. This is in accordance with what is known as the action of enzymes. A very decided difference in the production of asparagin is noticeable, there being no increase in the absence of oxygen, but only in its presence.

The amount of soluble albumin in different parts of plants, H. UNO (*Bul. Col. Agr. Imp. Univ. Tokyo*, 4 (1902), No. 5, pp. 391-393).—A report is given of studies of the different parts of plants for albumin, the investigations hitherto reported being mostly of seeds. Quantitative determinations were made of the roots, leaves, and flowers of rape, radish, cabbage, flax, barley, orchard grass, buckwheat, *Astragalus*, beans, peas, clover, *Lathyrus*, and potatoes. In most cases the leaves were found to contain the most soluble albumin. In leguminous plants, however, the greatest amount was present in the roots. This is doubtless due to the presence of tubercles upon the roots, the nodules not having been removed before the juice was expressed. In general, the stalks of the plants contain less soluble albumin than the roots. The influence of the flowering stage of the plant on the content of soluble albumin was investigated; but further studies will be required before general conclusions can be drawn.

On the juice of the pseudotrunk of *Musa basjoo* in winter time, S. SAWA (*Bul. Col. Agr. Imp. Univ. Tokyo*, 4 (1902), No. 5, pp. 399-401).—According to the author, banana plants grown in central Japan lose their leaves during the cold months, and there remains only the pseudotrunk, the interior of which seems to be sufficiently protected against the freezing temperature of the cold nights by the dead part surrounding it. This inner portion is subjected to a period of rest of about 4 months, and the investigations here reported were conducted to ascertain whether

during this time there was any noticeable decomposition of reserve protein. The juice of portions of the trunk was prepared for examination by methods which are described in detail. The results showed that neither asparagin, tyrosin, or leucin were present; hence that in the period of rest no decomposition of protein takes place in the juice of the plant.

The poisonous action of quinone, T. FURUTA (*Bul. Col. Agr. Imp. Univ. Tokyo*, 4 (1902), No. 5, pp. 407-410).—While many of the phenol derivatives have been tested for their poisonous properties, quinone seems to have been wholly neglected. According to Beijerinck, this substance is produced by the action of a soil fungus (*Streptothrix chromogena*) on certain proteids. The author has conducted a series of experiments with this substance to ascertain whether it is a general poison, his experiments being made with shoots, twigs, leaves, various algae and fungi, bacteria, insects, tadpoles, and mice. The different experiments are briefly outlined, and from the results obtained it is concluded that quinone is a strong poison, stronger indeed than the other closely related benzin derivatives. As a result of his investigations the author thinks there is little basis for the hypothesis of Beijerinck that the relatively large amount of humus in the soil is due to the action of quinone. He believes that if quinone is produced by the soil fungus it must be changed as soon as formed, for otherwise animal and vegetable life in the soil would be destroyed.

Are caffen and antipyrin in high dilutions poisonous to plants? S. SAWA (*Bul. Col. Agr. Imp. Univ. Tokyo*, 4 (1902), No. 5, pp. 411, 412).—The author carried on experiments with onion plants to determine the poisonous action of these alkaloids in high dilution. The plants remained alive for nearly four weeks in a solution containing 1 part of the alkaloids to 1,000 of the nutrient solution. The caffen gradually proved to be more injurious than the antipyrin. In the second experiment in which young celery plants were used the amount of the bases added to the solution was 0.1 and 0.25 per cent, respectively. In about 2 weeks the injurious action of the alkaloids was observed, commencing with the wilting of the leaves. The injurious effect of caffen in this high dilution appears remarkable since the epidermis of tea leaves is comparatively rich in it and remains uninjured. It is believed that the caffen here present is localized in the vacuoles and surrounded by such a density of cytoplasm as to protect the cell against injury.

Has urea any poisonous action on phænogams? S. SAWA (*Bul. Col. Agr. Imp. Univ. Tokyo*, 4 (1902), No. 5, pp. 413, 414).—As urine is sometimes applied as a manure before its urea is completely split up by bacterial action into ammonia and carbonic acid, the author has investigated the poisonous action of urea toward phænogams. Four plants were placed in a Knop's solution, two receiving an addition of 0.5 to 0.001 of urea. These plants were allowed to remain for 5 weeks in the solution, which was twice renewed during that time. They began the formation of flowers, but only one of those to which urea had been applied made a full flower development. The new branches developed by the 4 plants were much more vigorous on those plants grown in the control solutions than those which had received urea. The leaves began dying and at the expiration of 5 weeks the plants were measured. This showed the injurious action plainly, the control plants having made more than twice the growth of the others.

The poisonous action of potassium persulphate on plants, S. SAWA (*Bul. Col. Agr. Imp. Univ. Tokyo*, 4 (1902), No. 5, pp. 415, 416).—Experiments are reported in which a 0.5 per cent solution of potassium persulphate was applied to certain algae and diatoms, all of which died within 1 hour. Branches of rape plants in the same solution showed an injurious effect within 24 hours. An injurious effect of the same substance when still further diluted was shown on plum branches, the buds being entirely killed within 10 days. Onion plants were more resistant, showing the effects of the chemical on the tips of the leaves after 10 days, at which time growth seemed to stop.

The peculiar rôle of magnesia and sulphates in plant growth, R. DUMONT (*Prog. Agr. et Vit. (Éd. L'Est)*, 23 (1902), No. 10, pp. 292-297).—A brief general discussion of this subject based on the work of various investigators.

On the influence of different ratios of lime and magnesia upon the development of plants, K. Aso (*Bul. Col. Agr. Imp. Univ. Tokyo*, 4 (1902), No. 5, pp. 361-370, pls. 7).—A series of experiments is described in which the unfavorable effects of excesses of magnesia and lime are shown, and a ratio between the two for the most favorable development of crops is indicated. Experiments were conducted with barley, soy beans, and onions, in which the plants were grown under laboratory conditions, the effect of different quantities of both lime and magnesia being noted. In comparing the results it was found that with wheat, barley, and onions the excess of lime over magnesia may be less than with soy beans. The necessity for this difference is attributed to the greater leaf surface developed in the soy beans, necessitating an increase in lime. It is claimed that some attention should be paid to the proper ratio between lime and magnesia in the soils, especially in the available forms of those elements; and for liming the soil it is necessary to know the absolute quantity of lime present and also the ratio between the lime and magnesia. The poisonous action of the magnesia in the absence of lime is shown, and the influence of lime on the greater production of root hairs, and consequently of the absorptive area of the root, is pointed out.

To what extent should soil be limed? T. FURUTA (*Bul. Col. Agr. Imp. Univ. Tokyo*, 4 (1902), No. 5, pp. 371-379).—A series of experiments was carried on in soil mixtures in which the ratio of assimilable lime and magnesia was definitely fixed. The plants used in the experiment were cabbage, buckwheat, and oats. The ratio of lime to magnesia varied from 3 of lime to 1 of magnesia to 1 of lime to 2 of magnesia. The growth of the plants in the different soils is shown, and the conclusion drawn that the ratio of lime to magnesia for the best production of crops should be 3: 1, for crops which have an abundant leaf production; while for cereals a ratio of 1: 1 gives the best results.

The lime content of phanerogamic parasites, K. Aso (*Bul. Col. Agr. Imp. Univ. Tokyo*, 4 (1902), No. 5, pp. 387-389).—On account of the few ash analyses that have been reported of phanerogamic parasites, the author has investigated the subject and gives the results of analyses made of an orchid (*Gastrodia elata*). This plant, while probably not a parasite, exhibits some of the characteristics of parasitic plants in that there is little or no development of chlorophyll.

The lime factor for different crops, O. LOEW (*Bul. Col. Agr. Imp. Univ. Tokyo*, 4 (1902), No. 5, pp. 381-385).—The author reviews the papers of Aso and Furuta relative to the ratio between lime and magnesia required by plants, and comments upon their results.

Are our native horsetails and ferns poisonous? L. R. JONES (*Proc. Soc. Prom. Agr. Sci.* 1901, pp. 70-74).—A brief résumé is given of opinions relative to the poisonous properties of species of *Equisetum*, and an account of what is believed to be undoubtedly *Equisetum* poisoning of horses. It appears probable that *Equisetum arvense* often causes serious poisoning of horses in Vermont, and is fatal when eaten in considerable quantity. It is believed to be the cause of the sickness commonly called blind staggers or stomach staggers, and is doubtless the cause of more loss to stock owners in Vermont than any other poisonous plant. Conflicting evidence is presented relating to its poisonous action in reference to sheep, and cattle are said to feed upon it with impunity. Other species of *Equisetum* should be regarded as probably poisonous. The common belief seems to be that some of the ferns, particularly the sensitive fern (*Onoclea sensibilis*), are poisonous to horses, but the evidence in favor of this belief does not appear at all convincing.

Germination of Basidiomycetous spores, MARGARET E. FERGUSON (*Abstr. in Science*, n. ser., 15 (1902), No. 376, p. 407).—The investigations briefly outlined were

conducted to ascertain the conditions of germination in some of the Basidiomycetes, particularly in the common mushroom (*Agaricus campestris*). In the preliminary tests 12 out of 26 species studied yielded high percentages of germination in various media, the spores of 11 germinating in distilled water. In the case of those spores germinating in distilled water, the percentages of germination were invariably lower than when some food material was supplied. The effect of extremes of temperature, alkalis, acids, and organic substances on the germination of the spores of *A. campestris* was tested. The percentages of germination obtained in these experiments varied from 0 to 25. In other experiments higher percentages of germination were obtained, but these never occurred except in cultures containing the growing mycelium of the fungus.

Physiology of sea water, R. H. TRUE (*Abs. in Science*, n. ser., 15 (1902), No. 376, pp. 402, 403).—A series of experiments is reported in which the alga *Cladophora gracilis* was grown in various solutions to compare artificial and natural sea waters. The plant was able to survive without apparent injury in a cane-sugar solution containing 1.2 gram-molecules per liter. The greater or less proportion of the cells were able to live in weaker or stronger solutions, but their osmotic activity was somewhat disturbed. Plants were found to be fatally affected within an hour by solutions of common salt in all concentrations, and in a solution isotonic with sea water were destroyed within half an hour. A series of synthetic sea waters was prepared and tested, death occurring within half an hour in those solutions containing the amount of sodium chlorid present in the natural sea water at the location of the laboratory. When magnesium salts were added no marked change was to be seen. Upon the addition of a trace of calcium sulphate the time of survival was extended to about 2 hours, and upon the addition of potassium compounds the plants lived for about 24 hours. Although the synthetic solutions were isotonic with natural sea water, the artificial mixture was less saline to the taste than the former. Upon adding salt until about equal salinity was obtained, the artificial solution was found to be capable of supporting an apparently normal existence of the alga for 8 days. It appears from these experiments that not only the actual amount of substances dissolved, but the form in which they exist is of importance.

Water as a plant food, W. H. JORDAN (*Drainage Jour.*, 24 (1902), No. 3, pp. 53-55).—A popular discussion of this subject.

METEOROLOGY—CLIMATOLOGY.

Annual summary of meteorological observations in the United States, 1901 (*Mo. Weather Rev.*, 29 (1901), No. 13, pp. IX + 591-613, charts 7).—This number gives a table of contents, list of corrections, additions, and changes, and an index for volume 29; and a summary of observations on temperature, pressure, precipitation, wind movement, cloudiness, and other meteorological phenomena "based essentially upon data received from about 162 regular stations, 33 regular Canadian stations, and such voluntary stations as have forwarded their annual summaries in time."

Monthly Weather Review (*Mo. Weather Rev.*, 30 (1902), Nos. 1, pp. 1-60, charts 10; 2, pp. 61-108, figs. 5, charts 10; 3, pp. 109-156, figs. 7, charts 9).—In addition to the usual reports on forecasts, warnings, weather and crop conditions, meteorological tables and charts for the months of January, February, and March, 1902, recent papers bearing on meteorology, etc., these numbers contain the following articles and notes:

No. 1.—Special contributions on Earthquakes, Clouds, and Gales at Port Carolina, South Australia, by G. H. Styles; January Gales from the Great Lakes to the Maritime Provinces, by B. C. Webber; Abstract of a Comparison of the Minimum Temperatures Recorded at the United States Weather Bureau and the Forest Park Meteorological Observatories, St. Louis, Mo., for the year 1891, by W. H. Hammon and

F. W. Duenckel; Studies on the Statics and Kinematics of the Atmosphere in the United States—I, A new Barometric System for the United States, Canada, and the West Indies, by F. H. Bigelow; and the term Indian Summer, by A. Matthews; and notes and extracts on yellow snow in Michigan, Bartholomew's physical atlas—meteorology, the hurricanes of the far east, the Weather Bureau in the West Indies, fresh light on the Antarctic, a history of meteorological work in India, pamphlets relative to Wetterschiessen, the Third International Congress on Hail Shooting, general report on hail shooting presented to the congress at Lyons (by J. R. Plumondon), and Weather Bureau men as instructors and lecturers.

No. 2.—Special contributions on The term Indian Summer, by A. Matthews; and Studies on the Statics and Kinematics of the Atmosphere in the United States—II, Method of Observing and Discussing the Motions of the Atmosphere (illus.), by F. H. Bigelow.

No. 3.—Special contributions on Studies on the Statics and Kinematics of the Atmosphere in the United States—III, The Observed Circulation of the Atmosphere in the High and Low Areas (illus.), by F. H. Bigelow; Fog and Frost Formation, by D. Cuthbertson; and Some Experiments in Atmidometry (illus.), by J. S. Stevens; and notes and extracts on prize for pressure anemometer, hourly temperatures for Baltimore, Md. (illus.), meteorology and the schools, Pernter's meteorological optics, Second Mexican Congress of Meteorology, graduate study at Washington, the variation of the diurnal range of temperature with the latitude and locality, the "snow country" of central New York, and National Bureau of Standards.

Summaries of temperature, rainfall, and sunshine, E. F. LADD (*North Dakota Sta. Rpt. 1901*, pp. 11-13).—Tables give the maximum, minimum, and average monthly temperature, monthly rainfall, and sunshine for the year 1901.

Meteorology of 1901, A. BUCHAN (*Trans. Highland and Agr. Soc. Scotland*, 5. ser., 14 (1902), pp. 371-377).—A table gives the wind, mean pressure, temperature, rainfall, cloud, and sunshine for 1901, as compared with the average of the 45 years from 1856 to 1900 for all Scotland. The general features of the weather of each month of 1901 and the effect of the season on the growth of crops, especially wheat, barley, oats, potatoes, and turnips, are briefly discussed.

Meteorology, 1901-2, G. GINESTOUS (*Bul. Dir. Agr. et Com.*, 7 (1902), No. 23, pp. 237-241).—A summary of observations on temperature and rainfall during December, January, and February.

Report on the meteorological observations made in the society's gardens at Chiswick, 1901, E. MAWLEY (*Jour. Roy. Hort. Soc. [London]*, 26 (1902), No. 4, pp. 802-809, figs. 3).—Summaries for temperature and rainfall of each month are given.

A study of the climate of Tunis, G. GINESTOUS (*Bul. Dir. Agr. et Com.*, 7 (1902), No. 23, pp. 210-232, figs. 7, charts 3).—A summary of observations on temperature and pressure, wind, frost, humidity, evaporation, and casual phenomena during the months of March, April, and May.

The Third International Hail Protection Congress, Lyons, 1901, J. VANDERVAEREN (*Rev. Gén. Agron. [Louvain]*, 10 (1901), No. 12, pp. 529-544, pl. 1; 11 (1902), No. 1-2, pp. 1-30).—This is the report of the official representative of the French Ministry of Agriculture delegated to attend the congress and report its proceedings. It includes a summary of the proceedings and of the reports of the official representatives of the various countries participating in the congress, the resolutions adopted, and the author's conclusions from the proceedings of the congress. The principal features of the resolutions adopted have already been noted (E. S. R., 13, p. 626). In concluding his report, the author states that "if the reports, discussions, and conclusions of the congress at Lyons have not definitely solved the problem, neither have they produced a generally unfavorable impression regarding the firing,

nor have they served as a prelude to the funeral of the method, as some have thought; they encouraged, on the contrary, the most legitimate hopes of success in the struggle undertaken for protection against hail."

The mechanism and causation of hot waves, H. M. WATTS (*Jour. Franklin Inst.*, 153 (1902), No. 4, pp. 285-293, figs. 3).

SOILS.

Sixth annual report for the year 1900 of the Agricultural Experiment Station of Ploti (*Six. Rap. An. Sta. Expt. Agron. Ploty, 1900*, pp. XXVII+234, pls. 2, *dyms. 3*).—The report consists of separate reports of the experiment field, the chemical laboratory, the meteorological station, the vineyard, and of vegetation experiments, together with introductory articles by the founder and the editor-in-chief. The report is in the Russian language, but contains a French résumé of the work in the chemical laboratory (p. 5). (See also Field crops, p. 29.)

Report of the experiment field.—In experiments on the dependence of the temperature of the soil on the plant covering, one part of a small plat was planted to oats, while the other was left without a crop. Observations were made with 4 thermometers, of which 2 were placed under the plant on the surface of the soil and at a depth of 0.1 meter respectively, while the other 2 were similarly placed on the part without a crop. The experiments showed that the difference in temperature on the surface of the soil reached up to 15.4° C. and at a depth of 0.1 up to 7°.

In a study of the humidity of the soil in dependence on the kinds of fallow, the depth of plowing, and the plant covering determinations of humidity were made, as in previous years, on the green fertilized fallow of the four-course rotation, plowed to a depth of 7 in., on the black April and May fallows of the nine-course rotation, plowed to a depth of 7 and 10.5 in., and on an unplowed field. The results are summed up as follows: (1) The black fallow stands first in the matter of accumulating moisture, fields plowed in April next, while the fields plowed in May occupy the last place; (2) the loss of moisture during the winter, spring, and summer is greater on black fallow than on ground plowed in April or May; (3) the general amount of water stored up in the fields plowed in April was nearly the same as in those plowed in the fall, but as regards the yield the former exceed the latter; (4) deep plowing gave better results than shallow, except during the summer, when the influence of the plants reverses the conditions.

Vegetation experiments.—The comparative fertility of the different soil horizons was studied by taking samples of soil on which barley had grown to 3 different depths, from the surface to 10.5 in., 10.5 in. to 17.5 in., 17.5 in. to 24.5 in. Analysis showed that the soil at the lowest depth (subarable soil) was richer than the arable layer in all constituents except phosphoric acid. In the intermediate layer or horizon the amounts of potash, lime, and magnesia were larger than in the upper or arable layer, while the amounts of humus, nitrogen, and phosphoric acid were less. In pot experiments with the soil of these three horizons the yield of oats on the soil of the arable layer was much larger than in the other cases. This is explained by the fact that only the upper layer of soil has a sufficient supply of assimilable phosphoric acid. Assimilable nitrogen is distributed throughout the soil layers, and deep-rooted plants can secure all of this constituent which they require, even when the surface soil is somewhat deficient in nitrogen.

In the experiments with oats in the arable soil layer described above the amount of water evaporated daily from the soil receiving different fertilizers was determined throughout the whole period of vegetation. The results show that large crops were accompanied by larger absolute losses of water, although the relative amounts of water evaporated decreased. The increase of the yield in these experiments depended

on the nitrogen, i. e., on the element present in minimum. Hence the addition of nitrogen singly or in mixtures in almost all cases was accompanied by a decrease of the loss of water per unit of dry matter.

Report of the meteorological station.—Observations were made on the rainfall, evaporation, and humidity of the soil; on the temperature of the air and the soil; on the cloudiness, sun's radiation, and the intensity of the sun's rays; on the pressure of the air and on the wind, etc.

Report on the Plati vineyard.—The work here described relates to wine making as well as to grape culture.

The development of a soil survey, F. K. CAMERON (*Proc. Soc. Prom. Agr. Sci.* 1901, pp. 35-41).—This article discusses the development and the general features of the present method of conducting the soil surveys of the Bureau of Soils of this Department. It is stated that in general the main feature of the soil classification adopted is a physical one, but geological, chemical, and climatic conditions are also taken into consideration in the classification or establishment of types for particular areas. The soils are mapped in the field as the survey progresses from day to day on base maps in which the conventional scale of 1 in. to a mile is adopted. The observations in the field are supplemented by laboratory studies. The main advantages claimed for the system of classification are completeness and flexibility, permitting a ready correlation of the soil types of one area with those of another.

"The most striking practical result of the soil survey is the impetus which it has given to the idea of the adaptation of special crops to special soils," the prevailing idea in this line of soil investigation being to determine the soil areas adapted to particular crops, rather than the adaptation of the soil by the addition of fertilizers or by other means to some crop often selected without reference to its adaptability to the soil.

The soil as an economic and social factor, F. K. CAMERON (*Pop. Sci. Mo.*, 60 (1902), No. 6, pp. 539-550).

The investigation of cultivated soils, O. VIBRANS (*Bl. Zuckerrübenbau*, 9 (1902), pp. 25-31).—A general discussion of methods and results.

Agricultural soil studies, H. DUBBERS (*Jour. Landw.*, 50 (1902), No. 1, pp. 7-14).—A criticism of the practical usefulness of soil maps and charts based on geological classification, and suggestions as to their improvement in this respect by combining the agricultural with the geological classification. A system of nomenclature with convenient abbreviations for use on maps and charts is proposed.

Studies on cultivated soil, T. SCHLOESING (*Compt. Rend. Acad. Sci.*, Paris, 134 (1902), No. 11, pp. 631-635).—The author analyzed separately the particles which subsided after periods of 1 minute, 5 minutes, 1 hour, 5 hours, and 24 hours, in water in which soil had been shaken, as well as all the particles visible under the microscope which separated out from the dilute solution from the previous separations after several months' standing. It was found that the content of phosphoric acid and ferric oxid rapidly increased with the fineness of the particles, the ratio between the two remaining almost constant. The finest silt particles and the colloidal clay contained almost the same amounts of iron, ferric oxid, and phosphoric acid.

Soils of North Dakota, E. F. LADD (*North Dakota Sta. Rpt.* 1901, pp. 22-29).—This is a compilation of average analyses of typical soils and subsoils of the State examined during the past 12 years.

Soil moisture study, A. M. TEN EYCK (*North Dakota Sta. Rpt.* 1901, pp. 104, 105).—Determinations of the moisture in soils under different methods of treatment were made at seeding time (May 8) and at harvest time (August 8). At seeding time the moisture content of the soil to a depth of 2 feet was nearly uniform in 5 plats under observation. At harvest time summer fallowed land showed 24.4 per cent of moisture in 3 ft. of soil, corn land 24.2 per cent, and wheat land 10.2, and 11.2 per cent in plats fall and spring plowed, respectively.

Report on the clays of Maryland, H. RIES (*Maryland Geol. Survey*, 4 (1902), pp. 205-505, pls. 51, figs. 30).

On the plasticity of clay, P. ROHLAND (*Ztschr. Anorgan. Chem.*, 31 (1902), No. 1, pp. 158-160).—The plasticity of clay is ascribed to the constituents which form colloidal solutions with water.

Mineral in Jamaica soils, E. LEUSCHER (*Ztschr. Oeffentl. Chem.*, 8 (1902), pp. 28, 29).—An examination of black balls found in the clay soils and subsoils of Jamaica are reported, which show them to contain 14.75 per cent of manganese and 13.6 per cent of iron.

The Jurassic region of Belgium, A. HENRY (*Jour. Soc. Cent. Agr. Belg.*, 49 (1902), Nos. 2, pp. 90, 91; 3, pp. 120-122).—This is a brief account of the geological, soil, climatic, and agricultural conditions of this region.

The nature, value, and utilization of alkali lands, E. W. HILGARD (*Agr. Ledger*, 1901, No. 4 (Min. and Met. Ser., No. 17), pp. 41-69).—This is a review of California Station Bulletin 128 (E. S. R., 12, p. 221).

The effect of lime on the insoluble phosphates of the soil, W. F. SUTHERST (*Chem. News*, 85 (1902), No. 2210, p. 157; *Agr. Gaz. [London]*, 55 (1902), No. 1474, p. 204).—By mixing various iron and aluminium phosphates with twice their weight of slaked lime in the presence of water the following results were obtained: Proto-phosphate of iron, which originally contained only 2.47 per cent of phosphoric acid soluble in citric acid by Dyer's method, showed 19.55 per cent soluble after 24 hours' action of the lime, 22.15 per cent after 48 hours, and 22.26 per cent after 72 hours. Perphosphate of iron, originally containing 2.75 per cent of phosphoric acid soluble in citric acid, showed 21.96 per cent soluble after 24 hours, 22.41 per cent after 48 hours, and 22.45 per cent after 72 hours. Aluminium phosphate, containing originally 3.2 per cent of phosphoric acid soluble in citric acid, showed 18.45 per cent soluble after 24 hours, 19.88 per cent after 48 hours, and 20.65 per cent after 72 hours. "It is essential that the lime should be in the form of hydrate, the carbonate being of no value whatever."

What is the minimum content of lime in soils which respond to liming? LILIENTHAL (*Deut. Landw. Presse*, 29 (1902), Nos. 22, pp. 183, 184; 23, pp. 195, 196; 25, pp. 210, 211).—Comparative tests of lime, marl, etc., on a number of different kinds of soil are reported.

What practical deductions can the agriculturist draw from a knowledge of the calcium carbonate content of soils? M. PASSON (*Deut. Landw. Presse*, 29 (1902), No. 39, pp. 336, 337).—The author reviews a large number of experiments with fertilizers by different investigators to show that the action of different fertilizing materials is very largely dependent upon the lime content, especially assimilable lime, of the soil.

Irish soils, including the peat, G. H. KINAHAN (*Farmers' Gaz.*, 60 (1901), No. 51, pp. 922; 61 (1902), Nos. 4, p. 51; 5, p. 69; 7, p. 101; 10, pp. 156, 157; 12, p. 196; 13, p. 212).—A criticism of the publications of the Department of Agriculture and Technical Instruction of Ireland relating to soils, and a plea for the Geological Survey to undertake the study and mapping of soils, with suggestions as to how this should be done. The use of commercial fertilizers and of indigenous fertilizing materials, the soil-forming agencies, and the occurrence and character of the peat bogs are discussed.

Causes of sterility in peat soils, J. DUMONT (*Compt. Rend. Acad. Sci. Paris*, 133 (1901), pp. 1243-1246; *abs. in Jour. Chem. Soc. [London]*, 82 (1902), No. 472, II, p. 169).—"Whilst the nitrogen present in a sample of peaty soil nitrified extremely slowly, it was found that ammonium sulphate added to the same soil was quickly nitrified, indicating that the soil is favorable to nitrification, but not to the production of ammonia from organic nitrogen. Further experiments showed that the different samples of peaty soils examined contained very little potassium, and that the addition of potassium carbonate to one of them gave rise to the production of

ammonia. The best results were obtained by adding 2 per cent of potassium carbonate, but 1 per cent had a very considerable effect. The conclusion is drawn that potassium carbonate ought to be applied to peat land."

Soil temperatures at Flahult Moor Experiment Station, Sweden, 1897-1901. H. VON FEILITZEN (*Tidskr. Svenska Mosskult. Förening*, 16 (1902), No. 2, pp. 141-151).—Temperature measurements were made at depths of 20, 40, and 60 cm. on low and high moors, under various conditions of culture, some plats being sand-covered, others mixed with sand, drained by ditching to different depths, etc. The temperature of the soil was found to increase on the average about 1° C., through application of sand on the moor, and more with increasing quantities applied. The investigations furnish decisive evidence that moor soils may be rendered considerably warmer by applications of soil amendments. As a result the danger of frost is decreased, the soil can be worked and planted to crops earlier in the spring, and the crops grown therefore develop more rapidly.—F. W. WOLL.

The composition of soil samples from marsh land. O. VON CZADEK (*Ztschr. Landw. Versuchs. Oesterr.*, 5 (1902), No. 1, pp. 29-33, pl. 1; *abs. in Chem. Centbl.*, 1902, I, No. 6, p. 539).—A number of analyses of soil and subsoil are reported. These were made in connection with an attempt to improve the soils by the use of sewage from Vienna. The soils are generally fairly well supplied with plant foods, and their unproductiveness in many cases is attributed to unfavorable climatic conditions.

Results of vegetation experiments on marsh soils. B. TACKE (*Mitt. Deut. Landw. Gesell.*, 17 (1902), Nos. 18, pp. 99, 100; 19, pp. 101, 102).—These experiments were made in zinc pots containing about 19 kg. of the fresh soils. The two soils used contained only 8.24 and 8.99 per cent of organic and volatile matter, respectively. The results show that they were benefited by applications of lime and phosphoric acid, but apparently their greatest need was nitrogen. There seemed to be little demand for potash.

Soil tests and variety tests. E. W. HILGARD (*Proc. Soc. Prom. Agr. Sci.* 1901, pp. 89-94).—A paper discussing the methods of making soil and variety tests.

Nitrification in different soils. W. A. WITHERS and G. S. FRAPS (*Jour. Amer. Chem. Soc.*, 24 (1902), No. 6, pp. 528-534).—In continuation of previous studies on the rate of nitrification of different nitrogenous fertilizing materials (E. S. R., 13, p. 122), the authors studied the rate of nitrification of ammonium sulphate and cotton-seed meal in 11 soils obtained from different parts of the country and including sandy soil, light loam, heavy clay, black garden soil, etc., some of them being acid. The results are summarized as follows:

"(1) Addition of calcium carbonate invariably accelerates the nitrification of cotton-seed meal and ammonium sulphate, especially the latter.

"(2) In some soils a greater percentage of the nitrogen in ammonium sulphate is nitrified than that in cotton-seed meal, and in other soils the contrary is the case, even in the presence of calcium carbonate.

"(3) The factors which produce this result are probably as follows: (1) The presence of the ammonium sulphate diminishes the activity of the nitrifying organisms; (2) the acids produced also hinder them; (3) different soils contain different classes of organisms, some of which nitrify organic in preference to ammoniacal nitrogen.

"(4) We have found no evidence on record that organisms which nitrify organic nitrogen directly do not exist. The fact that they have not been isolated by present methods may be due to their elimination by the use of ammonium salts, on which they can not feed, in the nutritive medium.

"(5) Liming acid soils is favorable to nitrification.

"(6) Continuous application of ammonium sulphate to a soil previously limed increases its power of nitrifying ammonium sulphate."

Nitrogen of humus. A. DOJARENKO (*Landw. Vers. Stat.*, 56 (1902), No. 4, pp. 311-320).—Total nitrogen and nitrogen in form of amids, ammonia, and amido acids

are reported in humus derived from black humus soil and sandy and loam black soils. The percentage of total nitrogen in the humus varied from 2.74 to 4.59, from one-half to two-thirds of the nitrogen being in form of amido acids, a few hundredths per cent in form of ammonia, and the rest as amids.

Humus and soil fertility, H. SNYDER (*Proc. Soc. Prom. Agr. Sci.* 1901, pp. 62-65).—The value of humus for conserving moisture in the soil is discussed, and data for determinations of moisture at different dates on soils containing varying amounts of humus are reported. These show that "whenever the moisture content of the soil reached a comparatively low point the plat which contained the larger amount of humus and upon which the crops had been rotated always showed a higher per cent of water than the plat which had been under continuous wheat cultivation."

The chemical rôle of earthworms, H. D'ANCHALD (*Jour. Agr. Prat.*, n. ser., 3 (1902), No. 22, pp. 700, 701).—This is a summary of investigations by Dusserre,¹ which show that the excreta of earthworms contains more ammoniacal and nitric nitrogen and undergoes nitrification more rapidly than the original soil, that solubility of the phosphoric acid is increased in the soil by passing through the worms while that of the potash is not affected, and that there is a larger percentage of carbonate of lime in the excreta than in the soil.

The Campbell method of soil culture, H. M. COTTRELL (*Industrialist*, 28 (1902), No. 25, pp. 375-384, figs. 4).—The results of several years' tests of this method on the station grounds and on a farm in western Kansas are said to show it to be an effective means of conserving moisture in the soil in times of drought.

Interior land changes (*Queensland Agr. Jour.*, 10 (1902), No. 4, pp. 277-282, figs. 5).—An account is given of the changes which have been brought about in various parts of Australia by the shifting of sands during windy seasons. Various sand dunes are described, and for the prevention of their encroachment the author recommends the planting of wind-breaks wherever possible and the binding of the sands by planting various plants which are adapted to growth in such regions.

FERTILIZERS.

Organic nitrogen availability of fertilizing materials, C. H. JONES and B. O. WHITE (*Vermont Sta. Rpt.* 1901, pp. 219-221).—Determinations by the alkaline-permanganate method of availability of nitrogen in 61 samples of organic nitrogenous materials obtained from various sources are reported. The results confirm those of previous experiments (E. S. R., 12, p. 224) in showing "that the method is capable of making sharp and true distinctions between most nitrogenous materials used for fertilizing purposes, classifying them as good, medium, or poor. The chief material to which the method does injustice is cotton-seed meal, which has a recognized high availability, but which this treatment places in the medium to poor class. This eccentricity is due to the relatively large amount of nonnitrogenous organic matter contained in the cotton seed." It is recommended that fertilizers showing an availability of less than 50 per cent by this method be treated by the pepsin digestion process, "which does full justice to cotton-seed meal."

Observations on the number and depth of distribution of the roots of different plants under various systems of manuring the soil, C. VON SEELHORST (*Jour. Landw.*, 50 (1902), No. 1, pp. 91-104).—From the results of a number of experiments which are here reported the conclusion is drawn that plants when liberally fertilized not only have a larger root system, but these roots descend deeper into the soil, and are thus able to better withstand drought.

Manure from steers and swine, W. A. HENRY (*Breeders' Gaz.*, 41 (1902), No. 8, pp. 367, 368).—The percentage of nitrogen and ash voided as excrement or secured as animal produce with different farm animals is tabulated.

¹ Ann. Agr. Suisse, 1902, No. 2.

On the importance of recent bacteriological investigations for the question of rational utilization of the nitrogen content of farm-yard manure, H. G. SÖDERBAUM (*K. Landt. Akad. Handl. Tidskr.*, 40 (1901), No. 4, pp. 272-284).

The utilization of night soil as manure, R. S. JOSHI (*Dept. Land Records and Agr., Central Provinces [India], Bul.* 5, pp. 6).—The advantages of the method of dumping into shallow trenches with well pulverized bottoms from tank carts are explained.

On minerals occurring in Australian bat guano, R. W. E. MACIVOR (*Chem. News*, 85 (1902), Nos. 2212, pp. 181, 182; 2215, p. 217).—Analyses of phosphatic crystals found embedded in bat guano deposits are reported.

Green manuring on sugar estates (*Jour. Jamaica Agr. Soc.*, 6 (1902), No. 3, pp. 99, 100).—The general practice of green manuring to maintain the fertility of sugar-cane lands as is the case in Barbados is recommended.

The plowing under of green manures for winter plantings, CAUSEMANN (*Deut. Landw. Presse*, 29 (1902), No. 27, pp. 232, 233).

Experiments to test the value of 40 per cent potash salt as compared with kainit, M. MAERCKER and W. SCHNEIDEWIND (*Arb. Deut. Landw. Gesell.*, 1901, No. 56, pp. 240; 1902, No. 67, pp. 170; *abs. in Chem. Ztg.*, 26 (1902), No. 16, *Repert.*, p. 53).—These are detailed accounts of cooperative experiments during 2 years by a number of experiment stations in different parts of Germany to test the value of this new potash fertilizer. The 40 per cent salt is prepared from (1) carnallit or hartsalz by concentration, (2) sylvinite, (3) a mixture of crude, low-grade salts with potassium chlorid. The average composition of the product as put on the market is stated to be as follows: Moisture 3.6 per cent, potassium chlorid 62.5 per cent, potassium sulphate 1.9 per cent, magnesium sulphate 4.2 per cent, magnesium chlorid 2.1 per cent, sodium chlorid 20.2 per cent, gypsum 2.4 per cent, insoluble matter 3.1 per cent. The average percentage of potash is 40.53. In these experiments it was found that kainit gave better results than the 40 per cent salt on cereals on both light and heavy soils, and there was no appreciable injurious effect on the mechanical condition of the soil. In case of potatoes, however, the yields both of total crop and of starch were larger with the 40 per cent salt than with kainit. The highly bred varieties of sugar beets, unlike potatoes, appear to be very indifferent to mineral salts. The sugar content was increased by the application of the potash salts. The 40 per cent salt and the kainit were about equally effective. The 40 per cent salt may, however, be preferable for this crop, because it can be applied in large amounts without danger of injuriously affecting the mechanical condition of the soil.

Field experiments with ammonium sulphate in the Province of Posen, KLOEFFER (*Fühling's Landw. Ztg.*, 51 (1902), Nos. 6, pp. 193-197; 7, pp. 231-233).—Experiments on beets and potatoes with barnyard manure, and superphosphate with ammonium sulphate and sodium nitrate singly and combined are reported. There was a very close agreement in the results obtained from the use of the two sources of nitrogen.

Fertilizer experiments on moor soils, H. VON FEILITZEN (*Jour. Landw.*, 50 (1902), No. 1, pp. 77-90, *pls.* 3).—A brief account of experiments with potassic, phosphatic, and nitrogenous fertilizers at Flahult during 1887-1899. The soils were generally benefited by applications of potash and phosphoric acid, but responded most favorably to applications of nitrogen.

Phosphatic fertilizers for moor soils, K. C. LASSEN (*Ugeskr. Landm.*, 47 (1902), No. 6, pp. 70-72).

The better utilization of the nitrogen supply of the soil and air as a result of liberal applications of phosphoric acid, F. GIERBERG (*Deut. Landw. Presse*, 29 (1902), No. 37, p. 318, *fig.* 1).—Applications of from 200 to 800 kg. per hectare (178.51

to 714.04 lbs. per acre) of Thomas slag resulted in an increased total yield of wheat, potatoes, alfalfa, hay, and also an increase in total amount of nitrogenous matter.

The natural phosphates and their use in agriculture, MAIZIÈRES (*L'Engrais*, 17 (1902), No. 13, pp. 303, 304).—This article briefly reviews experiments with untreated phosphates by various investigators on different kinds of soils. The author considers the results inconclusive except as regards the favorable action of such phosphates on peaty soils and sandy plains.

Slags and superphosphates—results of 10 years' experiments, E. C. PRADEL (*Sta. Agron. Nancy, Bul. 4, 1901, pp. 15-24*).—The principal conclusion from these experiments is that slags are preferable to superphosphates on all soils containing less than 3 per cent of assimilable lime.

The agricultural value of Martin slag, A. PETERMANN (*Jour. Agr. Prat., n. ser.*, 3 (1902), No. 17, pp. 535, 536).—This is a basic slag similar to Thomas slag. Analyses of 4 samples reported in this article show percentages of phosphoric acid soluble in mineral acids varying from 2.12 to 10.8; of free lime from 0.19 to 3.7; soluble silica from 8.21 to 25.74. The solubility of the fine meal in Wagner's reagent varied from 76 to 100 per cent. In pot experiments with wheat using amounts of the two phosphates furnishing equal amounts of phosphoric acid the Martin slag was fully as effective as Thomas slag.

Discovery of mineral phosphates in South Australia (*Jour. Agr. and Ind. South Australia*, 5 (1902), No. 8, pp. 670, 671).—This is an extract from a report by H. Y. L. Brown to the minister of mines of South Australia announcing the discovery of phosphate deposits on Northern Yorke's Peninsula. The investigations made indicate "that the quantity of rock containing a sufficient percentage of phosphate of lime to render it of commercial value is very large, and the configuration of the country is most favorable to the opening of quarries, whereby the rock can be raised cheaply and expeditiously, and shipments averaging 70 per cent of tricalcic phosphate and less than 6 per cent of iron and alumina could be easily selected."

Note on free acid in superphosphate, J. OSTERSETZER (*Chem. News*, 85 (1902), No. 2213, pp. 195, 196).—A brief note on the appearance of intermediate tints between opalescence and complete neutrality when titrating superphosphates with half-normal or tenth-normal sodium hydroxid using various indicators.

Buying and using commercial fertilizers, L. A. CLINTON (*New York Cornell Sta. Bul. 201, pp. 179-195, figs. 6*).—This bulletin discusses methods of calculating the commercial value of fertilizers and the economy of buying unmixed fertilizing materials and mixing them on the farm, and reports the results of comparative tests of acid phosphate (dissolved rock phosphate), basic slag, floats, and dissolved boneblack on clover, Canada field peas, rape, radishes, oats, barley, and parsnips grown in boxes filled with quartz sand. The acid phosphate used contained 12.42 per cent of soluble phosphoric acid, 17.45 per cent available, and 18.36 per cent total phosphoric acid. The corresponding percentages for the dissolved boneblack were 10.71, 14.61, and 16.25. The basic slag contained 15.94 per cent of total phosphoric acid, the floats 31.37 per cent. The best returns were secured with acid phosphate and dissolved boneblack in nearly every case. The two were about equally effective on clover and peas. These crops were apparently able to make some use of the basic slag, but the product was only about half of that secured with the soluble phosphates. The untreated phosphate (floats) was apparently without effect on the clover and peas. Rape made best growth with floats, radishes with acid phosphate, although the yield of the latter was increased by the floats and basic slag. "The results seem to show that the members of the Crucifere order are able to extract food from the insoluble forms of phosphoric acid." The largest yields of oats and barley were obtained with the soluble phosphates, the oats making a better growth with basic

slag and floats than the barley. Parsnips gave better results with dissolved bone-black and apparently made little use of basic slag and none of floats.

The purchase of artificial manures (*Jour. Bd. Agr. [London]*, 8 (1902), No. 4, pp. 447-458).—A general discussion of the sources and valuation of fertilizing materials.

Fertilizers. I, Sources and composition, B. H. HITE (*West Virginia Sta. Bul.* 80, pp. 271-351).—A general treatise on this subject.

Commercial fertilizers, H. A. HOUSTON and W. J. JONES (*Purdue Univ. Spec. Bul.* 1902, Apr., pp. 35).—During the year 1901, 592 samples of fertilizers were collected and analyzed. The results are reported in detail with the text of the Indiana fertilizer law which went into effect March 11, 1901, and a list of all fertilizers that were legally on sale in Indiana April 1, 1902.

Analyses of commercial fertilizers and Paris green, W. C. STUBBS (*Louisiana Sta. Bul.* 65, pp. 629-774).—This is an account of fertilizer inspection in Louisiana during the season of 1900-1901, involving analyses of 2,510 samples of fertilizers and fertilizing materials. The bulletin also contains a discussion of the nature and sources of materials furnishing nitrogen, phosphoric acid, and potash; the valuation of fertilizers; the purposes and methods of inspection, with the text of the fertilizer law; and reports analyses of 140 samples of Paris green inspected during the season.

Analyses of commercial fertilizers, J. L. HILLS, C. H. JONES, and B. O. WHITE (*Vermont Sta. Bul.* 92, pp. 55-76).—Analyses and valuation of samples of 40 brands of fertilizers are reported, with a brief discussion of the commercial valuation and agricultural value of fertilizers, and the average composition of the leading brands sold in the State during the last 5 years.

Commercial fertilizers, J. H. STEWART and B. H. HITE (*West Virginia Sta. Bul.* 79, pp. 233-267).—Analyses and valuations of 262 samples of fertilizing materials examined during the year ended December 31, 1901.

The new fertilizer law, J. H. STEWART (*West Virginia Sta. Bul.* 77, pp. 199-212).—The text of the West Virginia fertilizer law, which took effect May 2, 1901, with comments and explanations.

Regulations concerning the sale of artificial fertilizers, feeding stuffs, and seeds in Finland, G. GROTEFELT (*Landbr. Styr. Meddel.*, No. 36, 1902, pp. 109).

Artificial manures in Russia (*Jour. Soc. Chem. Ind.*, 21 (1902), No. 7, p. 511).—The extent of the use of fertilizers in Russia is discussed.

Boiler scale, E. F. LADD (*North Dakota Sta. Rpt.* 1901, p. 21).—Analyses of 2 samples of boiler scale are reported.

FIELD CROPS.

Report on field crops, J. H. SHEPPERD and A. M. TEN Eyck (*North Dakota Sta. Rpt.* 1901, pp. 44-89, 98-104, 106, 107, fig. 1).—A general description is given of the work of the agricultural department for 1901, and the results obtained in the different experiments are presented in tables and briefly considered. The work for this season was largely in continuation of experiments previously reported (*E. S. R.*, 13, p. 336).

Wheat.—A field trial was made of 38 varieties, of which 17 were macaroni wheats. Aronautka, a macaroni variety, headed the list with a yield of 34 bu. per acre. Among the blue stem varieties American, closely seconded by Selected Haynes, stood first in yield. Among the Fife varieties Minnesota No. 285 stood first. The average yield for 8 years of blue stem varieties was 24.9 and of Fife varieties 24 bu. per acre. The average yield of the 5 leading varieties in each class in 1901 was 33.1 bu. per acre for macaroni wheats, 29.7 for blue stem varieties, and 27.6 for Fife varieties. For the 3 seasons that macaroni varieties have been grown at the station they have twice given better yields than the other wheats. In 1901 sowing at the rate of

5½ pks. of seed per acre gave the best yield, but the average yields for 4 years are in favor of 6 and 7 pks. of seed per acre.

Experiments in plowing for wheat begun in previous years were continued. As indicated by the average results fall plowing gave better yields than spring plowing. In some seasons spring plowing gave the best returns. For 5 years, including the season of 1901, fall plowing from 3 to 4 in. deep was compared with plowing from 6 to 7 in. deep. The results were in favor of deep plowing, but the difference in the average yields was only 0.6 of a bushel per acre. The outcome of a similar experiment carried on for 3 years with spring plowing also favored the deeper plowing, the difference in the average yields per acre in this case being 0.9 of a bushel. A comparison for 4 years of disk and moldboard plowing either in the fall or spring gave results in favor of the moldboard plowing. Trials with different makes of disk plows are reported in this connection.

Oats.—Of 26 varieties grown in 1901, Minnesota No. 202, Silver Mine, Early Gothland, Siberian White, and Bow of Promise, given in the order of productiveness, were the leading sorts. The yield of Minnesota No. 202, tested at this station for the first time, was 67.1 bu. per acre, while the yield of the other 4 varieties ranged from 60.3 to 60.9 bu. Early Gothland, which has proved a good yielder, and Siberian White and Bow of Promise produced a grain of fine appearance and quality.

Barley.—Fifteen varieties were grown this season. The best yielding varieties were Mandscheuri, Manshury, Minnesota No. 87, Minnesota No. 105, and Minnesota No. 32, producing 45.1, 42.1, 40.4, 40.3, and 40 bu. per acre, respectively. Mandscheuri and Manshury barley are considered identical. In trials carried on for 8 years, Manshury 6-rowed barley has proved to be one of the best yielding varieties.

Emmer.—Emmer from Dakota-grown seed yielded 48.7 bu. per acre, and from seed obtained from this Department 56 bu. A history of this grain is given, reference is made to its being erroneously called spelt, and its yielding capacity and feeding value are compared with barley, oats, and wheat.

Flax.—In growing flax for comparison it was estimated that the crop of common flax was at least one-fourth better than Argentine flax. The thinnest seeding, 1½ pks. per acre, produced the largest crop of seed and straw.

Potatoes.—A field trial of 21 varieties was conducted. The leading varieties were Sunlight, Daughter of Rose, Million Dollar, Rose of the North, and Mark Hanna, yielding 207.5, 199.2, 181.1, 174.2, and 171.6 bu. per acre, respectively. Early Andes and Rural New Yorker No. 2 have been grown at the station for several years and improved by selection. The results, with descriptive notes on all the varieties grown, are tabulated.

Brome grass.—A series of brief reports on the value of brome grass from farmers throughout the State is given, and the culture of brome grass discussed.

Results at the Edgeley substation.—A description of the station and its organization is given, and the results obtained in 1901 are briefly reported. Shallow plowing for wheat yielded 55 per cent more than deep plowing. A test of Aronautka macaroni wheat resulted in a yield of 9 bu. per acre. Harrowing wheat 3 times after it had begun its growth resulted in a failure of the crop. Culture tests with emmer, oats, flax, corn, millet, Kafir corn, Canadian field peas, Japanese barnyard grass, brome grass, Turkestan alfalfa, rape, potatoes, sugar beets, and artichokes are briefly recorded. A study of the distribution of the roots of corn between two hills 3½ ft. apart showed that some of the roots had attained a length of 5 ft., extending from hill to hill and from 2 to 3 ft. into the soil.

Report of the botanist, H. L. BOLLEY (North Dakota Sta. Rpt. 1901, pp. 30-44).—*Wheat.*—These experiments are in continuation of work in progress for 4 years and previously described (E. S. R., 13, p. 345). This season the results of tests in the selection of wheat from the individual heads were inconclusive. The general results of the tests for the 4 years show that perfect grains of large size and greatest weight

produce better plants than perfect grains of smaller size and weight even if the grains came from the same head. The importance of the quality of the seed and of a proper and even depth of seeding is also indicated by the results. It is concluded that the depth of seeding should be about 1 in. The results of selecting wheat from the bin corresponded closely to those of the previous season.

The growth of wheat from mature and immature seed showed that of weak and immature grains, although giving a high percentage of growth in the germinator, over 50 per cent failed to give good results under field conditions. The seed used represented three degrees of maturity, namely, grains harvested when in the milk stage, grains harvested in a soft doughy stage, and thoroughly mature grains. The mature seed produced the most stools and the heaviest yield.

Germination tests of wheat injured by moisture after maturity with brief descriptive notes on each sample are reported in a table. In connection with this work it was noticed that in a dry soil soft seeds came up quicker than hard seeds, but that when the soil was moistened the soft seeds decayed rapidly while the hard seeds survived.

The growth of wheat in the field was compared with laboratory germination tests, and these results are also given in tabular form. On an average for the 18 samples tested, the difference between the number of stools matured in the field and the percentage of growing grains in the germination tests was about 12.

Flax.—Germination and field tests of flax injured in different ways are reported. The highest percentage of plants which matured in the field in these experiments was 29. The results of experiments in the improvement of flax by the selection of seed from individual plants is reported in Bulletin 50 of the station (page 55). With reference to shallow and deep planting of flax, the author makes the following statement: "All my observations cause me to believe that the seed bed for flax should be as firm as possible and that the depth of planting should if possible not exceed an inch of dirt cover."

Potatoes.—The general results obtained in 1901 bear out the conclusions given in a former bulletin (E. S. R., 9, p. 942). The general conclusion is drawn from experiments conducted for several years that the two ends of a tuber are practically of equal seed value. An experiment to determine the possibility of root fusion is reported, but the results were negative.

Miscellaneous experiments.—A series of germination tests of weed seeds planted at different depths was made. The greatest depth from which a seed produced a plant was 5 in. in the case of *Ambrosia trifida*. The prevalence of different plant diseases during the year is briefly discussed. A short note on the work in general for the year is given, and the new laboratories of the department are briefly described.

Experiments with field crops, R. S. SHAW (*Montana Sta. Bul. 32, pp. 16-20*).—This is a concise report on variety, culture, and rotation tests. Forty-three selected varieties of wheat gave an average yield of 52.6 bu. per acre. The best results for several years have been obtained from Kubanka, Red Fife, Russian 2955, Wild Goose, Wellman Fife, and McKissock Fife.

The average yield of 33 varieties of oats selected from a collection tested for some years was 87.9 bu. per acre. This season Poland White, American White, White Wonder, and Nameless Beauty were selected. White Russian, a variety selected the previous year, yielded at the rate of 110 bu. per acre, and the grain after cleaning and grading weighed 44 lbs. per measured bushel.

From about a dozen varieties of peas, Mummy and Canadian Golden Vine were the only varieties considered valuable.

The selections made from 52 varieties of potatoes under test were as follows: *Early varieties*—Six Weeks Market, Acme, Early Ohio, Early Oxford, and Early Vaughan; *medium varieties*—Rural New Yorker No. 2, Lee Favorite, Snow Drop, American Wonder, and Oregon Pearl; *late varieties*—White Maine.

A test of a 6-year rotation has been in progress for 4 years, and the yields from the different plats are recorded. The crops in rotation are wheat, clover, barley, sugar beets, oats, and peas. All yields, with the exception of the yield of sugar beets, show an increase in the productiveness of the different plats.

Brief notes on the work with barley, rye, and root crops are also given.

The Woburn field experiments, 1899 and 1900, J. A. VOELCKER (*Jour. Roy. Agr. Soc. England*, 62 (1901), pp. 272-299, figs. 5).—The plan of these experiments has been previously described, and the results of former years reported (*E. S. R.*, 12, p. 132). In this report the results for 1899 and 1900 are tabulated and discussed.

In the continuous wheat-growing experiments, where the same fertilizers are applied every year, lime proved very beneficial in both years. In 1899 the nitrate of soda plats gave higher yields than the corresponding ammonia salts plats. The omission of nitrate of soda for a single year reduced the yield of grain 31 bu. per acre, and gave a crop only slightly exceeding the yield of the unmanured plats, while the corresponding omission of ammonia salts reduced the yield only 13 bu., and a crop of 10 bu. in excess of the unmanured wheat was obtained. The ammonia salts produced a better quality of grain than the nitrate of soda, the poorest grain being produced on the plat which had received nitrate of soda alone. Rape dust used in quantities furnishing the same amount of plant food as 100 lbs. of ammonia per acre proved more efficient than barnyard manure, and in each case previous applications of these slowly acting manures showed some effect on succeeding crops. In 1900, the twenty-fourth season of these experiments, the results with ammonia salts and nitrate of soda were relatively the same as in 1899.

The results of the continuous barley growing experiments in 1899 show that nitrate of soda gave better results than ammonia salts under the same conditions, the yields for both fertilizers being above the average. The use of lime with ammonia salts in these tests showed a very marked and favorable effect on the yield. Barnyard manure produced a better crop than rape dust, and here also, as in the case with wheat, the residual effects of these manures were quite marked. The quality of the barley as a whole, as well as the yield, was inferior, but the lower grade of barley was produced where nitrate of soda was used alone. The results of 1900 were similar to those obtained the year before. Pot experiments with barley, wheat, oats, and peas grown in soil from the plat on which ammonia salts alone had been used for 23 years showed that barley failed to grow, wheat grew fairly well, and oats excellently, while peas made only a stunted growth. The addition of carbonate of potash to the soil did not seem to have any effect.

The tabulated results of rotation experiments show that in one case wheat was more benefited by green manuring with tares than with cruciferous crops, such as mustard or rape, while in another mustard as a green manure was more effective than either tares or rape. The relative manurial value of decorticated cotton cake and maize meal was studied in this connection. In the rotation experiments the difference between manured and unmanured plats was inconsiderable, and the yields in general were lower than in previous years. Kiln-drying barley seed before sowing did not have any particular advantage. The best yielding varieties of barley were Danish, Golden Melon, and Goldthorpe, in the order given. Lucern on plats fertilized annually with 4 cwt. each of superphosphate, bone dust, and sulphate of potash, and 2 cwt. of nitrate of soda or sulphate of ammonia, gave much better yields than where other combinations or no manure were applied. A comparison of English and French sainfoin seed during the first year of the test did not show a very marked difference. An application of 2 tons of lime per acre in 1893 and 1900 on old pasture gave the best results as compared with other fertilizers. The lime plat presented a much better appearance and produced a decidedly finer herbage than any other plat. *Lathyrus sylvestris* grown since 1890 continued to yield good crops in 1899 and 1900. Spraying with Bordeaux mixture materially benefited the potato crop. In 1900 lime, gas-lime, and basic slag were tried as preventives of the finger-

and-toe disease in swedes. Lime was the most effective, although not entirely successful.

The Woburn pot-culture experiments in 1900. J. A. VOELCKER, (*Jour. Roy. Agr. Soc. England*, 62 (1901), pp. 317-334, figs. 12).—The purpose, plan, and previous results of these experiments have already been noted (E. S. R., 13, pp. 335).

The Hills experiments.—A test was made of treating the soil for wheat with lithium, potassium, and sodium chlorid at the rate of $\frac{1}{2}$, 1, and 2 cwt. per acre. An additional test was made soaking the seed for 10 minutes in a 1 per cent solution of these different salts, and in 1, 10, and 20 per cent solutions of sodium iodid and sodium bromid. Lithium chlorid retarded germination, produced shorter and weaker straw, and gave a smaller yield of corn than any of the other salts used. The effect was the more marked as the quantity of lithium salt used was increased. The potash applications slightly increased the yield of corn and straw, and the use of sodium chlorid gave even better results than the potash salt. Soaking the seed before sowing in 1 per cent solutions of the different substances above mentioned was productive of some benefit. A 10 per cent solution of sodium iodid was too strong, but solutions of sodium bromid or chlorid of the same strength did not show deleterious effects. The benefit derived from the use of sodium bromid or chlorid for this purpose is considered uncertain. A 20 per cent solution of these three different salts was found harmful, the sodium iodid being the most injurious.

Experiments similar to those with wheat were made with barley. In these tests lithium chlorid had no retarding influence, and did not decrease the yield of straw, but it stunted the roots, seriously interfered with the development of root hairs, and largely reduced the weight of the grain. The use of potassium and sodium chlorids did not bring out any particular point. No benefit accrued from soaking the barley seed in solutions of 1, 10, or 20 per cent of either sodium iodid or sodium bromid. The stronger solutions of these salts had only a slight detrimental effect. Sodium chlorid had a bad effect, which increased with the strength of the solution.

Miscellaneous pot-culture experiments.—Tests of thick and thin sowing of barley conducted in previous years were repeated in 1900. The barley was sown in pots at the rate of 5, 7 $\frac{1}{2}$, 9, and 13 pks. per acre, and the heaviest yield was obtained from the thickest seeding. The best yield of grain and straw was produced from seeding at the rate of 7 $\frac{1}{2}$ pks. per acre. It is considered advisable to sow barley thicker than wheat, the quantity recommended being 9 pks. per acre.

The experiments with hard and soft wheat on different kinds of soil begun in 1899, were continued in 1900, and the general observations of the first year were fully confirmed. "The soil . . . has the power of altering the character of the grain, and so it can not be said that soft seed necessarily produces soft wheat, or that the sowing of hard seed ensures a crop of hard wheat."

The Essex field experiments, 1896-1901. I, Permanent pastures, T. S. DYMOND (*Essex County Council, Tech. Instr. Com., Tech. Labs., 1901, pp. 42, fig. 1, dgm. 2*).—The results of these experiments on permanent pastures in various parts of Essex are briefly described and reported in tabular form. Experiments in seeding to grass showed that rye grass, cocksfoot, timothy, foxtail, and meadow fescue, together with leguminous crops, such as clover and lucern, make a good mixture for heavy clay soils with gravelly subsoil. Grazing allowed a quicker growth of grass than mowing for hay, but also encouraged weed growth and the disappearance of some of the sown grasses. The best means of increasing the nitrogen supply of the soil is to feed the stock liberally. Phosphatic fertilizers were found essential to the quality and quantity of the herbage on new and old grass land. Four cwt. of basic slag per acre applied every alternate year is recommended for old pasture. For new grass land mowing and grazing in alternate years, feeding the pastured stock with nitrogenous food to supply nitrogen to the soil, and dressing the land with 2 to 4 cwt. of basic slag per acre every alternate year is considered the best treatment.

In a test of improving old grass land an application of 4 cwt. of superphosphate of lime and 2 cwt. of nitrate of soda proved most efficacious. On abandoned grass land on heavy clay soil the only profitable fertilizer for a term of 3 years was basic slag. Potash, with which this soil is well supplied, was detrimental when used alone or with other manures. The use of barnyard manure was very unprofitable. It was found that the use of basic slag rendered the use of lime unnecessary.

Field experiments at Ploti Agricultural Experiment Station, A. G. KARABETOV (*Sir. Rep. An. Sta. Expt. Agron. Ploty, 1900, pp. 1-73*).—In addition to experiments noted elsewhere (page 17) the following are reported: Experiments with winter wheat and rye in a 9-course rotation showed that early sowing gave larger yields, while thin sowing in some instances improved the quality. Land plowed in the fall or in April produced a larger crop of grain than land plowed in May. Deep plowing was most effective as compared with shallow plowing, and the results were most marked with winter rye. In corn culture experiments plowing 10.5 in. deep presented no advantages over plowing 7 in. deep. Plowing at these depths for sugar and fodder beets resulted in an advantage of shallow plowing for late planting and of deep plowing for early planting. In the case of potatoes deep plowing generally increased the yield. In one test grasses, sainfoin, and alfalfa were grown alone and with corn and sunflowers. The grasses when grown alone gave the largest yields of hay. The next largest yield was obtained when the grasses were grown with corn. Sainfoin gave good yields even in dry seasons. The results with sunflowers, saffron, and flax showed that deep plowing as well as early sowing are to be recommended for these crops.

Comparative experiments with barnyard manure and commercial fertilizers for winter wheat, beets, barley, lentils, and oats resulted in increased yields in all cases with the barnyard manure, the largest increase being obtained with winter wheat and beets. Barnyard manure applied with superphosphate considerably increased the yields of grain, roots, and lentils, and also improved the quality of the last-mentioned crop. Nitrate of soda had a depressing influence on lentils, barley, and oats. The application of phosphoric acid gave the best general results on this soil.

A number of other experiments, mainly variety tests, are described.

Arid farming or farming without irrigation, J. A. WIDTSON and L. A. MERRILL (*Utah Sta. Bul. 75, pp. 67-116, figs. 9, chart 1*).—This bulletin discusses at some length the subject of farming in arid regions, with special reference to Utah conditions. The soil and climatic conditions of Utah, referring especially to the rainfall and relative humidity of the State, are considered, and different localities adapted to arid farming are pointed out. The various crops that can be grown in this connection are enumerated and the best methods of plowing, planting, fallowing, and harvesting in arid regions are described.

The moisture content of different kinds of soils at varying depths was determined and is reported in tables. The results of a number of tests reported show that fall plowing was more effective in the conservation of moisture than spring plowing.

In a pot experiment conducted to determine the quantity of water used by various plants to produce a pound of dry matter under Utah conditions, it was found that the quantity of water applied was equal to a rainfall of 22.4, 35.8, 16.3, and 29.2 in. for wheat, corn, peas, and sugar beets, respectively. Comparative yields of corn grown with and without irrigation from 1898 to 1901, inclusive, are also given.

Lucern, B. DYER (*Trans. Highland and Agr. Soc. Scotland, 5. ser., 14 (1902), pp. 63-76*).—This article considers the use of fertilizers in alfalfa culture, and presents notes on some other leguminous crops with reference to the same subject. The results obtained in fertilizer experiments with alfalfa at Rothamsted (*E. S. R.*, 7, p. 385) and Woburn (*E. S. R.*, 13, p. 133) are reviewed. The author's work along this same line, now in progress for 5 consecutive years, has shown that moderate quantities of nitrate of soda as a fertilizer for alfalfa are profitable. Taking the average

results for the 5 years, an annual dressing of 1 cwt. per acre increased the yield by nearly 3 tons of green fodder, and the use of 2 cwt. gave an increase of about $4\frac{1}{2}$ tons. An application of 4 cwt. per acre was less effective than an application of 2 cwt. Experiments with nitrogenous manures on garden peas and French beans also resulted in an increase of yield, being especially marked in the case of the French beans.

Lucern growing as fodder for stock, E. and O. EVANS (*Agr. Jour. Cape Good Hope*, 19 (1901), No. 13, pp. 812-821, fig. 1).—A prize essay on alfalfa and its culture.

Overdressing of barley, H. BAIRD (*Trans. Highland and Agr. Soc. Scotland*, 5. ser., 14 (1902), pp. 1-8, figs. 2).—This article discusses the close dressing of barley in thrashing and the injury resulting from the practice. The author points out how injured barley corns are detrimental to the malting process.

Planting beets in hills, M. RINGELMANN (*Jour. Agr. Prat.*, 1901, I, No. 26, pp. 818, 819, fig. 1).—A brief article discussing the relative advantages of planting beets in continuous drills, in broken drills, and in hills.

The breeding of cereals by means of artificial crossing, E. TSCHERMAK (*Ztschr. Landw. Versuchsw. Oesterr.*, 4 (1901), No. 11, pp. 1029-1060).—This article is a criticism and historical review of the artificial crossing of cereals. The percentage of a number of crossbred varieties of wheat, barley, rye, and oats is shown and the characters of the new varieties are described and discussed with special reference to the transmission of different characters as outlined by Mendel.

Stooling of cereals in its relation to their improvement, RIMPAT (*Jahrb. Deut. Landw. Gesell.*, 16 (1901), pp. 210-219).—An article considering the results obtained by different plant breeders with special reference to the stooling quality of the plants.

The influence of the color of clover seed on the progeny, C. FRUWIRTH (*Ztschr. Landw. Versuchsw. Oesterr.*, 4 (1901), No. 7, pp. 749-755).—The author sums up the results of different experiments in this line by other investigators and presents the report on his own observations. He found that pure yellow seed gave a higher yield of air-dry substance in leaves and stems than either spotted or dark violet seed. The color of the seed sown was in general predominant in the seed produced. The yellow seed was more prepotent than the violet. The different heads of the same plant did not always give like results.

Clover on soils poor in lime, P. P. DEHÉRAIN and E. DEMOUSSY (*Jour. Agr. Prat.*, n. ser., 3 (1902), No. 2, pp. 40-42).—The results of growing clover on lime-poor brush land showed that the bacteria necessary for the symbiosis with the clover plant were present in this soil and that a heavy application of lime gave only a slight increase in yield, while an application of garden soil was very beneficial, but less so in the presence of much lime. Clover was also grown in soil obtained from Brittany, but in this case an application of lime and phosphates was very efficient in increasing the growth of the plant.

Corn culture, J. H. SHEPPERD and A. M. TEN EYCK (*North Dakota Sta. Bul.* 51, pp. 61-102, figs. 5).—This bulletin gives the results of experiments in corn culture during 1900 and 1901 and republishes the results of earlier experiments (E. S. R., 11, p. 331). A study of root development of the corn plant is republished in abstract form from a former bulletin (E. S. R., 12, p. 516).

The yields of 23 varieties tested in 1900 and of 42 varieties tested in 1901 are tabulated. In 1900 Crossbred Dent, Mercer Flint, Squaw Flint, Triumph Flint, Selected Acme Dent, North Dakota White Flint, Crossbred Dimpled Dent, and Northwestern Dent were the best producing varieties, with an average yield of 39.1 bu. per acre. In 1901 Dawson Crossbred Dent, South Dakota Early White Dent, Smut Nose Dent, Compton Early Flint, Golden Dent, Triumph Flint, Mercer Flint, and Will Original Northwest Dent gave the largest yields of fodder and ears, the

average yield of fodder being 3 tons and 1,056 lbs. and the average yield of ears 46.6 bu. per acre. In the production of ears alone the best yielding varieties in 1900 were Triumph, Longfellow, Dutton, Mercer, and King Philip. The proportion of corn to cob, as determined for 2 varieties in 1901, was 86.7 per cent shelled corn to 13.3 per cent cob for Golden Dent, and 78.8 per cent shelled corn to 21.2 per cent cob for North Dakota No. 100. A number of the varieties tested did not fully mature.

Experiments in thickness of planting showed the largest yields of fodder from corn planted in hills in rows 22 in. apart. Drilled corn produced more fodder than corn planted in hills in rows 44 in. apart, but the largest yield of ears was obtained from planting in hills. Corn sown broadcast did not yield as well as corn sown in drills. Drilling corn 6 in. apart in rows 3½ ft. apart gave the best average total yield for two years. In this experiment the yield decreased almost regularly with an increase of the distance between the plants in the row. Planting 6 kernels in a hill gave a larger yield of fodder and ears than planting a smaller number of kernels. As to depth of planting, 2 and 4 in. gave the best results.

In 1901 2 plats of corn were planted each week from May 18 to July 2. One plat was drilled in rows 6 in. apart and the other in rows 42 in. apart. It was found that late planting gave a greater yield of stalks and smaller yield of ears than early planting. The corn in the 6-in. drills yielded on the average 1 ton and 620 lbs. of dry fodder more per acre than the wider planting.

The results of shallow and deep cultivation were generally in favor of shallow cultivation. Shallow cultivation early in the season and deep cultivation late in the season gave better results than continuous deep cultivation or deep cultivation early followed by shallow cultivation later on. Harrowing corn immediately after planting proved a very effective means of destroying young weeds.

Rotation experiments have shown that corn stood next to potatoes as a rotation crop for wheat. Corn also proved an excellent rotation crop for flax.

Directions are given for preparing corn ground for wheat or flax and for breeding, selecting, and saving seed corn. The harvesting and saving of corn fodder is discussed, and experiments with the corn crop in its relation to soil moisture are reviewed.

Analyses of corn with reference to its improvement, J. T. WILLARD, R. W. CLOTHIER, and F. C. WEBER (*Kansas Sta. Bul.* 107, pp. 57-98).—Work of originating varieties of corn richer in protein has been in progress since 1898. In connection with this work analyses were made of varieties, single ears, and single kernels to determine their nitrogen content. The nitrogen in 33 varieties ranged from 1.56 to 2.26 per cent; in different ears of a variety grown for 30 years without admixture it ranged from 1.53 to 2.24 per cent, and in ears of a cross originated the previous year it varied from 1.35 to 2.22 per cent. The nitrogen content of single kernels from the same ear varied considerably but not to an extent as great as among different ears of the same variety. Efforts to determine a connection between the specific gravity of the kernel and its nitrogen content showed that while there seemed to be a tendency toward a higher nitrogen content with lower specific gravity, these factors were very irregular. It is concluded that corn rich in nitrogen can not be selected by means of specific gravity.

Of the original 33 varieties, 21 were selected for breeding purposes. "Each ear saved was pollenized by hand, and all other fertilization prevented. The crosses originated in 1898 in this way were planted in 1899, and each close fertilized. The ears obtained that year were analyzed, and the next season those showing 2 per cent or more of nitrogen were planted, as a rule. These were again close fertilized, the crop of each analyzed, and the same ones, in general, planted in 1901. These were again close fertilized and the ears produced analyzed. These crosses show remarkably high percentages of nitrogen in many cases, and all contain 2 per cent or more

of nitrogen as the average for 3 years. In 12 cases the average is above 2.40 per cent of nitrogen, or 15 per cent of protein." The nitrogen content of each cross is recorded in a table.

A cooperative experiment in connection with this work is described, but for various reasons the outcome was unsatisfactory. The nitrogen content of commercial seed corn of 12 varieties was found to range from 1.39 to 1.81 per cent. This is considered deficient.

The cultivation of maize at the Cawnpore Experiment Station, P. V. SUBBIAH (*Dept. Land Records and Agr., Northwest. Provinces and Oudh, Bul. 16, agr. ser., 1901, pp. 29, pls. 5*).—This bulletin gives in a popular form brief descriptions of the methods of maize culture as practiced at the Cawnpore Experiment Station, and reports tabulated yields obtained during 19 years on plots permanently set apart for experiments with maize. A number of American varieties were compared with North Indian sorts. The author concludes that the American dent and flint varieties give larger yields and hence are well adapted for fodder, but that for the market the improvement of the lighter colored native maize must be the chief resource. The proportion of cobs to stalks and the measurement and weight of the cobs are briefly given in tables.

The cultivation of longer-stapled cottons at the Cawnpore Experiment Station, P. V. SUBBIAH (*Dept. Land Records and Agr., Northwest. Province and Oudh, Bul. 15, agr. ser., 1901, pp. 40, pls. 3*).—This bulletin presents tabulated results of experiments in acclimating foreign cottons and discusses the relative advantages of this work and the improvement of indigenous varieties. These experiments have been in progress since 1888. The results with American long staple varieties of cotton show that they can be successfully grown in North India. The seed of the American variety was uniformly larger than the seed of the native cottons. General directions for the cultivation of long staple varieties of cotton in North India are included in the bulletin.

Experience with cowpeas (*Rural New Yorker, 60 (1901), Nos. 2701, p. 739; 2702, p. 755; 2703, p. 770*).—This article describes cultural tests with cowpeas conducted in northern States. Satisfactory results are reported.

Modern flax culture in western France, H. BLIN (*Jour. Agr. Prat., n. ser., 2 (1901), Nos. 35, pp. 270-273; 36, pp. 306-308*).—This article discusses the culture of flax for fiber as practiced in the west of France.

Drought-resistant forage crops at Highmore (*South Dakota Sta. Bul. 74, pp. 16, figs. 10*).—This bulletin is a report of progress in range and forage experiments at Highmore, S. Dak., begun in 1899 in cooperation with this Department. Former reports have been previously noted (*E. S. R., 13, pp. 240, 639*). This report is composed mainly of notes by L. W. Carter, who was in charge of the work. The method of treatment and the results obtained are briefly described for each plot.

Nevada blue grass (*Poa nevadensis*), feather bunch grass (*Stipa viridula*), western wheat grass (*Agropyron spicatum*), and brome grass (*Bromus inermis*) are considered useful in range improvement. No satisfactory yield of hay has so far been obtained from any of the perennials. Sorghums, corns, and millets in the order mentioned are recommended for winter forage. Cultivated rape produced 14 tons of green fodder per acre. Manuring and pulverizing overstocked prairie lands largely increased the yield of hay.

Grass experiments, H. J. WHEELER and G. E. ADAMS (*Rhode Island Sta. Bul. 82, pp. 125-140*).—The work here reported is in continuation of experiments previously noted (*E. S. R., 12, p. 935*). The treatment of each series of plots for 3 successive years, including 1901, together with the results obtained, is given.

Three grass plots were treated exactly alike during the experiments excepting that 1 plot had received no nitrogen for 11 years, while the second had received a small dressing and the third a large dressing of nitrate of soda annually since 1892. The

large applications of nitrate of soda yielded much the greater profit. In 1901 the value of the hay from the plat receiving the heavy dressing exceeded the cost of the fertilizers by \$40.70 per acre, and for the 3 years of the experiments by \$90.72. In all instances the use of a complete fertilizer gave the best results. The formula used in 1901 in top-dressing the grass consisted of 807.5 lbs. of acid phosphate containing about 16 per cent of total phosphoric acid, 200.5 lbs. of muriate of potash, and 400.6 lbs. of nitrate of soda per acre. This application furnished the large dressing of nitrate of soda. The authors believe the results of 1901 to indicate that an application of 400 to 500 lbs. of acid phosphate, 250 to 300 lbs. of muriate of potash, and 350 to 400 lbs. of nitrate of soda per acre would perhaps have been more economical.

The original grass mixtures sown on these plats in 1898 consisted of $7\frac{1}{2}$ lbs. each of common red clover and redtop and 15 lbs. of timothy. In 1900 the plat without nitrogen contained 222 grass stalks per square foot; the plat with the small dressing, or one-third ration of nitrogen, 271, and the plat with the full dressing of nitrogen, 236. During the last season of the experiments the plat receiving the full dressing of nitrate of soda had the heaviest stand of timothy, the relative percentages of timothy and redtop being 67 and 33 per cent, respectively. The increase in nitrate of soda produced a heavier stand of timothy and with it a larger yield of hay. This plat yielded at the rate of 9,390 lbs., or 4.7 tons, of hay per acre. "The most plausible explanation which has suggested itself for this striking result is the influence upon the growth of the crop brought about by the soda of the nitrate of soda, by virtue of its tendency to render the soil alkaline."

The shrinkage in the hay from the full nitrogen plat, after storing until the following February, was 19.6 per cent as compared with 14.9 per cent for the hay from the no nitrogen plat and 15.7 per cent for the plat receiving one-third of the full application of nitrate.

It was determined by analyses that 1,000 lbs. of field-cured hay, free from clover, removed from 5.6 to 5.8 lbs. of nitrogen, 14.7 to 16.2 lbs. of potash, and 3.3 to 3.5 lbs. of phosphoric acid from the soil. The different analyses of hay made in connection with this work are given in tabular form.

Brome grass and timothy compared, E. F. LADD (*North Dakota Sta. Rpt. 1901, pp. 13-18*).—The analyses of brome grass and timothy, the samples being taken from a pasture, are compared, and analyses of brome grass hay, including an ash analysis, are reported. The yields of forage and dry matter per acre for the two grasses are given. These experiments were in continuation of work undertaken in 1900, and the results of this season bear out the conclusions drawn the year before and previously noted (*E. S. R.*, 13, p. 443).

Fowl meadow grass, L. R. JONES and A. W. EDSON (*Vermont Sta. Rpt. 1901, pp. 237-247, fig. 1*).—This grass is described and discussed, and results of experiments to cultivate it conducted from 1894 to 1901 are reported. It was found that from 6 to 7 bu. of seed, weighing 19 lbs. per measured bushel, may be obtained per acre. The yields of hay on the station plats were larger than the yields on natural overflowed intervale meadows, which produced from $1\frac{1}{2}$ to $2\frac{1}{2}$ tons per acre. The fowl meadow grass plats yielded more from year to year, while adjacent timothy plats, owing to the growth of sedges, showed a gradual decrease in yield.

"For sowing in wet soils a mixture is recommended which may include variable proportions of redtop, fowl meadow, timothy, and alsike clover. If the soil is favorable to it the fowl meadow will form an increasing proportion of the crop until the third or fourth year when it will have entirely replaced the other grasses and thereafter persists." Sowing in midsummer without a nurse crop is recommended.

Comparative analyses made at the station of the hay of fowl meadow grass and timothy are tabulated. Fowl meadow grass hay is considered of excellent composition and reported as being relished as well by stock as the best upland hay.

The hop and its English varieties, J. PERCIVAL (*Jour. Roy. Agr. Soc. England*,

62 (1901), pp. 67-95, figs. 22).—This article, taken from the author's agricultural botany (E. S. R., 12, p. 719), treats of the structure of the hop and describes the most important early and late varieties cultivated in England.

Manuring mangels (*Farmers' Gaz.*, 60 (1901), No. 45, p. 811).—A brief note treating of the kind of soil best adapted to mangel culture and the methods of fertilizing it.

Test of various kinds of oats and their composition, J. SPEIR and A. P. ATKEN (*Trans. Highland and Agr. Soc. Scotland*, 5. ser., 14 (1902), pp. 263-283).—In this experiment new cross-bred varieties were compared with the older varieties in general cultivation and 2 Canadian sorts. The varieties tested were Tartar King, Tartar King Improved, Hamilton, Potato, Longhoughton, Goldfinder, Waverley, American Beauty, and Banner. The earliest variety was Tartar King Improved, ripening a few days before Tartar King. The number of days required to ripen the different varieties in 1900 and 1901 is given in a table. The proportion of grain to straw for all varieties in 1901 was 37 per cent and 63 per cent, respectively. A change of seed with 3 varieties resulted in an increase of 13½ bu. per acre. The yields for the different varieties, together with other data, are shown in tables. The analyses of the straw, entire grain, husks, and kernels of the different varieties in 1900 and 1901 are reported. In 1901 a long, dry, sunny summer was favorable to a good yield and the production of a heavy grain. The results are briefly discussed and the different varieties given in the order of their fodder value.

The culture of oats, L. GRANDEAU (*Jour. Agr. Prat.*, n. ser., 3 (1902), No. 2, pp. 38-40).—The soil, application of manures, seeding, and cultural methods in connection with growing oats are considered.

Spring seeding of oats and barley, L. GRANDEAU (*Jour. Agr. Prat.*, n. ser., 2 (1901), No. 52, pp. 813, 814; 3 (1902), No. 1, pp. 10, 11).—A general discussion on seeding oats and barley and the subsequent development of the plants as affected by different conditions of soil and climate.

Boxing seed potatoes, J. SPEIR (*Trans. Highland and Agr. Soc. Scotland*, 5. ser., 14 (1902), pp. 147-166, figs. 7).—The system of germinating seed potatoes in boxes is considered at some length, and trials of its adaptability to different districts and to late varieties are reported. The results of these trials indicated that even late varieties may profitably be germinated in boxes before planting. The total average gain for all tests due to boxing the seed potatoes was 10½ cwt. of potatoes per acre.

Fertilizer experiments with potatoes, S. HAMMAR (*Landtmannen*, 12 (1901), No. 2, pp. 25-27).

Rice growing in British Guiana (*West Indian Bul.*, 2 (1901), No. 4, pp. 275-284).—A series of discussions concerning rice cultivation in British Guiana.

Sugar beets in Montana in 1901, F. W. TRAPHAGEN (*Montana Sta. Bul.* 33, pp. 15).—This bulletin reports the results of variety tests of sugar beets at the station and of cooperative culture tests carried on by farmers throughout the State. The general conditions of sugar-beet culture in Montana are reviewed. Of the samples analyzed, a sample of a Utah variety was the richest, containing 19.05 per cent of sugar in the beet, with a purity of 85 per cent. Kleinwanzlebener, Dippe, and 3944, headed the list of varieties, with an average sugar content in the beet of 17.61 per cent and a purity of 87 per cent. The lowest sugar content in the beet for the series of tests was 13.3 per cent. The general average for 37 samples of 7 different varieties was 16.98 per cent of sugar in the beet and a purity coefficient of 84.9.

Beets harvested October 12, 19, and 26 were richer than those harvested September 28 and October 5.

The results of the cooperative tests are given by counties, but no general averages are reported. In a general variety test with Kleinwanzlebener, Vilmorin, and Utah the best results were obtained with Kleinwanzlebener.

Sugar-beet experiments in Nebraska, T. L. LYON and A. T. WIANCKO (*Nebraska Sta. Bul.* 73, pp. 27).—Variety, fertilizer, and cultural tests with sugar beets are

reported. Among 37 varieties, Original Kleinwanzlebener produced the largest amount of sugar per acre. The yield of beets for the different varieties varied from 5.62 to 15.72 tons per acre on heavy soil and from 9.54 to 15.54 tons on light soil. The richest beets were obtained from the heavy soil. The use of commercial fertilizers did not increase the yield sufficiently to warrant their application. Of the different fertilizers used, phosphate was most effective. Cultivating about 4 to 5 in. deep gave the best results as compared with cultivating 2½ and 6 in. deep. The moisture content of the deep and shallow cultivated plats is shown in a table. "Very deep cultivation will, late in the season, interfere considerably with the fine lateral roots of the beets, but in this climate of hot, dry summers with high winds the soil mulch, in order to be effective, must be 3 or 4 in. thick."

Planting in rows 18 in. apart, with 8 in. between plants in the row, gave better results than planting at other distances. The results of early and late planting of beets were not altogether conclusive, but the author believes that although good yields may be obtained from late planting the chances of success are in favor of early planting. Late cultivation injured the beets and slightly lowered the sugar content and purity, but an increase in yield made up for this loss. It was found that late cultivation had been very effective in conserving the soil moisture. Comparison of beets grown on weedy and clean ground showed that weeds may very materially reduce the quality of the beets. Analyses were made of a large number of samples to determine the effect of wet weather during the latter part of the growing period on the quality of the beets, and it was found that the percentage of sugar is rapidly reduced, but that "unless the fresh growth is accompanied by buds upon the crown there seems to be no real loss of sugar—the beets seem to increase in size and weight while the sugar remains at a standstill." Surface applications of lime are reported as effective in checking the Rhizoctonia rot and repeated spraying with Bordeaux mixture as preventing leaf spot. The season's experience showed that sugar beets are a drought-resisting crop. The cost of producing an acre of sugar beets is estimated at \$40.74.

Sugar-beet investigations in 1901, J. W. AMES (*Ohio Sta. Bul. 132, pp. 53-72*).—This bulletin briefly summarizes the results for 1901 and presents them in detail in a series of tables. The results of variety tests in two different parts of the State were in favor of Original Kleinwanzlebener, showing in the one case a sugar content of 13.6 per cent with a purity of 82, and in the other a content of 16 per cent of sugar and a purity of 88. Of 216 samples of beets grown in cooperative tests, 194 came from the northern section of the State and 22 from the middle section. The average results show a sugar content of 12.8 per cent and a purity of 81.2 per cent for all these samples, and a sugar content of 14.5 per cent with a purity of 85 per cent for the samples from the northern section of the State, as compared with a sugar content of 11.2 per cent and a purity of 77.5 for the samples from the middle section.

Tests were made with different combinations of acid phosphate, sulphate of potash, chlorid of potash, nitrate of soda, tankage, and barnyard manure as fertilizers for sugar beets on yellow and black sand. On yellow sand the results on the fertilized and unfertilized plats were practically the same. On black sand the use of acid phosphate applied alone increased the yield of beets by 260 lbs. per acre, while the combination of phosphoric acid and potash and the application of a complete fertilizer increased the yield by 3,980 lbs. and 8,070 lbs. per acre, respectively.

Variety tests of sugar beets, J. J. VASHA (*Ztschr. Landw. Versuchsw. Oesterr., 4 (1901), No. 7, pp. 779-802*).—A test of 6 varieties of sugar beets is reported. The method of growing the beets is described and the mechanical and chemical analyses of the soil are given. The results are tabulated in detail and the merits of the different varieties are discussed. This being the first year of the test, no definite conclusions are drawn.

Large and small seed balls in sugar-beet culture, B. PROCHÁZKA (*Ztschr. Landw. Versuchsw. Oesterr., 4 (1901), No. 11, pp. 1061-1066*).—The results of com-

parative tests of large and small seed balls of the sugar beet, conducted by different investigators and by the author, are reported. The conclusion drawn from these results is that the seed balls should be of medium size, from 0.3 to 0.5 cm. in diameter, and weighing at least 2.5 gm. per hundred.

Breeding sugar beets, VON RÜMKE (*Jahrb. Deut. Landw. Gesell.*, 16 (1901), pp. 219-231).—A review of the work of breeding and improving sugar beets by different investigators. A detailed description is given of how this line of investigation is carried on.

The growth of the sugar beet, O. VIBRANS (*Bl. Zuckerrübenbau*, 8 (1901), Nos. 20, pp. 309-313; 21, pp. 323-331).—The vegetative functions of the plant are discussed and the influences of different factors on its growth are pointed out. Observations in this line made by different investigators are reviewed.

Superphosphate and nitrate of soda as fertilizer for sugar beets, F. LUBANSKI (*Bl. Zuckerrübenbau*, 8 (1901), No. 24, pp. 370-379).—Tabulated results of cooperative experiments with superphosphate and nitrate of soda for sugar beets are presented and briefly discussed.

Experiments with seedling and other canes at Barbados in 1901, J. P. D'ALBUQUERQUE and J. R. BOVELL (*Imp. Dept. Agr. West Indies, Pamphlet 13, 1901, pp. 47*).—A short account is given of the most important results of the year with experiments on selecting seedling and other canes in Barbados grown under the ordinary conditions existing on the estates where they were cultivated. The general field characters of the different varieties under test are briefly described and the results obtained with each variety on black and red soil are tabulated. Barbados Seedling 208, White Transparent, and Barbados Seedling 147, in the order mentioned, have given the best average results. Barbados Seedling 208 germinated readily, was generally free from disease, produced a juice of great richness and purity and a good yield of sugar. This variety also gave satisfactory results from plants and ratoons and on black and red soils.

Comparative culture experiments with various seed cane varieties, J. D. KOBUS and J. A. VAN HAASSTERT (*Meded. Proefstat. Oost Java*, 3. ser., 1901, No. 32, pp. 20).—A test with thirty unnamed varieties of sugar cane was carried on to determine their quality and manner of growth in different soils. The detailed results are given in tables. Great differences were found to exist, some varieties yielding only 50 per cent as much as others, some grew best on heavy clay, others on sand, while some grew equally well on all soils. It was also noted that certain varieties made the most rapid growth in the early stages, while others grew most rapidly during the latter part of the vegetative period.—H. M. PIETERS.

Composition of sugar cane, G. D'UTRA (*Bol. Agr. São Paulo*, 2. ser., 1901, No. 11, pp. 698-722).—Analyses of different varieties of cane are tabulated.

Sugar-cane diseases in Gôdávâri and Ganjâm districts, C. A. BARBER, J. W. LEATHER, and C. K. SUBBA RAO (*Dept. Land Records and Agr., Madras, Vol. II, Bul. 43, 1901, pp. 181-210, pl. 1*).—This bulletin consists of a collection of papers describing the culture of sugar cane in the two districts. Analyses of soils from the Gôdávâri district are shown in a table.

The cultivation of the teasel, L. A. CLINTON (*Rural New Yorker*, 60 (1901), No. 2703, pp. 769, 770, figs. 3).—A general discussion on teasel culture.

Effects of soluble and insoluble phosphate on the turnip crop, J. MILNE (*Trans. Highland and Agr. Soc. Scotland*, 5. ser., 14 (1902), pp. 103-105).—A brief report on cooperative tests of various forms of phosphate as fertilizers for turnips is presented. The greatest increase in the yield was obtained from the use of superphosphate applied with lime. The precipitation of the soluble phosphate in superphosphate by lime did not seem injurious to the turnip crop.

The adaptation and improvement of winter wheat, T. L. LYON (*Nebraska Sta. Bul. 72, pp. 23*).—This bulletin reports the results of variety tests with winter

wheat at the station and in different counties of the State. Of 118 varieties tested during the last 5 years Turkish Red and Big Frame have given the best results as to hardiness and productiveness. In 194 tests of these 2 varieties in 1900 and 1901 north of the Platte River or west of the 100th meridian, Turkish Red gave the better yields, while Big Frame was somewhat the hardier. In all the tests in that region there were only 19 cases of complete loss by winterkilling. Some of the Russian varieties under test have shown great hardiness and are considered promising for the northern part of the State, especially if they can be made to mature earlier.

Large, heavy seed gave much better yields than unselected seed. Wheat of the same variety from different sections of the country showed considerable variation in the habit of growth, much to the disadvantage of seed grown east of the Missouri River. It has been found that newly introduced wheats show a tendency to adapt themselves to their environment after a few years, and this fact is considered as hopeful that Nebraska-grown seed may become adapted to all arable sections of the State. The yields were nearly proportional to the tendency of early maturity of the variety. "Kansas-grown seed matured earliest and yielded best, but entirely winter-killed when Nebraska and Iowa grown seed of the same variety passed the winter successfully."

Ash analysis of wheat, E. F. LADD (*North Dakota Sta. Rpt. 1901, p. 18*).—An ash analysis of a sample of Fife wheat grown in the Red River Valley is reported.

Hybridization of wheat, A. VILCOQ (*Jour. Agr. Prat., n. ser., 2 (1901), Nos. 33, pp. 367-370, figs. 22; 39, pp. 396-400, figs. 7*).—An article giving some historical notes on the hybridization of wheat and the methods of performing the work.

Hybrid wheat de Massy, A. DUBOIS (*Jour. Agr. Prat., n. ser., 2 (1901), No. 40, p. 433, fig. 1*).—A brief description of this variety.

Thick v. thin sowing of wheat and rye, L. GRANDEAU (*Jour. Agr. Prat., n. ser., 2 (1901), No. 36, pp. 298-300*).—The results of tests conducted on the experiment field at Parc des Princes are reported. The varieties of wheat and rye grown were Alsace and Brie, respectively. It is concluded that sowing for both these varieties at about the rate of 2 hectoliters per hectare gives best results.

Universal nomenclature of wheat, N. A. COBB (*Agr. Gaz. New South Wales, 12 (1901), No. 12, pp. 1614-1629, pl. 1*).—This article considers nomenclature of varieties of wheat from an agricultural and commercial point of view. The author presents a colored plate and a description of Blount Lambriegg wheat as a sample of a series in which all varieties of wheat would be similarly described and illustrated, and which he considers as the chief need in connection with universal nomenclature.

Silos for grain, M. RINGELMANN (*Jour. Agr. Prat., n. ser., 2 (1901), Nos. 32, pp. 170-174, figs. 5; 33, pp. 210-214, figs. 5; 36, pp. 310-312, fig. 1*).—A number of underground silos formerly used for storing grain are described.

HORTICULTURE.

Experiments on the employment of chemical fertilizers in market gardening, E. HEGH (*Rev. Gén. Agron. [Louvain], 10 (1901), No. 10, pp. 464-475, figs. 8*).—A rather extensive series of cooperative experiments is here reported on the use of commercial fertilizers alone and as a supplement to barnyard manure for market garden crops. The experiments were carried out in duplicate at 10 different schools in Belgium, and for 2 years. The results secured are reported in considerable detail, and accompanied by illustrations showing the effects of the different manures on the growth of such crops as cabbage, leeks, celery, carrots, chickory, and peas. The tables contain data on a number of other vegetables also. Taken as a whole, the results are largely in favor of the use of commercial fertilizers in connection with barnyard manure for these crops. The use of chemical fertilizers alone resulted in yields equal to and sometimes in excess of the yields obtained with barnyard manure

alone, but in no case was the use of either alone equal to the yields obtained from the two combined.

Fertilizers for garden crops (*Amer. Gard.*, 22 (1901), No. 365, pp. 858, 859).—The advantages of the proper use of commercial fertilizers with certain kinds of vegetables are given. The work is based on the report of Truffaut and Denaiffe (*E. S. R.*, 12, p. 851) and that reported by the New Jersey Experiment Station in using large amounts of commercial fertilizers on soils already very rich in plant foods (*E. S. R.*, 11, p. 444).

The evolution of vegetable culture, W. W. RAWSON (*Gardening*, 10 (1901), No. 233, pp. 263-267).—A paper on this subject read by the author before the Massachusetts Horticultural Society. The vegetables mentioned include asparagus, beans, beets, cabbage, celery, corn, cucumbers, lettuce, onions, peas, radish, rhubarb, squash, and tomatoes.

Soils and fertilizers for greenhouse crops, H. J. PATTERSON and T. H. WHITE (*Maryland Sta. Bul.* 81, pp. 77-96, pls. 5).—Experiments are reported on the preparation of greenhouse soils with sand and clay loam, mixed with various stable manures, and with crimson clover; the use of stable manure and street sweepings in the greenhouse; transplanting lettuce; watering chrysanthemums with fertilizers in solution; and the use of commercial fertilizers in lettuce culture.

In the preparation of soils for lettuce no difference in the results was noticed, whether the stable manure used was mixed with the soil in a bed 6 in. deep or placed in a layer 2 in. deep at the bottom of the bed and covered over with 4 in. of soil, the amount of manure used being the same in both cases. Green crimson clover was successfully substituted for sod in the preparation of composts for use in the greenhouse. The use of well-rotted stable manure hastened the earliness of a crop of lettuce about 10 days, as compared with unrotted manure, but the total yield of lettuce was the same in both cases. Hog manure was most useful on light soils. A compost made with cow manure proved a more efficient soil for lettuce production than a like compost made with horse manure.

Street sweepings has been found very efficient and useful as a fertilizer for use in the greenhouse, both on account of its manurial value and its mechanical effects. A mulch of street sweepings 1 to 2 in. deep on lettuce prevented "damping off" and kept the under leaves of the plants in a nicer condition than when they lay on the soil. The use of two-thirds sweepings and one-third sand has given very satisfactory results as a soil for a number of potted plants. The sweepings made an excellent plunging medium for all classes of stock in the house and for rubber plants, and were valuable as a substitute for leaf mold and spent hops. It is believed that they may also be used in place of cocoa fiber, which is largely used by florists in Europe. The fertilizing value of fresh and of well-rotted street sweepings is given in the table below and compared with some other materials used in greenhouse soils.

Comparative analyses of street sweepings and other fertilizer materials.

Fertilizer materials.	Water.	Mineral matter.	Nitrogen.	Potash.	Phosphoric acid.
	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>
Street sweepings (fresh).....	25.56	57.59	0.51	0.06	0.27
Street sweepings (well rotted).....		36.40	.53	.42	.32
Horse manure (fresh).....	48.69		.43	.44	.29
Cow manure (fresh) ^a	75.00	5.15	.57	.20	.31
Spent hops.....			1.08	.40	.31
Oak leaves.....			1.00	.35	.20
Jadoo fiber ^b76	.21	.56

^a Samples from steers fed in concreted pits where all the liquid excrements were absorbed by the bedding.

^b Peat moss soaked in a solution of fertilizing materials.

In a test of different methods of handling lettuce, transplanting to 2½-in. pots gave better results than growing 2 in. apart in benches covered 2 in. deep with soil. Experiments with solutions of cow manure, cow urine, and of various other fertilizers for chrysanthemums, indicated that phosphoric acid was especially valuable in the production of bloom. In 1900 the use of 600 lbs. of raw bone meal per acre for chrysanthemums in a solid bed gave slightly more satisfactory results than the same amounts of either dissolved South Carolina rock or slag phosphate. This, it is thought, is due to the nitrogen which the bone meal contained and which contributed to the production of a longer stem and richer foliage. The following season equally good results were obtained with all 3 fertilizers, and when these were used in connection with dried blood and muriate of potash, better blooms, with stiffer stems, shorter joints, and heavier dark-green foliage were obtained than when well-rotted stable manure was used.

Of a number of fertilizers used on lettuce grown in cold frames, a formula made up of 250 lbs. nitrate of soda and 750 lbs. dried fish resulted in the heaviest yield.

Vegetable raising in greenhouses in the Klin district, Government Tver (Selsk. Khoz. i Lyesov., 202 (1901), Sept., pp. 549-593).—The raising in greenhouses in the winter of cucumbers, beans, salad plants, and radishes, as an industry, has been conducted in the Klin district for 45 years and forms now the chief occupation of the peasants of many villages. The method of cultivation and the structure of the greenhouses are very imperfect, however.

Forcing lettuce, C. P. CLOSE (Utah Sta. Bul. 76, pp. 119-125, figs. 2).—This bulletin contains the results of some experiments in the use of different soils for forcing lettuce, a test of the relative merits of Grand Rapids and Denver market varieties for forcing, and a test of the relative values for forcing of plants that appeared first above the soil from seed and those which appeared one day later. The experiment was repeated 4 times on a small scale, and the results are tabulated in some detail. They show, in general, that leaf mold is a safe substitute for rotted sod in Utah as a part of a mixture in forcing soils for lettuce. The soil which contained one part leaf mold produced a 15 per cent greater yield of lettuce than a similar soil containing one part of rotted sod. The total yield from Grand Rapids crops secured in these tests was nearly 40 per cent heavier than the total yield obtained from the Denver market variety. On the whole, the weight of the crop from seeds that germinated first was slightly greater than the weight of the crop from seed which germinated later. The advantage, however, is so slight as not to be worth considering.

Growing watermelons in the North; classification of watermelons, F. W. RANE (New Hampshire Sta. Bul. 86, pp. 79-107, figs. 14).—A successful method of growing watermelons in the North on a commercial scale, including directions for the selection of soil and location, planting, cultivation, picking, storing, and marketing watermelons, and the enemies affecting them, is given in this bulletin, together with the results of a variety test, including descriptive notes of 51 varieties, and the classification of these varieties, using the form and color of the fruit as a basis.

A rich, warm, sandy loam with a southern slope is advocated. Planting for southern New Hampshire should be between May 20 and 31. Hills 10 ft. apart each way should be made 18 to 24 in. across and 8 to 10 in. deep. In the station experiments these hills were first filled two-thirds full with a mixture of thoroughly rotted stable manure, to which a half pint of unleached wood ashes, fine hen manure, or a small handful of phosphate was added. Sufficient soil was then drawn over this and the whole thoroughly mixed together so that the hole was nearly full. More soil was then added, making the hill level with the ground. Ten or 12 seed were planted in a circle about 1 ft. in diameter in each hill, and these covered ½ to ¾ in. deep with fresh, moist soil and pressed down. A little loose soil was then added to keep the moisture of the soil from evaporating.

The best sized melon for either home or retail trade in New Hampshire is one weighing from 12 to 25 lbs.

The varieties believed to be especially desirable for the North, named in order of merit, are as follows: Cole Early, Boss, Black-Eyed Susan, Peerless, Kleckley Sweet, Black Boulder, Black Spanish, Phinney Early, Frontenac, and Hungarian Honey.

On the basis of the color of the fruit watermelons have been divided into the following 6 classes: (1) Light green, (2) medium green, (3) dark green, (4) light striped, (5) dull striped, and (6) mottled. Each of these classes is again subdivided into groups according to the shape of the fruit. These subclasses the author has termed types, and each class of fruit is likely to have 3 types according as the shape of the fruit is (1) round or oval, (2) oblong or medium, and (3) long. The types are also classified as to the color of the seeds, whether light or dark. The various types are named after the variety of watermelon which is most prominent in that type. Fourteen of these type groups are described, and the varieties of watermelons belonging to each noted. The following table will indicate the classification adopted:

Classification of watermelons.

Shape of fruit.	Class.					
	I. Light green.	II. Medium green.	III. Dark green.	IV. Light striped.	V. Dull striped.	VI. Mottled.
Round or oval	Light King.	Peerless..	Black Spanish..	Cole Early..	Pride of Georgia, Christmas.	Nabob.
Oblong or medium.....				Delaware....		Phinney Early.
Long.....	Seminole...	Kleckley Sweet.	Boss.....	Black Eyed Susan.	Cherokee Beauty.	

Muskmelons, J. CRAIG (*New York Cornell Sta. Bul. 200, pp. 159-176, figs. 12*).—This is a popular bulletin giving methods of commercial muskmelon culture observed in New York. The early crop is obtained by starting the plants in hotbeds or in the greenhouse. In the field the plants are set 6 ft. apart each way and manured in the hill by forking in either barnyard manure or a small amount of commercial fertilizers. Sometimes, however, the plants are grown in rows 5 to 7 ft. apart and the hills spaced 2 ft. apart in the row. Clover is the crop commonly used as the fertilizing agent in the crop rotation. The packages used in western New York are 12-lb. baskets, bushel baskets, and crates. The 12-lb. basket usually holds 16 melons, while the bushel basket and crate hold from 30 to 45 melons each. An average sized crate is 9 by 11 by 22 in. Brief notes are given on the insects and diseases affecting muskmelons, with suggestions for their control, and brief descriptive notes given on 63 varieties of muskmelons grown at the station in 1901.

American onions, A. R. GROSS (*Proc. Soc. Prom. Agr. Sci. 1901, pp. 115-132*).—Herewith is brought together a large amount of scattered information concerning the varieties of onions grown in America. A critical key is given to the garden varieties of *Allium cepa*, with a synopsis of a number of the more important varieties. Fifty-six varieties are described. Brief notes are also given on shallots (*A. ascalonicum*) and on Welsh onions (*A. fistulosum*).

The cooking quality of peas and beans as related to the commercial fertilizers applied to them, K. DE VRIEZE (*Deut. Landw. Presse, 28 (1901), No. 87, pp. 728, 729*).—Attention is called to the variation in the ease with which peas and beans grown under different conditions are thoroughly cooked and become soft and the probable cause of this variation is discussed. In conclusion the author states that peas which cook with difficulty are more common than beans of this character. This he explains as due to the fact that as a rule peas are planted earlier than beans

and on account of the cold and moisture in the spring are not furnished with sufficient nitrates by the action of nitric ferments or of *Bacillus radicicola*. He recommends that some nitrate of soda be applied to both peas and beans at the time of planting to insure a product which will be easy to cook and will consequently bring a higher price.

Early tomatoes in the open ground (*Agr. Expts.*, 1 (1901), No. 9, pp. 215, 216).—A paper on this subject read before the Minnesota State Horticultural Society. By sowing tomato seed in small window boxes the latter part of January and transplanting to a hotbed and the open ground May 10, the author was able to secure ripe tomatoes by June 27, and by July 11 in considerable quantities.

Experiments with tomatoes, B. D. HALSTED (*Proc. Soc. Prom. Agr. Sci.* 1901, pp. 58-61).—A brief account is given of a number of mutual crosses between Golden Sunrise, a yellow variety of tomato, and Dwarf Champion, an early red variety.

Ginger (*Indian Gard. and Plant.*, 9 (1901), No. 25, p. 334).—Description of method of culture in South India.

Raising plants from cuttings, J. W. COLEY (*Amer. Gard.*, 23 (1901), No. 370, pp. 56, 57).—This paper treats in a practical way of the details of making and growing cuttings and plants.

The influence of stock upon scion, J. BUVENICH (*Rev. Hort. Belge*, 27 (1901), p. 257; *abs. in Jour. Roy. Hort. Soc. [London]*, 26 (1901), No. 2-3, pp. 522, 523).—A general review is given of this whole subject, many citations of practical examples being given.

Selection of scions, P. DURAND-DASSIER (*Rev. Vit.*, 16 (1901), No. 415, pp. 598, 599).—Grape scions were selected from the base, middle, and tips of canes and compared for fruit production. Those taken from the middle of the canes have thus far given slightly the best yields.

Horticultural department, C. WILSON (*Montana Sta. Bul.* 32, pp. 53-56).—A brief report is given on the ornamental shrubs, shade trees, roses and other flowers that have been grown at the station, and also on the varieties of hardy apples, crabs, plums, strawberries, and raspberries. Of 50 deciduous shrubs tested for 4 years at the station, only 12 have been found to be hardy, 19 are semi-hardy, and 19 worthless. The 12 varieties of hardy shrubs are the American, European, and purple-leaved barberry; crimson dogwood; white-berried privet; yellow-flowering currant; white snowberry; snowball; and various species of lilac. Russian and Carolina poplars have proved especially valuable shade trees, both being particularly hardy. Boxelders grown from seed were also hardy, as well as mountain ash. The maple, English elder, ash, elm, and bur oak have proved worthless under station conditions. Of 28 kinds of roses tested, only 2—the Persian yellow and Magna Charta—have been found hardy enough to be grown without covering. Twenty varieties of apples have proved hardy and borne fruit. Notes are given on 4 of these—Longfield, Wealthy, Gideon, and Hibernia. Eleven crabs have proved hardy and are bearing fruit. Transcendant was one of the most satisfactory varieties. Of the many varieties of plums tested, only one—Moldorka—has succeeded in ripening fruit. Five varieties of strawberries are recommended, viz, Splendid, Bisel, Ivanhoe, Crescent, and Bederwood. Of the raspberries tested, only Marlborough, Hausel, and Brandywine have given satisfactory results under local conditions.

Report of the fruit experiment stations in Ontario, L. WOOLVERTON ET AL. (*Ontario Fruit Expt. Stas. Rpt.* 1901, pp. 64, figs. 18, map 1).—This report is similar in character to those of preceding years (*E. S. R.*, 13, p. 353). Notes, descriptions, and illustrations are given for the purpose of identification of 4 additional varieties of apples, 3 of grapes, 4 of peaches, and 6 of pears, grown in Ontario. A report of the inspection of the fruit experiment stations by H. L. Hutt is included, together with general notes by the experimenters on the growth and character of the fruit grown at the different stations. Ontario has 15 fruit experiment stations located in different parts between Georgian Bay, Lake Erie, and the St. Lawrence River.

Questions of hygiene in the fruit garden; on the basis of investigations of foreign stations for the protection of fruit trees, B. NALIMOV (*Selsk. Khoz. i Lysosor.*, 203 (1901), Oct., pp. 188-232; Nov., pp. 398-456).—This treatise is a comprehensive digest of the hygienic requirements of plant life. The author discusses the rational care and nourishing of cultivated plants; the selection of hardy varieties; the diseases of plants and the injurious animals; remedies for combating these, and the services of phenology in the protection of the orchard. He dwells especially on the different species of aphids, the bark borers (Scolytidae and allied species), the mold fungi (*Monilia fructigena*, *Penicillium glaucum*, *Botrytis cinerea*, etc.), the Acari, etc. In all cases the life of the insects or fungi are described and the remedies to combat them are given.

On the manuring of orchard fruit trees, L. GRANDDEAU (*Rev. Hort.* [Paris], 73 (1901), No. 22, pp. 525-527, figs. 2).—The root systems of orchard fruit trees in poor and good soil are discussed and the method observed by the author in setting trees in the poor soil of Princes Park for a number of years is given. The method observed by the author is to dig a hole for the tree about 80 cm. deep. The first 35 or 40 cm. of the surface soil is thrown in a pile by itself and intimately mixed with 6 kg. of slag containing 18 to 20 per cent phosphoric acid and 5 kg. of kainit. This mixture is then put in the bottom of the hole and the tree set on top of it, the lower subsoil being used to fill up the hole. In the spring with the beginning of growth a liquid solution of nitrate of soda is added. The large amounts of slag and kainit used are justified by the author on account of the poverty of the soil of Princes Park. The first cost is stated to be about 0.6 franc and the amount believed sufficient to last 7 or 8 years. This method of setting out trees has been followed with success by the author for the past 10 years.

Orchard management, cover crops in orchards, pruning of orchards, report on fruits, S. T. MAYNARD and G. A. DREW (*Massachusetts Sta. Bul.* 82, pp. 24, figs. 29).—This is a popular bulletin, dealing in a general way with the best methods to pursue in Massachusetts in the culture of orchard fruits. Some data are included on the growth of a number of cover crops in the station orchard, but no conclusion is drawn. A number of illustrations are given showing the best methods of pruning trees. The yields obtained in a test of 31 varieties of strawberries, 17 of which were new varieties, grown at the station, are tabulated. The heaviest yields under field culture were made by Haverland, Clyde, Sample, and Gandy Belle. Notes are also given on grapes, blackberries, raspberries, and currants grown at the station.

Orchard notes, W. M. MUNSON (*Maine Sta. Bul.* 82, pp. 81-96).—This is largely a report on the value of certain hardy Russian and American sorts of apples that have been grown at the station and elsewhere in the State. Experiments in apple growing have been conducted by the station since 1890. A catalogue is given of 66 of the hardiest of the newer ironclad varieties grown, with notes indicative of form, color, size, quality, and origin of the fruit, and its adaptability to the northern and southern portions of the State, respectively. Most of the 50 or more varieties of Russian apples grown at the station, though perfectly hardy and very productive, are reported to be of poor quality, ripen early, and drop before maturity. Only three—Alexander, Longfield, and Yellow Transparent—are recommended for general culture in competition with apples of American and western European origin. The varieties recommended for the coldest section of the State, in addition to those already named, are Anisim, Arabka, Borsdorf, Cross, Green Crimean, Hibernial, Koursk Reinette, Pink Anis, Prolific Sweeting, Repka Aport, and Russian Gravenstein. All of these varieties are described, as well as 12 other good, hardy varieties of American origin, and 4 seedlings. In growing fruit for market the author recommends that only a few standard sorts be planted.

The keeping qualities of 36 varieties, when placed in a cold cellar and examined from month to month, are tabulated. Based on the data thus obtained, the author

states that "Dudley, Haas, and most of the Russian varieties are comparatively poor keepers and should be used before January. Borsdörf, Longfield, Pewaukee, Porter, and Shiawassee are at their best before the first of February, though keeping well into March. Hurlbut, Milding, and Munson Sweet begin to break down in March; the latter is in good condition from October to this date. Arctic, Bethel, Boiken, Mann, Northwestern Greening, Rall Janet, Stark, Westfield, and Winesap are in prime condition up to April 1. Munson Sweet, Porter, and Shiawassee showed most surprising results and indicate that with care these sorts may be kept much longer than is generally supposed. Peter, which became too soft for market in January, made very good pies as late as the end of March."

Cross fertilizing of apples, W. SAUNDERS (*Ontario Fruit Growers' Assoc. Rpt. 1901*, pp. 34-37).—This notes the efforts being put forth at some of the more northern and western experiment stations in Canada to secure hardy varieties of apples. More than 200 of the hardiest varieties of apples and crabs have been planted at Brandon and Indian Head, but none of them have produced fruit except seedlings of *Pyrus buccata*. The blossoms of this apple have been cross fertilized with pollen from some of the hardiest of the improved varieties, such as Tetovsky, Wealthy, and Duchess, and also with pollen of Transcendent, Hyslop, and Orange crabs. The seedlings of the fruit thus obtained have been planted. Thirty-six trees obtained from these crosses have fruited. Most of them have proven a great advance on the original crab. The fruit of 1 or 2 was about the size of the Transcendent crab and much better in quality. The crossing has been continued, using 20 to 25 different varieties of the hardiest apples, and a number of these have fruited. Altogether, some 16 or 17 varieties have been named, and 9 have been of such size and quality as would warrant their distribution in small lots to different parts of the Northwest country. The apples were small, but promise to be of great usefulness to people in those cold regions. Some of them make very good apple sauce and all of them exceedingly good jelly.

Why apple trees fail, E. WALKER (*Arkansas Sta. Bul. 71*, pp. 32, figs. 16).—Considerable loss occurs in Arkansas orchards each year from the dying of trees. The author made a trip of inspection among the apple orchards of Benton and Washington counties to investigate, as far as possible, the cause. In a general way, it is stated that some of the causes tending to bring about the death of the trees are poor soils, too close planting, lack of culture, indifferent care of the trees, use of diseased and poor nursery stock, the effects of sun scald, diseases, injurious insects, improper methods of pruning, over bearing, root rot, etc. These different matters are discussed in some detail and correctives pointed out.

An inventory of apples grown in Grand Isle County, F. A. WAUGH (*Vermont Sta. Rpt. 1901*, pp. 277-313, map 1).—A bulletin on apple growing in Grand Isle County by the station has been previously noted (E. S. R., 8, p. 791). In the present work a complete inventory of all apples growing in the county has been made and complete descriptions given of the 116 varieties. Some notes are also given on the probable source from which most of the varieties now grown in the county were obtained. The varieties of apples now most extensively grown in the county are Rhode Island Greening, Fameuse, Northern Spy, Ben Davis, Baldwin, Tolman, Roxbury, and American Golden Russet.

Propagation of plums—second report, F. A. WAUGH (*Vermont Sta. Rpt. 1901*, pp. 257-269).—This is the second report of the station on the growth and behavior of 5 varieties of plums, representatives of the Americana, Domestica, Japanese, Wildgoose, and Chicasaw groups of plums, respectively, on 4 different stocks, viz, Americana, Wayland type, Marianna, and Peach. The growth of the top, tap root, secondary and fibrous roots, height of trees, and the number and percentage of merchantable trees on the different stocks in the nursery are noted in tables of measurements and comparisons. In general, the results agree with those of 1899-1900 (E.

S. R., 13, p. 555). The figures given show that Milton and Newman are easiest to propagate, and Bavay, a variety substituted this year for Green Gage of the Domestic group, used last year, hardest to propagate. Chabot made the largest and cleanest trees. The highest percentage of merchantable trees and trees making the best average growth were produced on Marianna stock, though the largest number of trees was made on Wayland stock. Trees produced on Americana roots appeared to be stockier than on any of the other roots.

The growth of 4 varieties of Japanese plums, 23 of Americana, 4 of Nigra, 8 of Miner, 6 of Wildgoose, 9 of Chicasaw, 2 of sand plums, 2 of Myrobalan, 1 of Peach, and 11 of hybrid plums on Americana stocks during the past year from whip grafts has been made a special study, and the measurements secured are tabulated. The growth made on this stock seems, on the whole, to be satisfactory from the standpoint of the nurseryman.

As recorded in the report of the station for 1900, 3 of the best trees from each of the lots of plums propagated on the 4 different stocks—Americana, Wayland type, Marianna, and Peach, as noted above—were planted out in the permanent orchard. Data on the growth of these trees on each of the different stocks in 1901 are recorded. They agree in general with those obtained during the season of 1900 (E. S. R., 13, p. 555). Trees of Milton on Wayland roots made an upright, narrow, vase form, with relatively few branches; while on Marianna roots they were low, round-headed, and bushy, with spreading and drooping tops. The leaves of the trees on Marianna stocks were also several shades darker than on Wayland roots, and the twigs were dark red instead of green. This difference in the growth of the tree on these two different stocks is stated by the writer as being one of the most striking instances of the influence of stock on scion which he has ever observed. The growth of the trees on the different stocks the second year in the orchard indicated that Peach stock should be entirely discarded by planters having climatic and soil conditions like those of the station. At the present time, the experiments would seem to indicate that "Marianna is the best all-round stock from the standpoint of the orchardist—though not from the standpoint of the nurseryman—but that Americana is probably much better for Americanas."

Hybrid plums—third report, F. A. WAUGH (*Vermont Sta. Rpt. 1901, pp. 269-277*).—Earlier reports have dealt with the hybrid parentage of plums (E. S. R., 12, p. 239), including descriptions of a number of varieties. In the present work descriptive notes are given on 13 new hybrid varieties, some of which have not yet been put upon the market, and further notes added on 10 old varieties.

The class of hybrid plums which claims the Japanese plum (*Prunus triflora*) as a parent on the one side, and either the Wildgoose plum (*P. hortulana*) or Chicasaw plum (*P. angustifolia*) on the other, has been classified by the author under the name of the Gonzales group, after the variety of this name. The Gonzales variety is believed to come nearer being representative of this group in form of tree, habit of growth, character of fruit and foliage, than any other variety in the group. "This hybrid group now numbers so many promising horticultural varieties, it presents so many good qualities, it offers so many encouraging possibilities as a point of departure for further hybridization, and it is otherwise so important in general interest that it seems necessary to give it more careful consideration. The group is equally well marked as the Wildgoose group, and it already contains more promising varieties. From every horticultural point of view it is more important than the Wildgoose group. These reasons seem to justify us in describing it by itself and giving it a separate name." The group is described as a botanical variety of the Wildgoose plum and given the name of *P. hortulana robusta*.

The following varieties are included by the author within this group: Alabama, America, Biconical, Breck, Daisy, Dora, Eggle, Excelsior, Franklin, Georgia, Golden, Gonzales, Govalle, Halcyon, Juicy, Kelsaw, Lannix, Louisiana, Minnie, Monolith, Nona, Preserver, Ragland, Red May, Ruby, Satin, Scribner, Watson, Waugh, and Yates.

Peaches and nectarines (*Jour. Roy. Hort. Soc. [London]*, 26 (1901), No. 2-3, pp. 596-598, fig. 1).—The very intimate relation existing between peaches and nectarines is pointed out. Nectarines are sometimes borne on peach trees and peaches on nectarine trees. An illustration is given of a fruit, three-fourths of which is a peach and the other quarter nectarine, not only in outside appearance but also in flesh.

Fruit culture in Egypt, G. BONAPARTE (*Jour. Khediv. Agr. Soc. and School Agr.*, 3 (1901), No. 5, pp. 210-216).—Notes are given on the varieties of citrus fruits and grapes grown in Egypt. Dried dates form the chief fruit of exportation. Methods of propagating and cultivating citrus fruits observed in Egypt are also noted.

Orange culture, picking, and packing, JOHNSTON (*Jour. Jamaica Agr. Soc.*, 5 (1901), No. 12, pp. 479-486).—Spanish and Jamaica methods of cultivating, picking, and packing oranges for market are contrasted. The author states that much more attention is given in Spain to field culture, picking the fruit, grading, wrapping, and packing, than in Jamaica.

Bananas under irrigation, H. J. CHARLES (*Jour. Jamaica Agr. Soc.*, 5 (1901), No. 12, pp. 467-476).—The nature and general culture of bananas, including irrigation, are briefly considered.

Report on the cultivation of pineapples and other products of Florida, R. THOMSON (*Jamaica Bd. Agr.*, 1901, pp. 15).—The author visited Florida and describes the methods followed there in growing pineapples under sheds and in the open. The cultural methods observed with oranges, cassava, mangoes, etc., are also reported upon briefly.

Seasons for planting pineapples (*Jour. Jamaica Agr. Soc.*, 5 (1901), No. 10, pp. 405, 406).—It is stated that while pineapples may be set out in Jamaica nearly any time during the year, the best results are secured when the plants are set in June and July or in November and December, and as soon after the "rains" as possible.

Pine cultivation in Jamaica, H. H. COUSINS (*Jour. Jamaica Agr. Soc.*, 5 (1901), No. 10, pp. 403-405).—Some of the difficulties in pineapple growing in Jamaica are pointed out. Drainage is stated to be the most neglected feature of pineapple cultivation in Jamaica. In confirmation of this statement the results secured on an 8-acre plantation of pineapples are noted. Four acres were planted on flat land, 2 acres with 1-ft. trenches, and the remainder with 2-ft. trenches. The pineapples planted on the flat land died out entirely, except on a few isolated hillocks. The 1-ft. trenches sufficed to save the plants on 2 acres, but the fruit was only moderate. Where the drainage was 2-ft. deep the pineapples were a success. Another mistake in the islands is the use of too rich soil. It is stated that soil containing 30 times the amount of plant food present in the Florida sands has been used in some instances, with the result that the plants made phenomenal growth of foliage, but scarcely any fruit. Nine-tenths of the plants were monstrosities. The fruits consisted of reduplicated crowns and in some cases a mass of axillary leaf shoots. The danger in using raw organic manures for fertilizing pineapples is pointed out. The following pests have been noted: Mealy bug, pineapple scale, blight, and the puccinia disease. In conclusion, the author states that pineapples can be grown to perfection in Jamaica on a large scale when proper attention is given to the natural requirements of the plant.

The date-palm tree, G. BONAPARTE (*Jour. Khediv. Agr. Soc. and School Agr.*, 3 (1901), No. 6, pp. 262-267).—Notes are given on the use of the date palm in Egypt and on 10 varieties growing there. Methods of propagation, irrigation, and drainage, cultivation and fertilization of dates observed there are also considered, and mention made of some of the secondary products of the date palm and their uses.

The "arctic" berry fraud, J. W. BLANKINSHIP (*Montana Sta. Bul.* 32, pp. 41, 42).—Attention is called to a fruit which has been more or less successfully peddled throughout the State, and which is claimed to be a new production obtained from crossing a large number of different berries and fruits. The fruit in question seems to be the white mulberry (*Morus alba*).

New classifications of fruits, G. BELLAIR (*Rev. Hort. [Paris]*, 73 (1901), No. 24,

pp. 566-570).—A classification has been made of the different varieties of pears grown in the pomological regions of France, as to choicest fruits, cooking and show fruits, market or local fruits, and varieties of still lower qualities. Under each heading an indication is given of the quality, time of maturity, and character of the tree of the different varieties coming under it.

Report of the committee on new fruits, H. L. HITT, W. T. MACOUN, and L. WOOLVERTON (*Ontario Fruit Growers' Assoc. Rpt. 1901*, pp. 13-17).—Brief descriptions are given of 6 new apple seedlings, 2 peaches, and 1 each of pears, plums, and raspberries, all of Canadian origin.

Old world contributions to western orchards, C. E. BESSEY (*Proc. Soc. Prom. Agr. Sci. 1901*, pp. 36-34).

Spring frosts and fruit trees, H. MÜLLER-THURGAU (*Ztschr. Pflanzenkrankh.*, 10 (1900), pp. 335-340, figs. 3; *abs. in Jour. Roy. Hort. Soc. [London]*, 26 (1901), No. 1, pp. 193, 194).—A study is here reported of the effects of late spring frosts on flower buds of cherries, apricots, peaches, and strawberries.

Fruit shipments to Britain, J. W. ROBERTSON (*Ontario Fruit Growers' Assoc. Rpt. 1901*, pp. 63-75).—An account of the experiments being made in Canada in shipping orchard fruits to England. The report is largely devoted to methods of cold storage observed.

Coffee culture, A. HEMPEL (*Bol. Agr. São Paulo*, 2, ser. (1901), No. 12, pp. 783-786).—Notes on coffee culture are presented in a popular manner.

Cacao culture and preparation, H. J. WIGMAN (*Teysmannia*, 12 (1901), No. 2-3, pp. 103-111).—The author describes the methods of harvesting cacao and preparing the beans for market. The beans must be well ripened, but not overripe, since both immature and overripe beans are of inferior quality. Fruits from different varieties must be kept separate, special treatment being required for each kind. Fermentation is necessary not only to enable the planter to remove the husk from the bean, but also to improve the quality and color. The white seeds of the Nicaragua cacao require only 4 to 8 hours of fermentation to take on the proper color. The varieties whose seeds have a white fracture give the best beans, as they take on the chocolate or light brown tint desired in the trade.

When the fruits are gathered they are piled up and allowed to remain for a few days before being taken to the husking sheds. Here the outer shell is removed, and on well-managed plantations is disposed of in such a way as to prevent the possibility of infecting future crops with fungus diseases. The husked beans are allowed to lie for a few hours, after which they are spread in the sun to dry for 5 or 6 hours. They are then raked into piles to sweat, and the next day are again spread out. This process is repeated until the beans are cured. The piles of fermenting beans attain a temperature of 100 to 120° F., and occasionally 190° F. is reached. The latter is, however, dangerous, for it has a very detrimental effect upon the quality of the beans. Frequently red clay, ocher, or annatto is used to give a good color to the cacao.—H. M. PIETERS.

The culture of rubber plants in Java, YERSIN (*Rev. Agr. Réunion*, 7 (1901), No. 4, pp. 152-160).—An account is given of the culture and growth of *Ficus elastica* and *Hevea brasiliensis*.

Notes on rubber strip for grafting, R. B. ROGERS (*Jour. Roy. Hort. Soc. [London]*, 26 (1901), No. 1, p. 248).—Pure rubber strip has been found very useful by the author in grafting. The material used is the same as that employed in insulating joints on electric wires, and can be bought in the form of a small roll of tape. The graft is cut to fit the stock in the usual way, and the rubber strip well stretched and then wound around the joint so as to cover the whole of it from end to end. It should be stretched tightly while laying it on, in order to form an air-tight covering and hold the graft firmly in place. A strip 4 to 5 in. long and $\frac{1}{4}$ in. wide is sufficient for ordinary grafts. Rubber solution should be used for moistening

the ends to make them stick. When old rubber strip was used it was found to perish quickly in the sun. This was avoided by covering the graft with raffia. The raffia should be removed as soon as the graft unites, in order not to form a harboring place for insects, etc. It is not necessary to remove the rubber strip, since it stretches and rots off with the growth of the graft.

The caoutchouc tapper, H. C. PRAASTERINK (*Trysmannia*, 12 (1901), No. 6, pp. 253-256, figs. 3).—The writer calls attention to the wasteful methods of gathering caoutchouc at present in use. By these methods the sap is not only wasted or obtained in a very impure state, but the trees and vines are greatly injured or destroyed.

He has devised a special chisel, with concave upper surface and with a hole near the handle end. This is to be driven into the tree in such a way that the sap will flow down the chisel to the hole, to drop through this into a wooden bucket. In a note the editors question the practicability of the use of this device in all cases.—H. M. PIETERS.

New method of propagating gutta-percha trees (*Indian Gard. and Plant.*, 9 (1901), No. 25, p. 432).—This is a Sumatra method, and consists in laying down young saplings, the size of a lead pencil or a little larger, in a horizontal position. When these make shoots 3 or 4 in. long at right angles to the stem, the stem is cut entirely through about an inch on either side of the shoot. The cuttings are then inserted in clayey soil and kept in a damp, cool place until rooted.

Possibilities of strawberry culture in the State, J. W. BLANKINSHIP (*Montana Sta. Bul.* 32, p. 42).—It is stated that there is about a week's difference between the opening of the flowers and the ripening of the strawberry fruit for each successive elevation of 2,000 ft. in Montana. It is pointed out that advantage might be taken of this to secure berries over a long period of time.

Culture of strawberries in the district of St. Geniez, E. MARRE (*Prog. Agr. et Vit. (Ed. L'Est)*, 22 (1901), Nos. 45, pp. 548-550; 46, p. 577; 47, p. 612; 50, pp. 699-707, figs. 14; 51, pp. 734-738).—The methods observed in growing and marketing strawberries are given.

Salicylic acid, a normal constituent of strawberries, L. PORTES and A. DESMOULIERES (*Ann. Chim. Analyt.*, 6 (1901), pp. 401-407; *Chem. Centrbl.*, 1901, II, p. 1360; *abs. in Jour. Soc. Chem. Ind.*, 21 (1902), No. 3, p. 182).—Analyses of several samples of fresh strawberries shows salicylic acid to be a normal constituent of this fruit to the extent of about 1 mg. per kilogram.

Notes on ringing and other like practices with table grapes, F. CHARMEUX (*Jour. Soc. Nat. Hort. France*, 4. ser., 2 (1901), Dec., pp. 1147-1156, figs. 11).—The author practices ringing of vines to produce large, early fruits for the horticultural fairs. When strong cord was firmly wrapped around the internode of a shoot below a bunch of fruit the effect was practically the same as though the shoot had been ringed. Like results were also obtained when the node below the fruit was twisted when the plant was in full bloom. The fruit above the twist grew large and beautiful, but the shoot thus twisted was more subject to the attack of the oidium.

Fruit forcing under glass, W. TURNER (*Amer. Gard.*, 23 (1901), Nos. 370, p. 56; 371, p. 72).—The growing of Vinifera grapes under glass is considered. It is advised that the grape house be entirely separate from the plant house in order to avoid the mealy bug. The early graperly should be started with a night temperature of 45° F., with 10 to 15° higher in the day time. The temperature should be raised 5° every 2 weeks until a night temperature of 70° is attained. The vines require syringing 3 times daily until growth begins, then once in the morning and once in the afternoon. When the vines are in heavy foliage syringing once in the morning is considered sufficient. On cloudy days no syringing is required. With the coloring up of the fruit, water should be withheld. The border however should receive a heavy watering at this time which, in the author's experience, is sufficient to mature the

grapes. The varieties Muscat of Alexandria, Black Hamburgh, and Madresfield Court are considered the 3 best table grapes.

Vine culture as exemplified at the Paris Exposition, J. BLYTH (*Jour. Roy. Hort. Soc. [London]*, 26 (1901), No. 2-3, pp. 428-449).—This is largely a statistical article showing the production of wine in the different countries of the world and giving a discussion of the more prominent wine districts of Europe and elsewhere.

Experiments with commercial fertilizers on vines, E. ZACHAREWICZ (*Prog. Agr. et Vit. (Érl. L'Est)*, 22 (1901), No. 46, pp. 568-577).—The results secured in a number of different vineyards where commercial fertilizers were used are recorded. Nitrate of soda was used advantageously in connection with sulphate of potash and superphosphate of lime. The use of these three materials together increased the yields, hastened maturity, and improved the quality of the wine.

Grafting of vines, A. VILLE (*Bol. Roy. Soc. Tosc. Ort.*, 26 (1901), No. 7, p. 195; *abs. in Jour. Roy. Hort. Soc. [London]*, 26 (1901), No. 2-3, pp. 551, 552).—A description is given of the English herbaceous or Lafleur graft.

The propagation and cultivation of the vine in South Africa, J. P. DE WAAL (*Agr. Jour. Cape Good Hope*, 19 (1901), No. 12, pp. 770-780; 20 (1902), No. 1, pp. 42-53).—An article on the establishment and care of vineyards and the varieties best suited to the colony.

A native hedge plant, J. W. BLANKINSHIP (*Montana Sta. Bul.* 32, pp. 38-40).—This refers more particularly to the buffalo berry shrub (*Shepherdia argentea*), which has been fairly successful in some portions of the State as a hedge plant. It is stated that the berry will not grow in the foothills above 3,000 ft. altitude, but it is thought possible that the black and red haw (*Crataegus coccinea* and *C. douglasii*) may take its place in higher situations. The barberry and privet, it is stated, are perfectly hardy in most situations below 5,000 ft.

Some talk about wild gardens, H. S. LEONARD (*Jour. Roy. Hort. Soc. [London]*, 26 (1901), No. 1, pp. 47-67, figs. 3).—A suggestive article on planting wild gardens, with a number of lists of hardy trees, shrubs, flowers, aquatics, etc., desirable for culture in wild gardens.

Production of double flowers, DOUGLAS (*Jour. Roy. Hort. Soc. [London]*, 26 (1901), No. 1, pp. XXXV, XXXVI).—The author states that in growing carnations for more than 30 years, when seed from the best double flowers were saved they produced on the average 5 per cent of double flowers as good as the parents, 12 per cent single flowers of every shade of color, and 83 per cent of flowers which were double, but in no respect equal to the parents in form, etc. It is noted that the largest amount of seed producing double flowered stocks is obtained from stocks grown in pots.

Carnation and dahlia scales, L. BARRON (*Amer. Gard.*, 22 (1901), No. 365, p. 858).—The scales of points used by the Carnation and Dahlia Society, of Victoria, in marketing these plants are given. In carnation, the points are: Color, 25; size, 20; form, 15; stem, 10; substance, 10; calyx, 10; fragrance, 10. The dahlia is divided into 3 classes—cactus, single, and fancy. With the cactus and fancy dahlia the points are: Form, 2; good center, 2; color and freshness, 2; size, 1—total, 7. With the single dahlias the points are: Effective arrangement, 1; color and freshness, 1; form, 2; size, 1—total, 5.

Ringling chrysanthemums, U. P. HEDRICK (*Amer. Florist*, 17 (1901), No. 707, pp. 729, 730).—In the author's experiments it was found that ringling promotes earliness and largeness of blooms in the chrysanthemum. One hundred plants were experimented with, a part of them being ringed at about the time or a little before the buds began to show color. A band of bark about one-half inch wide was entirely removed from the stem by the aid of a sharp knife just below the point where the stem was severed for cut flowers. It is stated that the plants suffered no perceptible injury from the ringling in any respect, not even wilting in the slightest degree. In

addition to increasing the size and hastening the development of the blooms, it was noticed that the leaves above the rings were larger and greener. From the results obtained it is believed by the author "that there is a valuable field for experiment by the florist in the ringing of the chrysanthemum and such other plants as are discarded after flowering."

The origin and development of the cactus dahlia, C. G. WYATT (*Jour. Roy. Hort. Soc. [London]*, 26 (1901), No. 2-3, pp. 467-477, figs. 6).—The cactus dahlia (*Dahlia juarezii*) is stated to have been introduced into Holland from Mexico in 1872. The author does not believe that the *D. juarezii* is wholly responsible for the cactus dahlia of the present day.

A new race of hybrid alpine irises, W. J. CAPARNE (*Gard. Chron.*, 3. ser., 30 (1901), No. 779, p. 367).—This race has resulted from hybridizing the dwarf bearded iris with many alpine and subalpine species. They blossom early and are suitable for exposed windy positions as well as elsewhere, and for forcing. The leaves are 3 or 4 in. long at flowering time and afterwards are prolonged 6 or 8 in. and $\frac{1}{2}$ to 1 in. wide. The flowers are borne on stiff succulent stalks 4 to 8 in. tall and are quite large, resembling in shape the German iris. The colors range from pure white to crimson, yellow, and blue.

On the cultivation of *Oncocyclus* irises, H. EWBANK (*Jour. Roy. Hort. Soc. [London]*, 26 (1901), No. 2-3, pp. 314-323, figs. 5).—The author has found that lime is an absolute necessity in the successful culture of these irises. Other cultural requirements are a sunshiny situation, overhead shelter in summer months, perfect drainage, firm planting, the rhizomes slightly covered—sufficient to protect them from frost, and the borders should be kept free from weeds or anything that obstructs the light.

On some experiments in the cultivation of *Oncocyclus* irises, J. HOGG (*Jour. Roy. Hort. Soc. [London]*, 26 (1901), No. 2-3, pp. 324-336, fig. 1).—An analysis is given of the soils in which *Oncocyclus* irises grow wild and of Dutch bulb garden soil. The soil in which the irises grew naturally contained 155.8 gm. of lime, 49.56 gm. of magnesia, 30.78 gm. of oxid of iron, and 7.58 gm. of alum, in each kilogram of soil; while the Dutch bulb soil contained but 1.84 gm. of lime, 0.52 gm. of magnesia, 5.24 gm. of oxid of iron, and only a trace of alum in a kilogram of soil. The much larger quantity of lime, magnesia, etc., in the soils in which the irises grow wild suggested a reason for the partial failure of these plants in Dutch bulb soil. Experiments were therefore undertaken in which increasing amounts of lime and magnesia were added to the bulb garden soils. It was found that when 20 kg. of marl and 9 of magnesite were added to a bed of soil 8 yds. long by 1 in width, the irises grew luxuriantly, and the secret of their culture is, therefore, thought to be solved for the soils in question.

Forcing lilac flowers, F. VAN DRIESSCHE (*Rev. Hort. Belge*, 27 (1901), p. 228; *abs. in Jour. Roy. Hort. Soc. [London]*, 26 (1901), No. 2-3, p. 559).—Lilac blossoms were obtained in August by removing all the leaves of the shoots soon after the flower buds formed in July.

Official report of the Conference on Lilies (*Jour. Roy. Hort. Soc. [London]*, 26 (1901), No. 2-3, pp. 332-427, figs. 52).—Herewith is contained an account of the Conference on Lilies, held at Chiswick July 16, 1901, and of the papers presented on that occasion. The titles and authors of these are as follows: Descriptions of the New Species and Principal Varieties of Lily Discovered since the Publication of the Monograph of Elwes (1880), J. G. Baker; Notes on Chinese Lilies, A. Henry; The Lilies of the Western United States and British Columbia, C. Purdy; Dutch Lilies, E. H. Krelage; *Lilium sulphureum*, F. W. Seers; Notes on *Lilium medeoloides*, A. Unger; Lily Diseases, G. Massee; Notes on my Experience with Lilies, G. F. Wilson; Lilies from Seed, F. W. Burbidge; Lilies in a Town Garden in the North, G. Yeld; Lilies in the Open-air Garden and Woodland, W. Goldring; Lilies, J. C. Ley; Lilies at Yalding, in Kent, S. Reid; Lilies in Devonshire, G. S. Patey; Experiences in

Growing Lilies, Dr. Bonavia; An Amateur's Attempt to Grow Lilies on Chalky Clay, H. Jonas; Lily Culture Under Glass, R. W. Wallace; Notes on a Supposed Hybrid Between *L. pardalinum* and *L. parryi*, J. S. Whall.

Rose Balduin, or Helen Gould (*Amer. Gard.*, 23 (1901), No. 370, p. 54).—This rose, which has been variously called Balduin, Helen Gould, Red Kaiserin, etc., has been found by a committee to be one and the same rose, the proper name of which should be Balduin.

Perfume plants (*Queensland Agr. Jour.*, 9 (1901), No. 5, pp. 492-494).—Extract from a paper by J. Chapelle, read at the Sixth International Agricultural Congress, held at Paris in July, 1900. Methods of hot and cold extraction of the perfume and essential oils of plants are noted, as well as the present condition of the cultivation of scent plants and of the manufacture of essential oils.

FORESTRY.

Forest work in the States (*Forestry and Irrig.*, 8 (1902), No. 4, pp. 149, 150).—A brief review is given of the forestry work being conducted in the different States of the Union. Thus far the subject of forestry has received legislative recognition in 18 States, and at present forestry is being actively pursued in 15 States, as follows: Connecticut, Kansas, Maine, Maryland, Michigan, Minnesota, New Hampshire, New Jersey, New York, North Carolina, North Dakota, Oregon, Pennsylvania, West Virginia, and Wisconsin.

Forests, Arbor Days, and manuring forest trees, F. E. H. W. KRICHAUFF (*Jour. Roy. Hort. Soc. [London]*, 26 (1902), No. 4, pp. 790-794).—A discussion is given of the forest area and production of the principal countries of Europe and America, and the practice of Arbor Day planting is commended. Compiled notes are also given upon the value of the use of various fertilizers in forest plantings. The use of fertilizers is particularly commended in nurseries. Where fertilizers are applied to single trees, it is said they should not be used in large quantities or without being well mixed with the soil.

Teaching forestry at Berea College, S. C. MASON (*Forestry and Irrig.*, 8 (1902), No. 4, pp. 168-171, figs. 4).—A brief outline is given of the course of instruction offered at Berea College, in central Kentucky, and the management of the college forest reserve is described.

The disabilities attaching to the planting of woods, G. CADELL (*Trans. Highland and Agr. Soc. Scotland*, 5. ser., 14 (1902), pp. 8-15).—Attention is called to a number of the factors which tend to make the planting of forests in Great Britain unprofitable. Among the factors mentioned are the increased cost of planting, taxation, the low quality of home-grown timber, scarcity of trained woodsmen, cost of transportation, etc.

Forest trees for calcareous soils, P. MOUILLEFERT (*Jour. Agr. Prat.*, n. ser., 3 (1902), No. 19, pp. 601, 602).—Attention is called to the value of a number of trees and shrubs for planting in calcareous soils. The rate of growth of a number of these species is given, as well as descriptions of the trees and suggestions for their utilization. Among those mentioned are larches, spruces, yew, Virginia juniper, beech, dogwood, cherries, hazel nuts, hornbeam, etc.

Exotic conifers, their timber and value as an investment, D. F. MACKENZIE (*Trans. Highland and Agr. Soc. Scotland*, 5. ser., 14 (1902), pp. 48-63).—After reviewing the forest conditions of Great Britain and commenting upon the rate of growth and yield of a number of exotic conifers, the author describes in considerable detail about 2 dozen species of trees, comparing them with the Scotch fir taken as a standard. The values given are the results of the measurements made of a large number of trees, and, as far as possible, show the true average rate of growth and comparative value. In general, the timber of the exotic trees is considered equal if not superior

to that produced by native species, and although not always as strong this defect can be remedied by proper sylvicultural treatment. As a rule the timber of the exotic species is more easily worked, and this is considered a decided advantage.

English coppices and copsewoods, J. NISBET (*Jour. Bd. Agr. [London]*, 8 (1902), No. 4, pp. 479-488).—In continuation of a previous article (E. S. R., 13, p. 959) the author describes the treatment of English coppices and copsewoods through the eighteenth and nineteenth centuries. On account of improved conditions of communication, abolition of duty on timber, the use of chemical extracts for tanning, the use of substitutes in place of wood, together with other causes, a decline in the profits from copsewoods has been occasioned, until at present there is hardly any revenue to be obtained from such forests in parts of England. Where land is said to be decidedly poor in quality it is questionable whether it would be more profitable to work it as a simple coppice or to clear it gradually and replant with pines and firs.

The forests of Prussia, G. H. MURPHY (*Tradesman*, 47 (1902), No. 7, p. 78).—According to the author, 20,435,499.8 acres, or 23.7 per cent of the area of Prussia, is occupied by forests and orchards. The ownership of the forests is as follows: State property, 6,319,072 acres; Crown property, 178,950.8 acres; forests partly owned by the State, 2,805.3 acres; communal property, 2,727,109.7 acres; forests owned by institutions, 242,089 acres; forests owned by companies, 584,216.3 acres, and private property, 10,381,156.5 acres.

The forests are divided into deciduous and evergreen, the deciduous forests amounting to 30.9 per cent of the total forest area, while the evergreen forests amount to 69.1 per cent. The forests yielded in 1900 in wood, tan bark, oziers, etc., a total of 868,977,586 cu. ft., or about 105.9 cu. ft. per hectare of the entire forest area.

The State forest nursery at Gosford (*Agr. Gaz. New South Wales*, 13 (1902), No. 1, pp. 54-58, pls. 5).—This nursery, which consists of 65 acres, is maintained by the New South Wales Government for the propagation and distribution of indigenous and exotic useful and ornamental trees and shrubs. About 500 species, selected according to their adaptability, have been introduced and are under cultivation. The methods of seeding and transplanting are described at some length. The present stock of seedlings is estimated at 600,000 plants, and during 1900 about 45,000 were distributed to municipalities, schools, and charitable and other institutions.

Algerian cork forests (*Jour. Bd. Agr. [London]*, 8 (1902), No. 4, p. 539).—A brief note is given on the condition and output of the Algerian cork forests. The annual production has ranged from 86,000 to 100,000 cwt. per annum during the past 3 years. The cork tree only becomes profitable after having undergone a process of stripping the tree of its virgin bark. After this operation a fresh bark is grown, the aggregation of the annual growth forming the cork of commerce. About 10 or 12 years elapse between the time of the first stripping and the production of cork of marketable value. On account of the demand for cork of greater thickness, the Algerian Government has decreed a minimum thickness of 25 mm. for stripping the bark.

The palm trees of Brazil, J. C. BRANNER (*Pop. Sci. Mo.*, 60 (1902), No. 5, pp. 387-412, figs. 25).—Descriptions are given of a number of the palm trees which are found in Brazil, and their economic uses are described at some length.

The Douglas spruce as a park tree, E. ANDRÉ (*Rev. Hort. [Paris]*, 74 (1902), No. 10, pp. 225, 226, fig. 1).—A description is given of a number of examples of the Douglas spruce (*Pseudotsuga douglasii*) in the parks of Europe, particular attention being called to specimens in Haute-Vienne. Notes are given on the growth of this tree and its habitat along the western coast of this country, and of its introduction into European sylviculture.

On some minor resources in connection with forestry, A. K. MYRHOVOLD (*Tidsskr. Norske Landbr.*, 8 (1901), No. 12, pp. 623-639).

Frost checks and wind shakes, E. S. BRUCE (*Forestry and Irrig.*, 8 (1902), No. 4, pp. 159-164, figs. 5).—The author attempts to point out the relation between frost

checks and the so-called wind shakes which occur in timber, and which are not generally understood. The conclusion is reached that the greater part of the so-called wind shakes in timber is in reality primarily due to frost. Two forms of frost checks are described. One crosses the annual rings in a radial manner and is due to contraction caused by frost. The other form, which is called expansion checks, extends in a circular direction, following along the annular rings. The first form extends from the outside of the tree inward, while the expansion checks do not show on the surface of the tree.

The use of anatomical characters in the identification of wood, H. STONE (*Nature*, 65 (1902), No. 1686, pp. 379, 380, figs. 2).—The necessity of some means of identifying woods is commented upon, and the attempts of various authors along this line are indicated. The microscopical characters of a number of kinds of wood are described, and, based on the examination of wood of about 1,500 species, the author is convinced that the character of the medullary rays is the most constant feature and could be used as a basis of an artificial key for the determination of different kinds of timber.

Table of the U. S. Government forest reserves arranged by States (*Forestry and Irrig.*, 8 (1902), No. 4, p. 152).—A tabular summary is given of the forest reserves of the United States, their location and area. The grand total amounts to 46,327,969 acres, embraced in 13 States and Territories, there being 39 reserves at the time of the compilation of the table.

SEEDS—WEEDS.

A study on the germination and growth of Leguminosæ, especially with reference to small and large seed, F. G. MILLER and L. H. PAMMEL (*Proc. Soc. Prom. Agr. Sci.* 1901, pp. 133-159, pls. 5).—Experiments are reported in which about 35 representatives of the family Leguminosæ were studied, equal lots of large and small seed being tested. Tabulated results of the germination tests are given and the rate of growth of some of the plants is also shown. While the number of experiments was so limited as to hardly warrant generalization, the results generally indicated the superior value of large seeds.

Some observations concerning the viability of red clover seed, S. HAMMAR (*K. Landt. Akad. Handl. Tidskr.*, 40 (1901), No. 4, pp. 269-272).

Weeds in general; two newcomers into Pennsylvania, W. A. BUCKHOFF (*Pennsylvania Sta. Bul.* 58, pp. 8, figs. 2).—A brief discussion is given of the distribution and means for eradication of weeds, and 2 species recently introduced in the State are recorded for the first time. These are the keeled garlic (*Allium carinatum*) and the Southern scabious (*Scabiosa australis*). The first species has quite recently been observed in one county of the State, and while still of very limited distribution its character for spreading would indicate that unless attention is paid to it it will soon spread to other regions. The characters of this plant are so similar to those of field garlic (*Allium vineale*) that the author believes it is liable to prove a troublesome weed over all the sections occupied by the last-named species. The second new weed has likewise been reported from but a single station. It apparently thrives best on low, wet grounds, and while not a prolific seed producer it has a vigorous root system, by which it can spread with considerable rapidity. While neither of these weeds is at present known to be a serious menace, they should be looked upon with suspicion and eradicated wherever found.

Two weedy plants new to America, L. R. JONES and A. W. EDSON (*Vermont Sta. Rpt.* 1901, pp. 255, 256).—Descriptions are given of the hoary alyssum (*Berteroa incana*) and the tuberous sweet pea (*Lathyrus tuberosus*). The hoary alyssum, which had not been previously reported from the United States, was first found at Burlington, Vt. It has since been found at a number of other places. The plant grows to a

height of 1 or 2 ft., produces seed abundantly, and grows persistently in grass cut by a lawn mower. The tuberous sweet pea resembles the garden sweet pea, except in the smaller size of its flowers. It has been under observation for 10 years or more, and has continued to spread over the field where it was first noticed. When first discovered the land was in grass, but has since been cultivated with corn and potatoes, and is now reseeded, but the weed persists in the field, doubtless owing to its root stocks and tubers which were not destroyed by cultivation.

The bird vetch or wild pea, L. R. JONES and A. W. EDSON (*Vermont Sta. Rpt. 1901, pp. 251-254*).—The bird vetch or wild pea (*Vicia cracca*) is frequently found in the meadows of Vermont and in some places is spreading quite rapidly. Wide differences in opinion regarding the plant have been expressed, some regarding it as a desirable forage plant, while others consider it a troublesome weed. A brief description is given of this vetch, and its value for pasture and hay are indicated. For the purpose of comparison the following table has been prepared in which the analysis of the bird vetch hay is compared with that of red clover hay:

Analysis of bird vetch hay.

	Original substance.		Crude ash.	Crude protein.	Crude fiber.	Nitrogen-free extract.	Ether extract.	Nitrogen.	Phosphoric acid.	Potash.
	Water.	Dry matter.								
Bird vetch hay.....	P. ct. 7.20	P. ct. 92.70	P. ct. 6.33	P. ct. 12.92	P. ct. 29.83	P. ct. 48.72	P. ct. 2.20	P. ct. 2.06	P. ct. 0.42	P. ct. 1.90
Red clover hay	15.30	84.70	7.32	14.52	29.25	44.98	3.90	2.33	.45	2.60

The plant is said to be very deceptive, as an apparently dense growth when cut for hay gives a much smaller yield than timothy and much less than clovers. It tends to make the hay dark colored and musty, and is difficult of handling on account of its growth in tangled masses. It is said to be difficult to eradicate from moist soils, but on the experiment farm it was killed by short rotation and clean cultivation. On the whole, the authors consider this vetch as a weed rather than a useful plant, and recommend its eradication.

The Canada thistle (*Cirsium arvense*), SAMSÖ-LUND and E. ROSTRUP (*K. Norske Vidensk. Selsk. Skr., 1901, pp. 152*).

Killing weeds with chemicals, L. R. JONES and A. W. EDSON (*Vermont Sta. Rpt. 1901, pp. 247-251*).—In continuation of previous work in this line, the authors tested carbolic acid, an arsenic-sal-soda mixture, arseniate of soda, and two trade preparations—Smith's Weed Killer and Henderson's Weed Destroyer. In 1900 further trials were made, in which sulphuric acid was tested, as well as carbolic acid and sodium arsenate. As a result of all the experiments, which are summarized, the authors conclude that walks, drives, tennis courts, and similar places can be kept free from weeds by the use of chemicals. The relative value of the chemical depends upon its immediate action as a herbicide and the persistence of its effect. When both of these factors were considered the arsenical compounds were found to be far superior to any other chemicals tried. Of the arsenical compounds tested, their efficiency in order of enumeration is as follows: Henderson's Fluid Weed Destroyer, arseniate of soda, Smith's Weed Killer, and arsenic-sal-soda mixture. The chief difference between these was found to be in the persistence of the effect, but all of them endured for a year or more. Considering the efficiency and cost, where small areas are to be treated and expense not considered, the authors would recommend Henderson's Weed Destroyer, since it is most convenient and most efficient. For larger areas, where convenience and economy are considered, the arseniate of soda is preferred. For killing weeds in lawns, where it is desired that useful plants shall occupy the soil as soon as possible, crude carbolic acid is preferred, since it is prompt in its action

and does not permanently poison the soil. Sulphuric acid ranks next to this, but is less efficient. For destroying the orange hawkweed in grass lands salt continues to be the best herbicide tested.

On public measures for the eradication of weeds and other injurious plants, E. KORSMO (*Tidsskr. Norske Landbr.*, 8 (1901), No. 11, pp. 571-604).

The eradication of prickly pear, G. VALDER (*Agr. Gaz. New South Wales*, 18 (1902), No. 1, pp. 59-62, pl. 1).—An account is given of experiments conducted on a hedge of prickly pear which had formed a very dense growth of from 5 to 15 ft. in width. In the preliminary experiment, portions of this hedge were sprayed with a sodium arsenite solution and 2 trade preparations, and powdered sulphate of copper was injected into the fleshy stems. As a result of this experiment the sodium arsenite was found to be much more efficient than any of the others. The copper sulphate gave the poorest results, not completely destroying any of the plants. The sprayed plants all died to the roots but in a few months fresh shoots were developed. As sodium arsenite proved the most suitable of the remedies tried, experiments were conducted to ascertain the best strength of solution. As a result of these experiments the author recommends the use of 1 lb. of sodium arsenite to 10 galls. of water. This dissolves readily and is easily sprayed over the plants. The best time for spraying appears to be when the plants are most active, which is in spring or summer after heavy rains. The total cost of materials and applications is less than \$10 per acre, even on very badly infested land. The action of the spray is rapid and within 24 hours the plants seem to be visibly affected. At the end of a week the fleshy stems had all turned brown and within 3 weeks or a month were sufficiently dry to burn readily. The effect of cutting or breaking the plants before spraying was tested but found to be without any advantage. A number of chemicals were injected into the basal joints of the stem of prickly pear, but aside from a local disturbance were without any appreciable effect. The substances so employed were sulphuric acid, carbolic acid, potassium oxalate, potassium ferricyanid, sodium arsenite, caustic potash, iron sulphate, and salt. Attention is called to the poisonous nature of the sodium arsenite when used as a spray. To avoid the risk of poisoning, cattle should not be allowed to graze where the treatment is being applied. After a week or 10 days little danger to stock need be anticipated. The author states that briars, lantana, thistles, and other weeds can be treated in a similar way to that recommended for the destruction of prickly pear.

DISEASES OF PLANTS.

Crop, orchard, and garden pests, T. W. KIRK (*New Zealand Dept. Agr. Rpt.* 1901, pp. 317-326).—A brief report is given on a number of the more common diseases of farm crops, orchard and garden products. Among the diseases of orchard trees a description is given of a disease called silver blight, which has been known for a number of years and which continues to spread throughout the country. This disease is readily detected as the foliage, usually beginning upon a single shoot or branch, is seen to assume a shiny, silvery appearance. Later other shoots and branches may be attacked or the disease may not spread farther. Experiments which have been conducted since 1894 led the author to suggest as remedial treatment cutting out of the affected branches and burning them when discovered. There seems to be evidence that the disease may be communicated by pruning implements, and on this account it is recommended that 2 knives should be employed, the first for pruning until the sound wood is reached, and the second to be used for cutting off a portion of the sound wood. The use of 2 knives may be dispensed with if the pruning knife be sterilized before making the final cut. The application of iron sulphate to the roots of the plants seems to be beneficial in improving the general condition of the trees.

A preliminary note on the cause of flax-sick soil, H. L. BOLLEY (*Proc. Soc. Prom. Agr. Sci. 1901*, pp. 42-46).—A preliminary report is given on the cause of a disease of flax which is designated as flax sickness. This disease manifests itself after a few years of continuous cropping to flax, the soil being said to become flax sick. Investigations of the soil show that there has been no exhaustion of soil fertility, and further investigations have shown that it is due to the development of a soil fungus, *Fusarium lini*. The behavior of the fungus toward the host is briefly described, and the details of the life history of the parasite are to be published in a future station bulletin.

Flax wilt and flax-sick soil, H. L. BOLLEY (*North Dakota Sta. Bul. 50*, pp. 27-60, figs. 18).—A preliminary account of the flax wilt is given above. In the present bulletin the author reviews the distribution of this disease and the various theories as to its cause. At present it is reported from a dozen or more localities in North Dakota, as well as from adjacent States. The appearance and characteristics of the disease are described, from which it appears that plants are attacked at all ages and die early or late according to the time and intensity of the attack. Young plants wilt suddenly and soon decay if the weather becomes moist, while older ones which have become woody take on a sickly yellowish appearance, wilt at the top, and slowly die. An examination of the roots shows that the smaller branches are dead, as well as the lower part of the tap root. The diseased roots have a characteristic ashen-gray color, and many of the mature plants show the dead gray tissue only on one side of the tap root.

A series of experiments is reported showing that soils infested by the fungus have not lost their fertility, nor accumulated chemical substances which are detrimental to the flax, as has been frequently claimed. As previously stated, the cause of this disease is a fungus parasite, to which the name *Fusarium lini* is given. The life history of the fungus so far as known is described, and it is said that while living normally as a saprophyte it attacks the flax through the young tissues of the seed, leaves, stem, or roots. The means of spreading the disease were investigated, and it was found that it can be readily introduced by particles of soil, dirty implements, through seed, etc.

Experiments were conducted to ascertain means for seed treatment, from which it was found that the seed could be advantageously treated with a formalin solution of 1 part to 330 parts of water. A number of other chemicals were tested, and among them copper sulphate and corrosive sublimate proved effective, but possessed no advantage over the formaldehyde treatment.

In treating flaxseed the author calls attention to the necessity for having the seed thoroughly cleaned before treatment, and applying the solution evenly and only enough to dampen the surface of the seeds, after which they should be thoroughly stirred and dried immediately. From the author's investigations there seems to be little possibility of finding any substance which would destroy the fungus in the soil without injuring the germinating crop. On this account crop rotation seems to offer the best solution of soil treatment.

Potato diseases and their remedies, L. R. JONES and A. W. EDSON (*Vermont Sta. Rpt. 1901*, pp. 227-235).—The authors report on experiments for the control of potato blights as they occurred in 1900, and potato-scab experiments of 1901. The summer of 1900 is said to have been unfavorable to the development of the fungus. There was a considerable amount of early blight, but the late blight and dry rot were almost entirely absent from the station fields. This is attributed to the use of clean seed and spraying. In the spraying experiments the efficiency of several fungicides and their use at different dates was tested. Standard Bordeaux mixture and 2 trade compounds, known as Boxal and Bodo, were tested. The Bordeaux mixture to which Paris green was added gave the best results. Rows of potatoes which were sprayed twice with this mixture yielded at the rate of 285 bu., and gave an increase

of about 60 bu. over the yield from control rows. The fungicide known as Bodo compared favorably with standard Bordeaux mixture, while the third was not as efficient as either of these two. Boxal is primarily an insecticide and was not used early enough to compare its merits with those of Paris green.

The relative value of applications at different dates was tested, the sprayings being made July 2 and 16 and August 4 and 23. No difference was observed in any of the rows until after the third spraying. Soon after this time those plants which did not receive the application of August 4 were badly affected by tip burn, and the stems of many died. The fourth spraying did not appear to make much difference in the character of the foliage. Those plants that had received only the first and second sprayings were severely affected by disease, and those which received the third application continued to thrive whether they received the fourth application or not. The greatest yield obtained was from the plants receiving the four applications.

In the experiments with potato scab the seed was disinfected with corrosive-sublimate solution, formalin, formaldehyde gas, formalin vapor, sulphur fumes, sulphur, and bran, the latter being used at the request of several potato growers, it having been stated that trials where bran were used showed that it not only served to prevent scab, but at the same time was a good fertilizer. The results of the different treatments are shown, from which it is apparent that the corrosive-sublimate solution and the formalin solution were both practically successful in preventing scab and were of about equal value. When the ease of application of the formalin solution and the poisonous nature of the corrosive sublimate are considered, the former is preferred. None of the other applications were of practical success. The sulphur gas and formalin gas, which were both considered promising in the previous year's work, are considered without practical value and cannot be recommended for field use. The formalin vapor and wheat bran were so evidently valueless as to deserve no further trial.

Diseases of sugar cane in Bengal, A. T. GAGE (*Agr. Ledger*, 1901, No. 5 (*Crop Disease and Pest Ser.*, No. 5), pp. 71-96, pl. 1).—A report is given of an examination of a large series of diseased sugar canes which had been collected from a number of different regions. Of 79 sets examined, 10 were affected with the fungus *Colletotrichum falcatum* alone, 7 were infested with the beetle *Dinoderus minutus*, while the remainder showed both fungus and beetle associated in the destruction of the cane. The percentage of disease observed varied from 1 to 75 per cent, with an average of about 23.5 per cent. The author is inclined to believe that the beetle is more destructive to cane than the fungus.

The dying of the cane in the fertilizer test garden, J. D. KOBUS (*Meded. Proefstat. Oost Java*, 3. ser., 1901, No. 30, pp. 11).—The object of this experiment was to determine whether any connection exists between fertilizers and root rot. Plats were fertilized with sulphate of ammonia, stable manure, sulphate of ammonia and stable manure, and with various native fertilizers made from *Arachis*, *Ricinus*, and *Eriodendron*. These fertilizers are highly nitrogenous, containing, respectively, 6.1, 5.2, and 4.6 per cent nitrogen.

When root rot made its appearance, the plants on the stable manure and sulphate of ammonia plats were first and most affected. These plants sent up many more shoots than those on the other plats, but owing to the disease the total product of these plats, was but slightly greater than that of the others. The sugar content of the sap was markedly less on these plats than on those fertilized with sulphate of ammonia alone. It appears from the above that the application of large amounts of organic matter increases the tendency toward root rot, and the author offers a hypothesis to account for this phenomenon. He observed that the plats near flowing water were more free from the disease than others, although no material difference could be detected either in the moisture content or in the amounts of organic matter present. He concludes, therefore, that the organic matter in decaying draws heavily

upon the oxygen in the soil, and that the roots, first stimulated into great activity by the sulphate of ammonia, are deprived of the abundant supply of oxygen necessary for their health. When running water is near, the oxygen is renewed from the fresh water, and it is the oxygen rather than the moisture that is beneficial.—H. M. PIETERS.

Beet-root tumor, M. C. COOKE (*Jour. Roy. Hort. Soc. [London]*, 26 (1901), No. 1, pp. XLV, XLVI).—The presence of globose tumors of about the size of an orange, on the side of beets, attached to the root by a narrow neck, is reported. When cut, the substance of the tumor seems to be not unlike that of the root. It is believed to be caused by the fungus *Edomyces leproides*. Hitherto reported from North Africa, it now is known to occur in England. So far there has been no production of spores, and it is thought that this may be due to the effect of climatic conditions arresting the growth.

Disease in turnips and swedes, R. S. MACDUGALL (*Trans. Highland and Agr. Soc. Scotland*, 5. ser., 14 (1902), pp. 244-263, figs. 6).—In August, 1900, the author's attention was called to a disease of turnips and swedes that was proving very destructive in the south of England. Upon examination it was found to be due to bacteria (*Pseudomonas destructans*), the disease being the same as that previously described (E. S. R., 13, p. 467). The effect produced by the organism is described at considerable length. The organism was isolated and cultivated through various media, and by inoculation proved to be the cause of the disease. As possible means of combating this rot the author recommends the destruction of diseased plants, lengthening the period of rotation, and rendering the conditions as favorable for crop production as possible.

The destruction of cell walls by bacteria, E. F. SMITH (*Abs. in Science*, n. ser., 15 (1902), No. 376, p. 405).—Experiments are reported in which the destruction of the inner tissues of the turnip by the organism *Pseudomonas campestris* is shown. A study of diseased tissue shows that the bacterial masses occupy a considerable proportion of the host when in advanced stages of destruction, and cavities are formed by the solution of cell walls, some of them representing places formerly occupied by hundreds of cells. The cells are crowded apart by the growth of bacteria, the middle lamella first disappearing, but in a short time the cell walls become very faint in outline and finally disappear.

Formalin treatment for grain smuts, R. S. SHAW (*Montana Sta. Bul.* 32, pp. 25, 26).—A brief report is given of results of 3 years' work with formalin for the prevention of smuts of wheat, oats, and barley. Formalin has proved more easily applied and more efficient than any other fungicide tested. It is used upon the seed grain at the rate of 1 pt. of formalin to 40 galls. of water. The seed may be treated either by dipping in the solution or sprinkling over piles of seed, the grain to be well stirred to increase the thoroughness of application.

Concerning the parasitism of Botryosporium, V. PEGLION (*Ztschr. Pflanzenkrank.*, 11 (1901), No. 2-3, pp. 89-92).—The author reports the occurrence of the fungus *Botryosporium* upon leaves of wheat grown in pots in the laboratory. A study of the fungus seemed to show that it was identical with *B. pulchrum*. This led to a study of the related species of the genus and their parasitic habits. The author believes that a number of the species which have been described are identical. As a result of his inoculation experiments it is claimed that *B. pulchrum* can only attack plants that have been weakened by nematodes or other causes.

Disease of ginger in Jamaica (*Bul. Bot. Dept. Jamaica*, n. ser., 8 (1901), No. 11-12, pp. 180-182).—A report is given of the disease which attacks ginger roots and is known as the black rot. This disease is well known and may be recognized by the sickly yellow foliage and black and decaying stems, and the rhizomes when dug will be found black and decaying. Intelligent growers are said to dig up the affected plants and the healthy ones growing near them and destroy them, also turning the

soil so as to expose it to the sun. An examination of the rhizomes showed an abundant fungus mycelium which from its spore formation resembles *Allantospora radicola*. Further studies will be required to demonstrate the specific relations of the fungus. As a precautionary measure, it is recommended that the rhizomes should be washed and soaked for half an hour in Bordeaux mixture prior to planting.

The asparagus rust, V. H. DAVIS (*Agr. Student*, 8 (1901), No. 3, pp. 57-60).—The occurrence of the asparagus rust in the gardens connected with the Ohio State University is noted. The 1-year-old plants began to show the effects of the disease about the middle of August, and by the first of September the old beds showed the signs of a general attack of the fungus. Various suggestions are given for the prevention of the disease, quotations being made from experiment station publications.

Cucumber leaf disease, M. C. COOKE (*Jour. Roy. Hort. Soc. [London]*, 26 (1901), No. 2-3, p. CXLIV).—The author reports having received badly affected cucumber leaves which contained a fungus which has been previously described by him as occurring on melons under the name *Cercospora melonis*.

The prevention of onion smut, A. D. SELBY (*Ohio Sta. Bul.* 131, pp. 47-51).—In continuation of the experiments reported in Ohio Station Bulletin 122 (E. S. R., 13, p. 257), cooperative experiments were conducted upon 3 tracts of smutted soil devoted to onion growing. The effect of soil treatment of 2 strengths of formalin solution and 2 different rates of lime was tested. The results obtained demonstrated the value of dilute formalin solutions and of heavy applications of ground lime for the prevention of onion smut in infected soils. The formalin should be used at the rate of 1 lb. to 25 to 30 galls. of water, applied to the seed and then covered with earth. If the lime treatment is adopted, 75 to 125 bu. per acre of ground quicklime should be applied just before seeding.

A peculiar rotting of Greening apples in 1900, L. R. JONES and A. W. ENSON (*Vermont Sta. Rpt.* 1901, pp. 235-237).—During the autumn of 1900 a peculiar rot of Greenings was reported after the apples had been put in storage. The trouble was common throughout a considerable portion of the orchards in the Champlain Valley. The affected apples exhibited small, clearly defined, brown spots which gradually increased in size. When the spots attained a diameter of about half an inch, a white fungus growth appeared in the center which gave to the apple a very peculiar and marked appearance. This fungus proved to be the blue mold which is a common ripe-rot fungus of apples. The mold is not believed to be able to attack the uninjured fruit, and careful examinations showed the presence of the apple-scab fungus in the center of the rotting spots. It is believed that the peculiarly moist weather of the latter part of September led to the unusual development of small scab spots. This condition of weather, following a very dry summer, was unfavorable to the development of the fruit, and the scab fungus prepared the way for the invasion by the mold which was the immediate cause of the decay. The combination of conditions which made it possible for the attack of this fungus was unusual and will probably not occur again soon. If it could have been foreseen, the trouble might have been prevented by a single application of fungicide late in the season.

Peach-leaf curl and its treatment, G. QUINN (*Jour. Agr. and Ind. South Australia*, 5 (1901), No. 4, pp. 329, 330).—A report is given on experiments conducted to combat the peach-leaf curl due to attacks of *Erioseca deformans*. During the previous season the disease is reported to have been very severe. At the beginning of the season reported upon the trees were thoroughly sprayed with Bordeaux mixture, and as a result entire immunity seems to have been secured to those trees receiving the application of the fungicide. Of the trees not sprayed a decided difference in susceptibility to the fungus is reported. In all, 40 varieties of peaches are reported upon, of which about half are classed as resistant.

A Monilia-like disease of sour cherries, ADERHOLD (*Ztschr. Pflanzenkrank.*, 11 (1901), No. 2-3, pp. 65-73, pl. 1).—A description is given of a disease of sour-cherry

trees that has been under investigation since 1898. The general characteristics are those exhibited in an attack of *Monilia cinerea* on the cherry, but the fungus seems quite distinct. Subsequent studies showed that the disease was caused by an undescribed species of *Fusarium*, to which the author has given the name *Fusarium gemmiperda*, n. sp. Inoculation experiments are reported which seem to establish the parasitism of the fungus, and the author points out the apparent relationship that exists between the amount of rainfall during the period of flowering and the destructiveness of the disease. In 1899 there were but 2 days between April 15 and May 15 on which no rain fell, and the disease proved very destructive, while in 1900, with only 13 rainy days and about one-fourth the rainfall of the previous year, the disease did little damage. It is believed that during the years of normal rainfall this disease will not prove troublesome.

A disease of plums and cherries, M. C. COOKE (*Jour. Roy. Hort. Soc. [London]*, 26 (1901), No. 2-3, pp. CXLII, CXLIII).—The author reports examining the plum, cherry, and other orchard trees, in which he found a white mycelium growing between the bark and the wood, ultimately destroying the tree. This is presumed to be the mycelium of some agaric, probably growing in the vicinity of the tree. No fruiting organs having been observed, it was impossible to determine the species, but *Collybia fusipes* was growing near by, and it is thought to be probably the cause of the disease.

Cherry diseases, W. CARRITHERS (*Jour. Roy. Agr. Soc. England*, 62 (1901), pp. 241-247, figs. 7).—An account is given of a leaf disease of cherry, due to *Gnomonia erythrostoma*. This disease has been previously noted (E. S. R., 13, p. 567). In addition to the foregoing, an attack of *Cladosporium epiphyllum* upon cherries is noted. This fungus causes small brown specks upon the fruit, and while the growth appears to be entirely superficial the development of the fruit under the spots is arrested. The fungus also grows on the dead leaves which are quite prevalent as a result of attacks of the disease first described. A third disease, due to *Exoascus cerasi*, which produces distorted branches on the cherry tree, known popularly as witches' brooms, is described. Miscellaneous notes are given on a number of other plant diseases, the principal of which are due to attacks of *Botrytis parasitica* and *Sclerotinia sclerotiorum*.

Silver leaf, M. C. COOKE (*Jour. Roy. Hort. Soc. [London]*, 26 (1901), No. 2-3, pp. CXXXVI, CXXXVII).—The author states that there is no essential relation between gumming and the so-called silver-leaf disease of peaches, plums, etc. He suggests that the silver leaf is possibly a modification of the disease known in the United States as peach yellows and recommends that the treatment here employed for the eradication of peach yellows be adopted for the prevention of the spread of silver leaf.

Silver leaf (*Jour. Roy. Hort. Soc. [London]*, 26 (1901), No. 1, p. 252).—This disease is said to attack all species of the *Prunus* tribe, being particularly troublesome to peaches and plums. It is called silver leaf because of the silvery or ashen appearance of the surface of the leaf, which seems to be due to a separation which takes place between the outer skin of the leaf and its inner substance and a thin film of air separating them. What causes the separation is as yet unknown. It attacks trees in apparently robust health, spreading from twig to twig until at last it destroys the entire tree. At present the only means for preventing the spread of the disease is the complete destruction of trees which are affected.

A disease of the black locust, H. VON SCHRENK (*Rpt. Missouri Bot. Gardens*, 12 (1901), pp. 21-31, pls. 3).—Detailed descriptions are given of a disease of black locust (*Robinia pseudacacia*), which is caused by the fungus *Polyporus rimosus*. A preliminary note of this disease has already been given (E. S. R., 13, p. 154).

The Botrytis disease of coniferous seedlings, J. TUZSON (*Ztschr. Pflanzenkrankh.*, 11 (1901), No. 2-3, pp. 95-98).—A description is given of the attacks of *Botrytis cinerea* on spruce and larch seedlings, and comparisons are drawn between that spe-

cies and *B. douglasii*, which has been described as occurring upon the Douglas spruce. The investigations of the author seem to indicate that the 2 species of Botrytis are identical.

A disease of betel-nut palms, G. WATT (*Agr. Ledger*, 1901, No. 8 (*Crop Disease and Pest Ser.*, No. 6), pp. 129-180, pls. 3, figs. 4).—An account is given of a disease of the betel-nut palm (*Areca catechu*) which has been under observation since 1896. The disease has been reported from a number of localities in India, and examinations of the infected material seem to show the almost total absence of fungi and bacteria as contributory causes of disease, although they were abundant in the decaying material. The author believes the disease is due to the formation of tyloses within the cells of the plant and the gradual breaking down of the cell walls. Thus far he has been unable to produce the disease under artificial conditions. Improved methods of cultivation and thorough soil drainage are recommended as possible remedies.

Cacao canker in Ceylon, J. B. CARRUTHERS (*Roy. Bot. Gard. Ceylon, Circ.*, 1. ser., 1901, No. 23, pp. 295-323).—The cacao canker was first brought to general notice in Ceylon in 1896 and within a few years spread over a wide area, causing great destruction. Investigations by the author seem to show that the disease must have been present for a number of years prior to the sudden outbreak, as it is ordinarily of rather slow development. The disease attacks the stem and pods and is due to a species of Nectria. It has associated with it in some cases a species of Phythophthora. The results of a number of inoculation experiments are shown by which the definite cause of the disease is established. The treatment suggested is to cut out the cankered places in the trunk, shaving the bark, and burning the wood by holding to the exposed surface a vessel filled with hot coals or by some similar method. The diseased pods should also be collected and destroyed by burning or burying with lime. If these precautions are taken and persisted in, the disease can be held in check.

Some spraying experiments for 1901, L. F. HENDERSON (*Idaho Sta. Bul.* 31, pp. 55-67).—Spraying experiments were conducted for the prevention of the grape powdery mildew (*Uncinula spiralis*). This fungus has been noted as doing considerable damage to grapes for a number of years, in some localities destroying nearly the entire crop. The experiments were conducted with Bordeaux mixture, ammoniacal copper carbonate, and potassium sulphid solutions. Of the fungicides used, Bordeaux mixture gave the best results. The Bordeaux mixture, prepared with 6 lbs. of copper sulphate, and 4 of lime, to 45 galls. of water, was injurious to the tender leaves and vines, but where equal amounts of lime and copper sulphate were employed no injury was done. The experiment shows that sprayings should be continued as late as August or the middle of September for the best results. The rows treated with sulphur were not as free from mildew as those treated with ammoniacal copper carbonate, and those treated with potassium sulphid were more affected by disease than the others. The American varieties of grapes were found to be little subject to the powdery mildew in Idaho, while of the European varieties the Black Moroccos and Black Hamburgs were most subject to disease and the Flame Tokays and Malagas the least.

A spraying experiment was conducted for the control of peach-leaf curl, in which Bordeaux mixture and the lime, sulphur, and salt wash was tested. The lime-sulphur-salt mixture as a fungicide proved effectual in reducing the amount of peach-leaf curl, and incidentally proved that the lime and sulphur would destroy the San José scale without the salt additions. It is believed doubtful whether salt is of any material benefit in this mixture.

Spraying for grape rot, A. D. SELBY and J. F. HICKS (*Ohio Sta. Bul.* 130, pp. 29-41).—In continuation of the experiments reported in Bulletin 123 of the station (E. S. R., 13, p. 259) experiments have been conducted for the prevention of grape rot. Bordeaux mixture, ammoniacal copper carbonate, and soda-Bordeaux mixture

were tested, all the sprayed vines receiving 4 applications of Bordeaux mixture, followed with 3 of ammoniacal copper carbonate on 1 portion and the other with 3 applications of soda-Bordeaux mixture. In all about 12 acres of vines were sprayed, at a cost of \$7.10 per acre. The grapes from the unsprayed area were sold at \$5.90 per acre, while the average return from the sprayed areas was \$125.21 per acre. Comparisons between the ammoniacal copper carbonate and the soda-Bordeaux mixture are drawn, from which it appears that the soda-Bordeaux mixture is to be preferred to the other. A warning is given against the use of eau celeste, as it is not as efficient as the other fungicides and frequently causes injury to the foliage. In continuation of the experiments in 1900 on the number of sprayings required, the results obtained were more or less conflicting. The sprayings should, as a rule, be made at weekly intervals from the close of the flowering period until there is no danger from loss. As a rule, from the experiments which have been conducted by the station, the author thinks that it is demonstrated that grape rot, which has almost destroyed the grape industry in parts of Ohio, may be prevented, and that the future for the grape growers is much brighter than for a number of years past. Directions are given for the making of the soda-Bordeaux mixture and for the testing of the caustic soda which is used in its preparation.

The relation of grape spraying to public health, A. D. SELBY (*Ohio Sta. Bul.* 130, pp. 42-46).—At the suggestion of the State Dairy and Food Commissioner of Ohio, the author has prepared a statement relative to the use of fungicides as affecting public health. A number of analyses were made of grapes which had been thoroughly sprayed in the experiments for control of the grape rot, and the highest amount of copper obtained was 0.0004 gm. to 100 gm. of berries. This amount was so small as to be hardly worth consideration. The effect of copper compounds on wine fermentation is commented upon, the author quoting from foreign authorities which show that there is no danger to be apprehended, the fermentation either removing the copper or rendering it insoluble and without any importance in wine. An experiment was conducted with sprayed grapes in which jelly was made from a lot of grapes which had been heavily sprayed and which would ordinarily be rejected in the market as improperly sprayed. One hundred gm. of grapes and stems contained 0.00084 gm. of copper. When made into jelly 100 gm. of the incinerated jelly yielded 0.00018 gm. of copper. The grapes in this case were very ripe and both the grapes and stems were cooked together. Had the green berries been used or the stems removed the amount would have been much smaller.

The meteorological conditions requisite for injurious fungi, K. SAJO (*Prometheus*, 13 (1901), Nos. 633, pp. 132-135; 634, pp. 154-157).—The relation existing between outbreaks of powdery mildews, *Peronospora*, white rot, etc., and the atmospheric conditions are pointed out. The direction of long-continued winds is said to aid materially in spreading these diseases. The observations cover the period from 1895 to 1901.

Experiments with the fungicide sulfurin, K. MOHR (*Ztschr. Pflanzenkrank.*, 11 (1901), No. 2-3, pp. 98, 99).—This fungicide, which has been highly recommended for use in protecting grapes against the powdery and downy mildews, is said to be calcium disulphid. This material the author has tested in connection with a number of diseases, and, based upon 10 years' experiments, he strongly recommends it for the prevention of the powdery and downy mildew of grapes, grape anthracnose, peach curl, and apple and pear scab, as well as a number of diseases of roses and other plants.

The meteorological conditions for the development of mildews, K. SAJO (*Ztschr. Pflanzenkrank.*, 11 (1901), No. 2-3, pp. 92-95).—It is said that the powdery mildew (*Oidium tuckeri*) made its appearance in a certain part of Hungary in 1899, and the downy mildew (*Peronospora viticola*) in 1900. The meteorological conditions for both years from April to August are shown, from which the author concludes

that for the best development of the powdery mildew cool weather and a low degree of moisture are necessary, while for the downy mildew a higher temperature and greater amount of moisture are required.

Lily fungi, M. C. COOKE (*Jour. Roy. Hort. Soc. [London]*, 26 (1901), No. 2-3, pp. CXXVIII-CXXX).—A brief review is given of some of the more important parasitic fungi which attack cultivated lilies. Among those described are *Botrytis elliptica*; *B. conescens*; *Rhizopus necans*; *Æcidium convallaria*, which ordinarily occurs on lilies of the valley and has also been reported on *Lilium canadense* and on Martagon lilies; *Uromyces lilii*; *Phyllosticta*, etc. The only fungus which is thought of particular injury to lily cultivation in England is the *Botrytis*, and most of the so-called "lily disease" is due to this organism.

Iris-leaf blotch, M. C. COOKE (*Jour. Roy. Hort. Soc. [London]*, 26 (1901), No. 2-3, pp. 450, 451).—A brief account is given of the occurrence of *Heterosporium gracile* on the foliage of *Iris germanica*. The leaves become spotted with elliptical oblong reddish spots which enlarge and finally become confluent and the whole surface of the leaf becomes brown and dead. This disease has caused considerable injury in some parts of England, and the author recommends thorough spraying with ammoniacal copper carbonate for its prevention.

A snowdrop disease, G. MASSEE (*Jour. Roy. Hort. Soc. [London]*, 26 (1901), No. 1, pp. 41-46, fig. 1).—A description is given of a disease which is caused by attacks of *Botrytis cinerea* on the snowdrop. The young leaves and flowers are attacked by the fungus just below the surface of the soil, and by the time they emerge above ground they are much distorted and covered with a dense brownish mold. This attack often occurs when the ground is covered with snow, and the leaves and flowers soon fall to the ground and the bulb, in many instances, is reduced to a soft pulp. The relationship of this disease with other diseases is indicated, and as practical measures for the prevention of the disease the author recommends the removal of soil overlaying the plants during the winter and application of fresh uninfected soil. It will also be found advantageous to mix lime with the newly added soil wherever this is practicable.

A review of the literature relating to plant protection during 1900, M. HOLLRUNG (*Jahresbericht über die Neuerungen und Leistungen auf dem Gebiete des Pflanzenschutzes. Berlin, 1902, pp. 291*).—After reviewing the organization and means taken for combating plant diseases in different countries, the author reviews the literature of fungus diseases and insect enemies of plants, the subjects being arranged according to the host plant. A review is also given of the natural and artificial means adopted for combating these pests, and an annotated list is given of papers relating to the subject which appeared during 1900, many of the articles being abstracted in the report.

ENTOMOLOGY.

Miscellaneous notes on injurious insects, II, V. H. LOWE (*New York State Sta. Bul. 212, pp. 25, pls. 9*).—Notes are given on the life history, habits, and means of combating the periodical cicada (pp. 3-16). A large brood of the periodical cicada is expected in various parts of New York during the spring, and the species is therefore described in its various stages for the purpose of making fruit growers familiar with the insect. The methods of controlling the insect are not well developed. As a rule nothing can be done in the way of a direct remedy against its injuries. Small trees, shrubs, and vines may be protected by covering them with wire netting or other similar material.

The palmer worm (pp. 16-22), which caused quite widespread destruction in apple orchards in 1900, is reported to have nearly disappeared. A few were found in several orchards and in rare instances trees were found quite badly infested. The insect is described in its various stages and an account of its feeding habits is added from

observations made in Kansas by P. J. Parrott. The observations made in 1900 showed that it was a comparatively simple matter to control this insect by spraying.

White grubs attacking aster plants (pp. 22, 23). The larvae of *Lachnosterna fusca* are reported as causing considerable destruction of asters which were grown on land on which nursery trees had been raised during the previous year. The aster plants showed the first signs of injury about the middle of July, and began to wilt and died. As many as 4 grubs were found at the roots of a single plant. The only remedy attempted was the removal of the asters and destruction of grubs. A short rotation of crops is recommended for the purpose of preventing the too extensive infestation by these insects.

Papilio asterias was unusually numerous in the vicinity of Geneva during 1900-1901, and caused great destruction of celery, especially in the seed bed. A brief description is given of the insect in its different stages. The caterpillars of this species are seldom numerous enough to cause great injury, but if they are abundant they may be held in check by jarring from infested plants or by hand picking. Spraying with arsenical poisons is an effective method. For this purpose Paris green may be used at the rate of 1 lb. to 150 galls. of water, with the addition of enough lime to make the mixture somewhat cloudy.

Four lesser insect enemies, F. H. HALL and V. H. LOWE (*New York State Sta. Bul. 212, popular ed., pp. 12, pls. 2*).—A popular summary of the above bulletin.

First report of the State entomologist, W. E. BRITTON (*Connecticut State Sta. Rpt. 1901, pt. 3, pp. 227-278, pls. 11, figs. 2*).—This article contains a copy of the insect pest law passed by the legislature of Connecticut which went into effect July 1, 1901. The duties of State entomologist are briefly outlined. An attempt will be made to inspect all nurseries in Connecticut between September and October, and orchards, gardens, storehouses, and greenhouses will be inspected at any season of the year when convenient. Bulletins 135 and 136 of the station, relating to San José scale, are reproduced, with slight changes and corrections (E. S. R., 13, pp. 776, 970).

During 1901 carnations were greatly injured by the variegated cutworm. The chief point of attack was on the unopened buds. Brief notes are given on the habits and life history of this species, with especial reference to the possibility of its becoming injurious in greenhouses. The elm-leaf beetle is reported as having been unusually abundant during the season and recommendations are made concerning the most efficient remedies to use against this insect. Hickory trees were much injured by *Scolytus quadrispinosus*. The beetles bored holes in the axils of compound leaves. The trunks of dead and dying trees constituted the breeding ground of the beetles and the insects were found in all stages in such situations. Apparently no direct remedy can be used against this insect. It is suggested that arsenical sprays be attempted in cases of unusual outbreaks. The fall webworm was very abundant during the year and defoliated a large number of trees of all kinds. Brief notes are given on the habits of this species.

In experiments with common soap as an insecticide it was found that $\frac{1}{4}$ lb. dissolved in 1 gall. of water destroyed the insects on chrysanthemums, but injured some of the plants. After diluting the mixture one-half, carnation plants infested with red spider were sprayed with satisfactory results. A tomato house badly infested with white flies was largely freed from this pest by the use of soap and water. Many other remedies had been tried, but none were more effective than this.

Brief notes are also given on the following: *Empretia stimulea*, *Phobetron pūhectum*, *Oedemasia concinna*, *Datana ministra*, *D. integerrima*, *Chrysomela elegans*, *Papilio cresphontes*, *Vespa crabro*, green pea louse, pear psylla, tulip-tree scale insect, snowy tree cricket, and maple borer.

Report of the entomologist, R. A. COOLEY (*Montana Sta. Bul. 32, pp. 45-49*).—Brief notes are given on the habits and occurrence of *Phoxopteris comptana*, *Gymnonychus appendiculatus*, *Plutella cruciferarum*, *Aphis brassicae*, and *Rhynchites bicolor*.

Report on injurious insects and plant diseases in 1901, W. M. SCHÖYEN (*Beretning om Skadeinsekter og Plantesygdomme i 1901. Christiania: Grøndahl & Sons, 1902, pp. 42, figs. 26*).—During the season of 1901 an unusual amount of damage was caused by various species of injurious insects upon different crops. The greatest destruction of cereals was due to *Hydrellia griseola*, and to the common smuts and rusts. Meadows and pastures were more or less seriously injured by *Charaxes graminis*, *Adimonia brucei*, crane flies, and *Phyllopertha horticola*. Cabbages and related cruciferous plants were considerably injured by attacks of *Meligethes aeneus*, *Plutella cruciferarum*, *Mamestra brassicae*, and *Linax agrestis*. Great injury was caused to apples by *Argyresthia conjugella*. This insect has caused the loss of a portion of the apple crop in Scandinavia for a number of years. Spraying experiments thus far conducted have proved ineffective in controlling this species. Notes are also given on *Aporia crataegi*, *Hyponomeuta variabilis*, *Eriocampa adumbrata*, pear psylla, apple aphid, currant sawfly, gooseberry fruit worm, *Cheimatobia brumata*, *Monophadnus bipunctatus*, and various species of insects injurious to domesticated animals and to food products and household furniture.

Insect attacks in 1901, R. S. MACDOUGALL (*Trans. Highland and Agr. Soc. Scotland, 5. ser., 14 (1902), pp. 230-244*).—During the season of 1901 the author reports more or less serious damage done by a number of injurious insects. The pine beetle (*Hylesinus piniperda*) is described in its various stages and notes are given on its habits and life history. It was found that the egg stage extended over from 14 to 20 days, while the larval stage occupied about 8 weeks, and the pupal stage 2 weeks or more. In preventing injuries from this insect it is recommended that diseased trees be cut out and that fallen timber be removed. Good results are obtained by giving attention to trap trees, to which the beetles may be lured and in which they may subsequently be destroyed. The 2 chief insect enemies of this beetle are *Clerus formicarius* and *Rhizophagus depressus*. Notes are also given on another insect enemy of the pine, *Retinia resinella*. *Agrotis segetum* is reported as injurious to various root crops. The remedies recommended against this insect are trapping the moths during the summer months, hand picking the caterpillars, destruction of the caterpillars by harrowing, and scattering soot or lime about the base of the garden plants.

Notes are also given on *Plutella cruciferarum*, insects injurious to stored grain, *Hyponomeuta pudellus*, and *Anobium domesticum*.

Insect pests attacking truck crops, F. W. MALLY (*Texas Sta. Bul. 64, pp. 18*).—In this bulletin a general account is given of the life history of the insects and of insecticides which are especially applicable in controlling insect injuries to truck crops in hotbeds, cold frames, and in the field. Special notes are given on the use of bisulphid of carbon, tobacco dust, kerosene emulsion, whale-oil soap, Paris green, arsenate of lead, the blast torch, bran mash, other poisoned baits, and Bordeaux mixture. Directions are also given for protecting certain crops from insect pests. These crops include cabbage, cauliflower, cucumbers, cantaloupes, watermelons, onions, potatoes, tomatoes, and squashes. The insects which are most injurious to these various crops in Texas are mentioned, with a brief description. Recommendations are made concerning the selection of spraying apparatus for use in combating these insects.

The onion thrips, F. M. WEBSTER (*Proc. Columbus Hort. Soc., 16 (1901), No. 1, pp. 74-80, pl. 1*).—The insect is described and mention is made of the plants upon which it usually feeds. Brief notes are given on its life history and natural enemies which serve to some extent in holding it in check. It is recommended that grass and weeds should be destroyed in the neighborhood of onion fields, so as to reduce the available breeding locations for this insect.

An eight years' study of chinch bug outbreaks in Ohio, F. M. WEBSTER (*Proc. Soc. Prom. Agr. Sci. 1901, pp. 47-57, figs. 9*).—Brief descriptive notes explanatory of maps which show the distribution of chinch bugs for a period of 8 years in the different counties of the State.

The plant lice of sugar cane in Java, L. ZEHNTNER (*Meded. Proefstat. Suikerriet West Java, 1901, No. 53, pp. 22, pls. 2*).—The author gives descriptive, biological, and economical notes on *Aphis sacchari*, *A. adusta*, and *Tetraneura lucifuga*.

Insect enemies to fruit, and their remedies, W. B. SMITH (*Proc. Columbus Hort. Soc., 16 (1901), No. 1, pp. 58-62*).—Brief notes on the habits and life history of codling moth, apple-tree borer, apple-tree tent caterpillar, San José scale, plum curculio, peach borer, currant aphid, and other injurious insects. The approved remedies are mentioned in the discussion of each insect.

Insects injurious to fruit, A. H. SNYDER (*Proc. Columbus Hort. Soc., 16 (1901), No. 1, pp. 54-58*).—The author presents brief notes on the habits, life history, and means of combating codling moth, round-headed apple-tree borer, apple-tree tent caterpillar, plum curculio, rose chafer, spring and fall cankerworm, May beetle, and other injurious insects.

Rhynchites minutus an enemy of the strawberry, J. RITZEMA BOS (*Tijdschr. Plantenziekten, 7 (1901), No. 2, pp. 39-41*).—This species is reported as having caused injury to strawberries since 1897. The stems, which are attacked, wilt, and the leaves die. No successful remedies have been devised for combating this species.

Combating the root louse of gooseberry and currant by injections of benzene in the ground, J. RITZEMA BOS (*Tijdschr. Plantenziekten, 7 (1901), No. 2, pp. 37-38*).—*Schizoneura grossulariae* was not known as an injurious insect in Holland until within the past few years, when it has become quite important as an enemy of the gooseberry and currant. Experiments were made in 1900 to determine methods for destroying this insect. The use of either carbon bisulphid or benzene proved to be very effective when these substances were injected into the ground about infested bushes. All of the root lice were destroyed by a single application.

Report of the State entomologist, J. B. SMITH (*New Jersey State Bd. Agr. Rpt. 1901, pp. 237-242*).—The greater part of the work of the State entomologist has been done in combating the San José scale. Notes are given on the practical working of quarantine laws and on the use of certificates of inspection. It is argued that San José scale can not be exterminated by artificial means but may be held in check by the use of appropriate remedies. It is stated that, as a rule, the owners of nursery stock and orchards have readily responded to directions given concerning treatment for injurious insect pests and that no resort to force has become necessary.

Report on the inspection of Roanoke County for the San José scale, W. B. ALWOOD (*Virginia Sta. Spec. Bul., 1901, Dec. 10, pp. 37, map 1*).—In this report the author gives a list of localities in Roanoke County infested with the San José scale. The total number of infested localities is reported as 636; the total number of infested trees as 4,144, and the number of trees in the infested orchards, 74,588.

Three common orchard scales, H. T. FERNALD (*Massachusetts State Bd. Agr. Rpt. 1901, pp. 353-363, pl. 1, figs. 2*).—Brief descriptive and biological notes are given on oyster-shell bark-louse, scurfy scale, and San José scale. The food plants of these scale insects are mentioned and notes given on their distribution, natural enemies, and the treatment which is most effective against them. The insecticide treatments recommended include fumigation and spraying with kerosene, crude petroleum, and whale-oil soap, together with pruning of infested trees before spraying.

Treatment for San José scale, J. H. STEWART (*West Virginia Sta. Bul. 78, pp. 213-230, figs. 6*).—In this bulletin the author gives a popular account of the means of combating the San José scale, the conditions which are favorable for successful treatment, brief notes on the most effective insecticide treatments, and on spraying apparatus. The insecticide treatments which are recommended for destroying the San José scale include mechanical mixtures of kerosene and water, kerosene containing from 5 to 10 per cent of vaseline, kerosene mixed with vaseline and paraffin, crude oils, whale-oil soap, kerosene emulsion, fumigation, and the destruction of badly infested trees. The bulletin also contains a copy of the law recently enacted by the legislature of West Virginia on the subject of nursery inspection and the prevention of injury from insect pests and fungus diseases.

The oak scale insect, J. RITZEMA BOS (*Tijdschr. Plantenziekten*, 7 (1901), No. 5-6, pp. 141-145).—*Asterodiaspis quercicola* is reported as attacking the native as well as introduced oaks in Holland. The injury from this species has not yet reached any alarming proportion, but attention is called to it in order that reports may be made and operations begun against the species if it becomes too numerous.

The oak flea-beetle (*Haltica erucæ*), J. RITZEMA BOS (*Tijdschr. Plantenziekten*, 7 (1901), No. 5-6, pp. 129-141).—Notes are given on the habits and life history of this species of flea-beetle, which is reported as attacking a number of species of oak. The insect appears every year, but not always in large numbers. When the larvae and beetles occur upon the leaves they may be destroyed by spraying with kerosene emulsion or with arsenical poisons, but these methods are ordinarily too expensive. A cheaper way of combating the insect consists in attacking the beetles during the winter. They may usually be found concealed in rubbish and in the cracks of old bark upon the trees, and by scraping off the loose bark and burning it, together with other rubbish, the beetles may be readily destroyed.

Insect enemies of the pine in the Black Hills Forest Reserve, A. D. HOPKINS (*U. S. Dept. Agr., Division of Entomology Bul. 32, n. ser., pp. 24, pls. 7, figs. 5*).—In this bulletin a report is made on a study of the insect enemies of the rock pine (*Pinus ponderosa scopulorum*) in the Black Hills. The attention of settlers was attracted to the extensive destruction of this tree by insects about 1895. The species of beetle which is chiefly concerned in killing the pines is described as a new species, under the name *Dendroctonus ponderosa*. After the primary attack is made by this species, several other species of beetles may also set to work upon the trees and cause a more rapid death and decay. Among the latter species brief notes are given on the following: *Tomicus oregoni*, *T. calligraphus*, *T. calatus*, *Dendroctonus valena*, *Hylurgops subcostulatus*, and *Hylastes porosus*. A number of small pine trees were dying apparently of other causes which were not definitely determined. Among the natural enemies of *D. ponderosa* special mention is made of *Trogosita virescens*, and certain other predaceous beetles and bugs. No parasitic insects of any importance were found preying upon the pine beetle, nor did parasitic fungi or birds appear to exercise any important influence in checking the work of the pine beetle.

According to the observations of H. E. Dewey and the author, the beetles migrate from dying trees in swarms during August, and settle on living trees, which they attack from near the base to the upper part of the trunk. The first indication of the infestation is the presence of red dust in the loose bark or at the base of the tree; this is followed by the appearance of numerous small masses of pitch on the surface of the bark. After the tree is once thoroughly infested other insects and fungi cause its rapid destruction. It appears that unless trees are cut within 2 or 3 years after they begin to die very little of value is left. The attack of this species is apparently becoming less serious.

The author recommends, in combating this insect, that the location and extent of infested areas be determined, after which the infested trees in these areas should be marked for cutting. Contracts for cutting trees should specify that only infested trees should be cut. An investigation of railroad ties which were cut according to contract on account of being infested with the insect, showed that only 55 out of 207 ties showed any evidence of having been attacked by the beetle. It is suggested that further experiments be conducted in cutting and removing the bark from infested trees, and in girdling and otherwise treating living trees so as to make them serve as traps for the beetles.

Some insect enemies of living trees, A. D. HOPKINS (*Proc. Soc. Prom. Agr. Sci. 1901, pp. 66-69*).—Brief notes on *Dendroctonus brevicornis*, *D. monticola*, *D. pseudotsugæ*, *D. piceaperda*, and other common insects injurious to forest trees.

The shade-tree insect problem, A. H. KIRKLAND (*Massachusetts State Bd. Agr. Rpt. 1901, pp. 77-107, pls. 6, figs. 8*).—This was a paper read before the State Agricultural Society and is concerned with a discussion of the habits, life history, and

means of combating San José scale, elm-leaf beetle, gypsy moth, brown-tail moth, white-marked tussock moth, fall webworm, and imported willow weevil (*Cryptorhynchus lapathi*), together with notes on the more important insecticides for use in combating these insects.

Killing the eggs of the gypsy moth by means of kerosene, J. RITZEMA BOS (*Tijdschr. Plantenziekten*, 7 (1901), No. 5-6, pp. 162-165, figs. 5).—Brief notes are given on the use of kerosene in killing the eggs of this insect in masses on trees during the winter.

Report of committee on gypsy moth, insects and birds, A. PRATT ET AL. (*Massachusetts State Bd. Agr. Rpt. 1901*, pp. 313-319).—After the appropriation for insecticide operations against the gypsy moth was discontinued by the legislature, the gypsy moth commission was ordered to turn over all apparatus to other departments of the commonwealth or to sell the same. A considerable part of the apparatus was transferred to the Metropolitan Park Commission, office of the State Board of Agriculture, and the Massachusetts Agricultural College. It is reported that the gypsy moth is increasing in numbers throughout its range, in some localities to a serious extent. Much damage is also reported from the depredations of the brown-tail moth, elm-leaf beetle, and San José scale.

A new nomenclature for the broods of the periodical cicada, C. L. MARLATT (*U. S. Dept. Agr., Division of Entomology Circ. 45*, n. ser., pp. 8).—Reprinted from Bulletin 18, new series, of the division (E. S. R., 10, p. 1062).

General review of the animal and vegetable parasites of the cocoanut, A. ZIMMERMANN (*Centbl. Bakt. u. Par., 2. Abt.*, 7 (1901), No. 25, pp. 914-924).—The animal and plant enemies of the cocoanut are briefly mentioned, in connection with a bibliographical list of the literature relating to this subject. Notes are given on rats, squirrels, various families of beetles, ants, moths, bugs, grasshoppers, crustacea, and a number of fungi belonging to the various groups of this class of plants.

The small rose-leaf wasp (*Blennocampa pusilla*), J. RITZEMA BOS (*Tijdschr. Plantenziekten*, 7 (1901), No. 4, pp. 126-128).—This insect is reported as having caused injury to rose leaves throughout the Netherlands; both wild and cultivated species were attacked. As a rule, however, the injury is not of such importance as to require any special attention in combating it.

Certain Javanese Ascomycetes which are parasitic on Coccidæ, A. ZIMMERMANN (*Centbl. Bakt. u. Par., 2. Abt.*, 7 (1901), No. 24, pp. 872-876, figs. 5).—Descriptive and biological notes on the following species of fungi parasitic on bark lice: *Torubiella luteostrata*, *Nectria coccidophthora*, *Lisea parlatoria*, *Ophioneetria coccicola*, *Broomella ichmaspidis*, *Hypocrella raciborskii*, and *Myriangium duriei*.

South African locust fungus (*Agr. Jour. Cape Good Hope*, 19 (1901), No. 13, pp. 850-855).—A brief discussion is given of the various parasitic fungi which have been found growing upon injurious insects. The South African locust fungus has proved to be *Mucor exitiosus*, and was described by Massee as a new species. The fungus was first observed in 1896, since which time it has been found useful in controlling locusts and cockroaches.

Concerning certain mosquitoes, J. B. SMITH (*Science*, n. ser., 15 (1902), No. 366, pp. 13-15).—*Culex sollicitans* is considered the most common species in New Jersey. Observations show that the larvæ live only in brackish water; they were never found by the author in fresh water, and were observed in several instances in water which was 25 per cent saltier than sea water. Despite the fact that they breed only at the seashore, these mosquitoes are carried by the wind or migrate to distances of from 10 to 40 miles inland, where they may be found in large numbers. Notes are also given on *C. pungens*. Larvæ of this species were found until late in November. Species of *Anopheles* continue to breed until long after frost has occurred. On a few occasions adults were bred from larvæ that had been confined under ice for several hours. Observations of the author in New Jersey clearly indicate "that there is absolutely no connection between the abundance of *Anopheles* and the prevalence of malaria."

The mosquito pest and how it may be abated, J. B. SMITH (*New Jersey State Bd. Agr. Rpt. 1901, pp. 245-249*).—Brief notes are given on the prevalence and distribution of mosquitoes in New Jersey, including the 2 genera *Anopheles* and *Culex*. *Stegomyia* is said not to occur in New Jersey.

FOODS—NUTRITION.

Food and food adulterants, W. D. BIGELOW ET AL. (*U. S. Dept. Agr., Bureau of Chemistry Bul. 13, pt. 10, pp. IX+1375-1517*).—The process of canning different sorts of meats is described from personal observations. Analyses are reported of many samples of canned and fresh meat of different sorts, meat broth, etc., the methods of analysis being described. In addition to the constituents ordinarily determined in proximate analyses, determinations are reported of different members of the nitrogenous group. Special studies are also reported of the fat of different sorts of fresh and canned meat, as the authors believe an examination of the fat furnishes valuable means of determining the character and origin of such goods. Of the 290 samples of American origin, 6.2 per cent, and of the 69 samples of imported goods, 40.6 per cent, contained chemical preservatives. The authors found that meat undergoes shrinkage when parboiled previous to canning. It is stated that loss in weight "consists very largely of water and fat, partly of meat bases and ash, and that the amount of proteid matter removed would be so small as to be within the limits of error of analysis. The following table shows the average results obtained in the examination of the fats of different sorts of fresh and preserved meat:

Fats from roast and boiled meat.

	Canned roast and boiled beef.	Canned corn beef.	Canned dried and smoked beef.	Horse meat.	Canned ham and bacon.	Canned tongue.	Canned fowl (of known origin).	Canned fowl.	Potted beef.

Chemical analysis of a flour made from India corn, S. GRIMALDI (*Staz. Sper. Agr. Ital.*, 34 (1901), No. 10, pp. 952-965).—Analytical data reported and discussed.

Flour from Arnautka wheat, E. F. LADD (*North Dakota Sta. Rpt. 1901*, pp. 18, 19).—An analysis is given of flour from this macaroni wheat.

The food value of starch, flour, and grits, P. CARLES (*Répert. Pharm.*, 57 (1901), pp. 289-291; *abs. in Ztschr. Untersuch. Nahr. u. Genussmit.*, 5 (1902), No. 1, p. 29).—A general discussion.

Substitutes for bread used in times of famine and the digestibility of such materials by man, ERISMANN (*Ztschr. Biol.*, 42 (1901), pp. 672-709).—The composition and digestibility of a number of sorts of bread substitutes used in Russia in time of famine are reported. Results are discussed at some length.

The amount of bread obtained from flour, BALLARD (*Compt. Rend. Acad. Sci. Paris*, 133 (1901), p. 251; *abs. in Centbl. Agr. Chem.*, 31 (1902), No. 3, pp. 186-188).—The comparative yield of round and oblong loaves was studied. On an average the weight of the round loaves from a given quantity of flour was greater than that of the square loaves, the difference being due to the proportion of crust and the corresponding water content of the two sorts. Analytical data are also reported.

Adulteration of wheat flour with flour from other cereals and legumes, M. LOZANO Y CASTRO (*Mem. y Rev. Soc. Cient. "Antonio Alzate,"* 16 (1901), No. 3, pp. 91-101).—Directions for recognizing adulteration of different kinds are given.

A plant butter used as a substitute for cocoa butter, G. POSSERRO (*Giorn. Farm. e Chim.*, 51 (1901), pp. 337-340; *Chem. Rev. Fett u. Harz-Ind.*, 8 (1901), p. 233; *abs. in Ztschr. Untersuch. Nahr. u. Genussmit.*, 5 (1902), No. 10, p. 472).—From an examination of a sample the conclusion was drawn that this material consisted of Japanese wax and cocoa fat.

Gluten alimentary pastes, G. TEYXEIRA (*Staz. Sper. Agr. Ital.*, 34 (1901), No. 10, pp. 993-995).—The author compares a number of different brands of gluten alimentary pastes, quoting the composition.

Fersan—its therapeutic and nutritive properties, H. F. TOURLET (*Thesis, Univ. Paris*, 1901, pp. 61).—Experiments are reported on the effects of feeding fersan, a food product made from the red corpuscles of beef blood.

Plasmon, E. F. LADD (*North Dakota Sta. Rpt. 1901*, pp. 20, 21).—Three preparations of this material were examined.

Infant foods, E. F. LADD (*North Dakota Sta. Rpt. 1901*, p. 20).—Analyses are reported of 4 preparations.

Food products of Canada and names of some exporters (*Dept. Agr., Ottawa*, 1901, pp. 44).—A description and statistical article with an address list.

An improved method of preparing and preserving meat for use in metabolism experiments, W. J. GIES (*Amer. Jour. Physiol.*, 5 (1901), No. 4, pp. 235-239).—According to the author, meat may be satisfactorily preserved by grinding, removing moisture by pressure, forming the dry mass into balls, and storing in glass bottles at a temperature of 0° C. or lower. The advantages gained, the author states, are: "The perfect freshness of the food at the time of its consumption, even weeks after its preparation; therefore, its similarity in appearance, odor, and taste to ordinary fresh meat, and its superiority to forms of nitrogenous food to which the animal is unaccustomed, or for which it has no desire. The constancy of composition of the food throughout even the longest experiments, by which circumstance the labor of analysis is reduced to a minimum."

Recent investigations concerning dietary studies of the people of the United States of America, P. O. SMOLENSKI (*St. Petersburg: Department of Interior*, 1901, pp. 128).—This volume contains an account of the agricultural experiment stations of the United States, and a summary of all the nutrition investigations carried on to date under the auspices of the Office of Experiment Stations of the United States Department of Agriculture, the author's object being to familiarize Russian readers with the large amount of material which has been thus accumulated.

Dietary computer, ELLEN H. RICHARDS (*New York: John Wiley & Sons; London: Chapman & Hall, 1902, pp. 54, chart*).—This volume contains specially prepared tables showing the composition of a number of common food materials and dishes made from them. The material is arranged in such a way that the author believes the food value of a given menu may be readily computed and compared with the commonly accepted dietary standards. A chart accompanying the volume consists of a cardboard frame with movable slips upon which the composition of food materials may be written in such a way that the total food value of the day's ration can be conveniently ascertained.

Therapeutic value of vegetable diet, L. KUTTNER (*Berlin. Klinik., 1902, Jan.; abs. in British Med. Jour., 1902, No. 2159, Epit., p. 79*).—The author concludes that a mixed diet is most suitable for man in health. The conditions requiring a partial or complete vegetarian diet are discussed.

The valuation of a vegetarian diet, ALBU (*Berlin. Klin. Wchnschr., 1901, No. 24, p. 647; abs. in Hyg. Rundschau, 12 (1902), No. 5, pp. 237, 238*).

Metabolism on a vegetarian diet, ALBU (*Ztschr. Klin. Med. [Berlin], 43 (1901), p. 1; abs. in Hyg. Rundschau, 12 (1902), No. 5, pp. 237, 238*).—The author studied the diet of a woman who had been a vegetarian for 6 years. The daily diet, which consisted of graham bread, apples, plums, grapes, nuts, dates, and lettuce, furnished 34.14 gm. protein and 36 gm. fat. On this diet there was an average daily gain of 0.37 gm. nitrogen. On an average 67 per cent protein and 65 per cent fat was digested. The diet is discussed in relation to a normal diet.

Precautions to be taken by consumers of vegetables, CESEROLE (*Queensland Agr. Jour., 10 (1902), No. 4, p. 301*).—In an article quoted from *Agriculture Moderne*, the author recommends that vegetables should be well washed and immersed for $\frac{1}{2}$ hour in a 3 per cent solution of tartaric acid to rid them of injurious micro-organisms and parasites and their eggs if such are present. He calls attention especially to the fact that injurious parasites may be transmitted to men by raw vegetables which have been manured with contaminated material unless they are thoroughly cleaned.

The energy value of the diet of man, M. RUBNER (*Ztschr. Biol., 42 (1901), pp. 261-308*).—Experiments are reported in which subjects (men and boys) were fed milk, potatoes, rye bread, coarse bread, meat, a mixed diet containing a little fat, and a mixed diet containing a large amount of fat. The fuel value of food, urine, and feces was determined. In a number of cases the fuel value of the food as determined was compared with the value calculated by the aid of the factors ordinarily used. The following table shows the physiological nutritive effect of the foods and rations studied—that is, the percentage of energy available:

Physiological nutritive effect of different foods.

Food material.	Fuel value per gm. ash-free material.	Energy lost.			Physiological nutritive value.
		In urine.	 feces.	Total.	
	Calories.	Per cent.	Per cent.	Per cent.	Per cent.
Milk.....	5,932	5.13	5.07	10.20	89.80
Mixed diet, containing an abundance of fat; boy E.	5,916	2.52	6.27	8.79	91.21
Mixed diet, containing an abundance of fat; boy O.	5,718	3.30	7.91	11.21	88.79
Mixed diet, containing little fat; man F.	5,095	5.00	7.43	12.40	87.60
Mixed diet, containing little fat; man T.	4,917	4.30	4.58	8.90	91.10
Mixed diet, containing an abundance of fat; man F	6,204	5.20	4.32	9.50	90.50
Mixed diet, containing an abundance of fat; man T	6,479	4.48	4.44	8.90	91.10
Rye bread.....	4,190	2.40	15.50	17.90	82.10
Coarse bread.....	4,243	2.20	24.30	26.50	73.50
Potatoes.....	4,178	2.30	5.60	7.90	92.10
Meat.....	5,862	16.30	6.90	23.20	76.80

The author notes that determinations like those reported furnish a means of judging of the energy value of foods, but that special studies of a different nature are needed to determine their protein value.

Meat and meat preparation in the diet of man, H. PODA and W. PRÄUSNITZ (*Ztschr. Biol.*, 42 (1901), pp. 377-406).—Digestion experiments with man are reported in which roast meat, salt meat, and meat albumen, with and without the addition of meat extract, were added to a simple mixed diet. From a number of the experiments the following average figures were deduced, showing the amount of the different nutrients excreted in the feces—that is, not digested:

Nutrients excreted in the feces when meat and meat preparations were eaten.

Diet.	Dry matter.	Nitrogen.	Ether extract.	Ash.
	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>
Meat albumen	4.10	10.27	22.87	4.52
Roast meat	3.33	7.12	19.14	3.68
Salt meat	3.26	6.79	10.04	4.76

Artificial digestion experiments were also made, which led to the conclusion that fresh meat was more quickly dissolved than the dry meat preparations, and that different preparations made by drying meat differed among themselves in the quickness with which they were dissolved. The experiments are discussed in detail.

The power of alcohol to protect protein, R. O. NEUMANN (*München. Med. Wchnschr.*, 1901, No. 28, p. 1126; *abs. in Hyg. Rundschau*, 12 (1902), No. 5, pp. 248, 249).—From experiments in which the author was himself the subject, he concluded that under the experimental conditions alcohol was directly comparable with fat. He regards alcohol as a nutrient.

The cleavage of protein in man when severe work is performed, C. JACKSON (*Atti R. Accad. Lincei. Rend. Cl. Sci. Fis. Mat. e Nat.*, 5. ser., 10 (1901), II, No. 8, pp. 186-188).—Experiments are reported in which the urine of 5 persons was examined after severe work which consisted in climbing a mountain, the results being compared with similar data obtained when no work was performed. The author believes that muscular work increased the cleavage of protein. [It should be noted that no statements are made concerning the food eaten. The variations in the amount of nitrogen excreted may have been due to variations in the amount of protein consumed.]

Concerning the tryptic cleavage of protein, J. MOCHIZUKI (*Beitr. Chem. Physiol. u. Pathol. Zschr. Biochem.*, 1 (1901), p. 44; *abs. in Hyg. Rundschau*, 12 (1902), No. 5, pp. 235, 236).—A chemical study of trypsin.

The influence of environment, and especially of inorganic substances, upon the properties of protein, J. STARKE (*Ztschr. Biol.*, 42 (1901), pp. 187-227).—A theoretical discussion of the structure and properties of the albumen molecule with special reference to the author's investigations.

ANIMAL PRODUCTION.

Commercial feeding stuffs in the Connecticut market (*Connecticut State Sta. Bul.* 133, pp. 39).—In accordance with the State feeding stuff law, analyses were made of a number of samples of cotton-seed meal; old and new process linseed meal; wheat products from winter, spring, and unclassified wheat, including bran, middlings, and mixed feeds; corn meal; gluten meal; gluten feed; hominy feeds; rye feed; malt sprouts; buckwheat shucks; buckwheat middlings; and miscellaneous feeds, including the by-products from cereal breakfast foods, proprietary feeds, condimental feeds, and meat meal, and other poultry feeds.

"Cotton-seed meal, linseed meal, the gluten meals and feeds, and the factory mixed feeds of two firms are, as a rule, sold with a guaranteed percentage of protein and fat as is required by the State law.. On the other hand, the wheat feeds, and

the corn feeds—other than those named above—as well as most other feeds, are, as a rule, sold without guaranties, which is contrary to law.

“The only evidence of deliberate fraud in the feed market which is shown by the analyses, is the mixing of finely ground corncobs with wheat feed. . . . There are in the feed market a considerable number of very inferior oat feeds, and mixed corn-and-oat feeds, which contain a large proportion of hulls and chaff, and which can not profitably be used by the stock feeder at any price.

“The dairyman’s chief concern in buying feeds to supplement his farm supply of corn, stover, hay, etc., should be to buy, on the most reasonable terms, protein in digestible and palatable forms. Seldom will it pay him to buy any feed containing less than 12 to 15 per cent of crude protein.”

Analyses of commercial feeding stuffs, J. L. HILLS (*Vermont Sta. Bul.* 91, pp. 39–52).—Analyses were made in accordance with the State feeding stuff law of a number of samples of cotton-seed meal; linseed meal, old and new process; gluten meals, and feeds; cereal breakfast food by-products, and other commercial feeds; ground oats; wheat bran; wheat middlings; mixed wheat feed; buckwheat bran; buckwheat middlings; buckwheat hulls; calf meal; ground beef scrap and poultry feeds. According to the author none of the samples of cotton-seed meal, linseed meal, or gluten products was adulterated, although several brands of the latter and some of the germ oil meals were inferior to the guaranteed composition.

“The oatmeal manufacturers’ brands of oat feeds, corn-and-oat feeds, etc., were found, as usual, more or less loaded with oat hulls. Some of these brands are extremely inferior. One is called a ground oats, yet carries less than half the protein which oats should contain. Another is nothing more nor less than finely ground oat hulls, selling at \$20 a ton. Ninety per cent of the provenders (other than the output of the oatmeal mills) seem to be above reproach, while the remaining 10 per cent are hardly more than open to question. The wheat offals appear to be of excellent grade, no cases of adulteration being found, but, on the contrary, exceptionally high protein contents being observed.”

Indian food grains and fodders—their chemical composition, J. W. LEATHER (*Agr. Ledger* (1901), No. 10 (*Med. and Chem. ser.*, No. 14), pp. 349–376).—Analyses are reported of *Andropogon halepensis*, *A. sorghum*, *Sorghum andropogon*, peanuts, oats, *Brassica campestris*, cocoanut cake, a number of legumes, millets, etc.

The composition of tendon mucoid, W. D. CUTTER and W. J. GIES (*Amer. Jour. Physiol.*, 6 (1901), No. 3, pp. 155–172).—Among the conclusions drawn from a chemical study of tendon mucoid were the following:

“The average composition of mucoid separated from white fibrous connective tissue by the customary methods is very nearly the same as that of chondromucoid and osseomucoid. Thermochemical studies of the mucoids in tendon, cartilage, and bone emphasize the probability that these bodies are very intimately related.”

The chemical constituents of tendinous tissue, L. BUEGER and W. J. GIES (*Amer. Jour. Physiol.*, 6 (1901), No. 4, pp. 219–231).—The composition of tendinous tissue from a steer and a calf was studied.

The composition of yellow fibrous connective tissue, G. W. VANDEGRIFT and W. J. GIES (*Amer. Jour. Physiol.*, 5 (1901), No. 5, pp. 287–297).—A chemical study of ligaments from a steer and a calf is reported.

The nutritive value of gelatin, O. KRUMMACHER (*Ztschr. Biol.*, 42 (1901) pp. 242–260, *dgm.* 1).—On the basis of experimental data, including determinations of the heat of combustion and feeding tests with a dog, the author concludes that gelatin supplies the body with energy and hence prevents the cleavage of protein. When gelatin was fed in his experiments, the cleavage of protein was 62.6 per cent less than during fasting.

The effect of variations in the method employed for the artificial digestion of proteid materials, G. BERJU (*Deut. Med. Ztg.*, 22 (1901), pp. 567, 568; *abs. in Ztschr. Untersuch. Nahr. u. Genussmit.*, 5 (1902), No. 6, p. 275).—Experimental data are reported.

Some observations on the metabolism of protein, M. GRUBER (*Ztschr. Biol.*, 42 (1901), pp. 407-427, *dgms.* 3).—A number of the principles of metabolism are discussed at length in connection with the author's experiments. The author believes that fat is formed from protein and cites experiments in proof of this contention. The possibility of increasing the size of the organs of the body by any system of diet is also discussed, the author believing that this is only possible within the most narrow limits. The small gains or losses of nitrogen which are observed in metabolism experiments are discussed in detail and are believed by the author to depend upon a retention of protein or an increased metabolism of this nutrient, as the case may be. The protection of protein by different materials is also discussed.

Heat of combustion and physiological nutritive value of foods. I, Meat, J. FRENTZEL and M. SCHREUER (*Arch. Anat. u. Physiol., Physiol. Abt.*, 1901, pp. 284-298; *abs. in Ztschr. Untersuch. Nahr. u. Genussmit.*, 5 (1902), No. 6, pp. 266).—Experiments with a dog are reported which led to the conclusion that 74.84 per cent of the energy supplied in meat was rendered available by the body.

An experimental contribution to the question of the physiological protein minimum, M. CREMER and M. HENDERSON (*Ztschr. Biol.*, 42 (1901), pp. 612-618).—Experiments with a dog are reported, in which the metabolism of nitrogen was studied.

Concerning the cause of increased proteid metabolism during fasting, F. N. SCHULZ (*Ztschr. Biol.*, 41 (1901), No. 3, pp. 368-377).—A controversial article.

The influence of body fat in fasting animals, E. VOIT (*Ztschr. Biol.*, 41 (1901), No. 4, pp. 502-549, *dgms.* 5).—A number of experiments, some of which were made by the author, with different animals, are quoted and discussed in detail. According to the author, proteid cleavage in a fasting animal is markedly influenced by the fat content of the body. If a large amount of fat is present, the metabolism of protein is not increased at the beginning of the fasting period. However, as soon as the fat is diminished to a certain amount the cleavage of protein is relatively increased. Apparently the relation between the body fat content and the cleavage of protein is the same with different classes of animals, so that it is possible by means of the amount of proteid cleavage to estimate the amount of fat present. The effect of body fat upon the amount of proteid cleavage is dependent upon the relation between the amount of fat in circulation and the amount present in the fat reservoirs of the body. The relation between death due to fasting and the fat content of the body is also discussed.

Concerning the cause of the increased cleavage of protein during fasting, E. VOIT (*Ztschr. Biol.*, 41 (1901), No. 4, pp. 550-571).—A further discussion of the subject noted above. Respiratory quotient experiments are reported. These tests also indicate that the cleavage of protein is dependent upon the amount of fat present in the body.

The formation of fat from carbohydrates, K. B. LEHMANN and E. VOIT (*Ztschr. Biol.*, 42 (1901), pp. 619-671).—A large number of experiments are reported which, the authors believe, show that fat may be formed from carbohydrates. In some of the experiments food, urine, and feces were taken into account; in others the respiratory products were also studied.

The utilization of rhamnose by the animal body and the related question of the physiological value of carbohydrates, M. CREMER (*Ztschr. Biol.*, 42 (1901), pp. 428-467).—The work of earlier investigators is reviewed at some length and exper-

iments made by the author with a dog and rabbits are reported. The conclusion was drawn that rhamnose diminishes the cleavage of fat in the body.

On the occurrence of oxy-phenyl-ethyl-amin in pancreas digestion, and on the cleavage of carbon dioxid by ferments, R. L. EMERSON (*Beitr. Chem. Physiol. u. Pathol.*, 1 (1901), pp. 501-506; *abs. in Chem. Centbl.*, 1902, I, No. 8, p. 485).—Experimental data are reported and discussed.

Studies on the motor activity of the stomach, II, MORITZ (*Ztschr. Biol.*, 42 (1901), pp. 565-611, fig. 1).—A number of experiments are reported and discussed in detail.

The breeders' associations of the German Empire, January 1, 1901, O. KNISPEN (*Arb. Deut. Landw. Gesell.*, 1901, No. 66, pp. 257).—Statistics and other data are given regarding the breeders' associations in the different States of the German Empire.

On the influence of awards of prizes for live stock on the development of Swedish animal industry, J. EKELEND (*K. Landt. Akad. Handl. Tidskr.*, 40 (1901), No. 4, pp. 217-269).

Animal husbandry in Russia, R. MÜLLER (*Fühling's Landw. Ztg.*, 50 (1901), No. 23, pp. 818-824; 51 (1902), Nos. 2, pp. 74-77; 3, pp. 108-114).—A descriptive and statistical article.

Stock feeding, C. M. CONNER (*South Carolina Sta. Bul.* 67, pp. 13).—The general principles of animal feeding are discussed, the composition of a number of feeding stuffs of the most importance locally is quoted, and rations composed of such materials suggested.

Waste products of western farms may become a source of profitable gain through the use of live stock, R. S. SHAW (*Montana Sta. Bul.* 32, pp. 26-30).—With a view of determining the value of grain, weeds, grass, etc., in stubble fields, 11 yearling steers, 8 heifers, 3 colts, 25 pigs, and 230 lambs were pastured for from 1 month to about 6 weeks on 112 acres which had been planted with wheat and other cereals, potatoes and other roots. During stormy weather the steers were fed some hay, the lambs some clover, and the pigs some barley meal. The original weight of the steers was 4,613 lbs., and the gain 447 lbs. The lambs at the start weighed 11,699 lbs., and gained 2,249 lbs. The pigs gained 877 lbs., the original weight being 2,731 lbs. Data for the other animals are not recorded. The author calculates that the "waste products" eaten by live stock yielded a "profit of \$1.44 per acre over and above the value of the food secured by the animals and required for maintenance."

Beef production in Iowa, W. A. McHENRY (*Iowa Agr.*, 1 (1902), No. 3, pp. 2-5).—A general article.

Report on cod-liver oil as a substitute for cream in calf rearing, R. S. SETON (*Yorkshire Col., Leeds, and East and West Ridings Joint Agr. Council, Pamphlet* 18 (1901), pp. 7, tables 2).—Continuing previous work (E. S. R., 12, p. 668), 12 calves, about a month old, were fed whole milk for some 5 weeks. The ration of 8 of them was then gradually changed to skim milk and cod-liver oil, the amounts fed daily being finally 5 qts. of skim milk to 2 oz. of cod-liver oil. The remaining calves were continued on whole milk, 6 qts. per day being finally fed. After some 6 weeks all the calves were given meadow hay ad libitum and about 1 lb. per head daily of linseed cake and bran, the amount being gradually increased. The average weight of the calves at the beginning of the whole-milk period was a little over 112 lbs. each. The average daily gain of the calves fed whole milk in the 140 days of the test was 1.7 lbs. per head, that of the calves fed cod-liver oil 1.2 lbs. To test the value of continued oil feeding, the calves immediately after weaning were divided into 3 lots of 4 each. Lot 1, composed of the calves accustomed to it, was fed 2 oz. of oil daily with linseed cake and meal. The others were fed cake and meal only. In 28 weeks the average daily gain of the calves formerly fed whole milk was 2 lbs.; of those fed

skim milk and oil and continued on an oil ration, 2.4 lbs.; and of those formerly fed oil, but not continued on it, 2.1 lbs. At the close of the test the calves were slaughtered. The following general conclusions were drawn: Cod-liver oil as a substitute for fat may be used with safety, supplementing separator skim milk for calves, and they readily become accustomed to it. Feeding cod-liver oil does not involve much labor, and with skim milk furnishes a cheap feed. Judging from the experiment reported above, it seems advisable to continue the oil feeding with linseed cake and meal for a time after weaning. The use of cod-liver oil in the early stages of calf feeding does not seem to have any bad effect on the flesh of the animals when slaughtered as bullocks.

Some notes on sheep husbandry, H. W. MUMFORD (*Proc. Soc. Prom. Agr. Sci.* 1901, pp. 163-165).—The author quotes statistics covering several years which were kept of a flock of sheep. It was noted that on an average wether lambs gained in 60 days 2.25 per cent in live weight and 4.0 per cent dressed weight more than bucks of the same age. The feed consisted of early-cut clover hay. While with the ewes the latter were given 1 to 1.5 qts. shelled corn daily.

The goat in Germany, F. DETTWEILER (*Arb. Deut. Landw. Gesell.*, 1902, No. 69, pp. 207, figs. 11).—Historical statements are made concerning the goat in Germany and the importance of the goat-raising industry. Goat raising in the different provinces of the German Empire is discussed and methods for further development of the industry suggested.

Pig-feeding experiments, J. R. CAMPBELL (*Yorkshire Col., Leeds, and East and West Ridings Joint Agr. Council, Garforth Expts.*, 1899, Pamphlet 8, pp. 4).—The value of several grain rations mixed with different amounts of water was tested with 4 lots of 6 pigs each after a preliminary period of 124 days, during which the pigs had gained on an average 1.1 lbs. per head daily. The test proper covered 56 days. Lot 1 was fed barley meal, sharps, i. e., middlings, and gluten meal 2:1:1; lot 2 a mixture of equal parts of barley meal and maize meal; lots 3 and 4 barley meal and sharps 1:1. The grain ration of lots 1, 2, and 3 was mixed with four times and lot 4 with twice its weight of water. The average daily gain of the 4 lots was 1.1, 0.9, 1.1, and 1.4 lbs. per head, respectively, the food eaten per pound of gain being 5.3, 6.1, 5.7, and 4.9 lbs. According to the author, the effect of the rations was most marked with lots 3 and 4, the former receiving the ration in a sloppy condition, the latter in the form of a porridge. Larger gains were made on the drier ration and less food was required per pound of gain. The author believes that "the mixture of barley and meal and sharps is better than barley meal and maize, and that the latter mixture may be somewhat improved by the addition of a highly nitrogenous meal, and, finally, that a great deal of food may be wasted, particularly in winter, when pigs are fed upon food containing more water than is necessary for the requirements of the body. The cost of food supplied to lot 4 was about \$4.56 greater during 8 weeks than that given lot 3, but the value of the increase of pork for the same lot was \$10.20, thus leaving a balance of \$5.64 in favor of the drier food."

Investigations on the metabolism of pigs fed sugar, starch, and molasses, E. MEISSEL and W. BERSCH (*Ztschr. Landw. Versuchsw. Oesterr.*, 4 (1901), No. 8, pp. 805-921, pls. 2, figs. 6).—Metabolism experiments with pigs are reported to compare sugar, starch, and molasses as the principal sources of carbohydrates in a ration. The basal ration in all the tests consisted of barley and dried brewers' grains. Food, urine, feces, and respiratory products were analyzed. For the collection of the respiratory products a Pettenkofer respiration apparatus was used. Experimental methods are discussed in detail, and the experiments reported in full. The following table shows the balance of income and outgo of carbon and nitrogen in the different periods, and the calculated gains of flesh (muscular tissue) and fat.

Summary of metabolism experiments with pigs.

[Quantities per day.]

Principal feeding stuff.	Carbon.					Nitrogen.					Muscular tissue gained.	Fat gained.
	In food.	In feces.	In urine.	In respiratory products.	Gain.	In food.	In feces.	In urine.	Gain.

A number of general deductions were drawn from the experiments, some of which follow. In all the experiments in which a normal ration was fed—i. e., one in which the starch was furnished by barley or potatoes—the protein was very well digested. In periods in which molasses was fed the digestibility of proteids was diminished and that of non-nitrogenous nutrients increased. Generally speaking, the coefficients of digestibility of fats were low. As noted by other observers, the amount of carbon dioxide excreted was proportional to body weight. Less was excreted in the molasses period than in other periods. On the whole the authors regard molasses as a somewhat better feeding stuff than starch in the form of barley. Better results were also obtained with molasses than with sugar. From these experiments sugar does not appear to possess a higher nutritive value than other carbohydrates. The authors note that it can be regarded also as a stimulant. An examination of the fat of the pigs showed that molasses did not exercise an unfavorable effect on its composition.

Tankage as a food for swine, C. S. PLUMB (*Proc. Soc. Prom. Agr. Sci.*, 1901, pp. 95-98).—Noted from another publication (E. S. R., 13, p. 1079).

Experimental contributions to the theory of heredity, J. C. EWART (*Trans. Highland and Agr. Soc., Scotland*, 5. ser., 14 (1902), pp. 172-229, figs. 26).—The author discusses in a critical manner a number of the cases usually mentioned as supporting the hypothesis of telegony in horses. In all cases other simpler explanations are found for the actual phenomena which were observed without resorting to any theory of "infection," "corruption," or influence of a previous sire. The experiments conducted by the author were chiefly confined to the production of crosses between horses and zebras, and the raising of colts from the same mares after production of the hybrids. In these experiments chestnut, brown, and black mares were employed, and in some cases the mare was bred alternately to zebra and horse stallions, in order to give the best possible opportunity for judging any influence of the zebra upon the appearance or conformation of the offspring. No evidence whatever was obtained in support of the theory of telegony. The colts obtained in mares which had previously been bred to zebras were true to their parents in every respect and exhibited no mental or physical traits of the zebra. A brief review is given of the results of the experiments of Baron de Parana, in Brazil. His experiments were based on extensive raising of mules, and the observations of de Parana and his acquaintances engaged in the same occupation are distinctly opposed to the theory of the influences of the previous sire.

The author also conducted experiments for the purpose of determining whether any support of the hypothesis of telegony could be obtained from breeding mares to different breeds of stallions. These results were also unfavorable to the theory of telegony, as were similar experiments in breeding mares to various stallions of the same breed. The author states that although at the beginning of his experiments he "hoped to prove the fact of telegony," his experiments and observations have thoroughly convinced him that there never has been an undoubted case of "infection" in dogs, rabbits, or horses.

Poultry experiments, J. H. SHEPPERD (*North Dakota Sta. Rpt. 1901, pp. 89-91*).—A comparison was made of the egg production of 19 hens 1 year old and 12 hens 2 years old. The average number of eggs laid by the hens 1 year old in 180 days was 49.4 and of the hens 2 years old 15.7. The number of eggs laid by individual hens is reported in connection with a brief discussion of breeding for egg production.

Subdepartment of poultry, H. C. GARDNER (*Montana Sta. Bul. 32, pp. 50-52*).—Brief notes are given regarding the station poultry equipment and management of poultry. Two feeding tests are noted, no details being reported.

Incubators and brooders and their management, D. S. THOMPSON (*Agr. Gaz. New South Wales, 13 (1902), No. 1, pp. 15-21*).—Incubators are described and tests of a number of sorts at the Hawkesbury Agricultural College are reported.

On the determination of the soundness of eggs by their specific gravity, C. COGGI (*Gior. R. Soc. Ital. Ig., 1901, Apr. 30; abs. in Public Health, 14 (1902), No. 7, p. 423*).—From experiments reported in detail, the author concludes that the specific-gravity method of testing the freshness of eggs with a salt solution does not give reliable results.

DAIRY FARMING—DAIRYING.

The immediate effect on milk production of changes in the ration, W. P. WHEELER (*New York State Sta. Bul. 210, pp. 373-433*).—Records of 981 cows for limited periods, obtained for the most part in extensive tests of breeds covering a number of years, are grouped to show the immediate effect upon milk production of changes in the ration as regards total digestible organic matter, fuel value, amount of protein, and nutritive ratio. The record in each case is taken for the 2 to 4 weeks preceding and following a change in the ration. No ration was fed that was radically deficient in any respect, and the change was never very marked. Averages of the 111 groups based upon the character of the ration fed are presented in tabular form and discussed. The author's summary of the results in part is as follows:

"Total nutrients.—In general, the milk flow increased most or diminished least when the greatest increase of total nutrients was made without regard to moderate changes in protein content. The most rapid shrinkage of milk flow generally occurred when the percentage reduction of total nutrients was greatest, although this usually was associated with a reduction of protein.

"On the average for all records when an increase of the total nutrients was made, there was no change in milk production. On the average for all when the amount of nutrients was reduced, the shrinkage in milk flow was at twice the normal rate. . . .

"Fuel value.—An average of all records when an increase in the fuel value of the ration was made shows a diminution in milk yield about one-fifth as great as would usually occur under unchanged rations. An average of all records when the fuel value was reduced shows about twice the usual diminution in milk yield. . . .

"Protein.—In general, changes in the amount of protein within ordinary limits produced less effect than changes in the amount of total nutrients. On the whole, the diminution of milk flow was less when the amount of protein was increased than when it was reduced.

"On the average for all records when the protein was increased, those including also an increase of total nutrients show no falling off in milk production, those with but little change in nutrients show a normal diminution or less, those with a reduction of nutrients show a shrinkage greater than usual. On the average for all records when the protein was reduced those with an increase of total nutrients show less than the usual decrease in milk production, those with but little change of nutrients show about the normal shrinkage, those with a reduction of nutrients show a falling off at twice the normal rate.

"The average of those records where there was an increase of protein without change in amount of total nutrients shows an increased cost of production. There was no increase in the cost of production, on the average, when the protein was reduced without change in amount of nutrients. . . .

"*Nutritive ratio.*—Changes in the nutritive ratio within the ordinary limits had considerably less influence on the milk flow than did changes in the amount of total nutrients. In general, however, a narrowing of the ratio had a favorable effect on milk production, while a widening of the ratio tended toward the reverse.

"When but little change in the amount of total nutrients occurred, a narrowing of the ratio was followed by less than the usual decrease in milk yield and a widening of the ratio by more than the usual decrease.

"With an increase in the amount of total nutrients, a narrowing of the ratio was followed by an increase in milk yield. A widening of the ratio was followed by a decrease (to less than the usual extent), although the average increase of total nutrients was nearly a pound greater than when the ratio was narrowed."

How changes in feed affect the yield of milk, F. H. HALL and W. P. WHEELER (*New York State Sta. Bul. 210, popular ed., pp. 8*).—A popular summary of the above bulletin.

Feeding trials with cows, J. L. HILLS (*Vermont Sta. Rpt. 1901, pp. 314-369, I-XLV*).—In continuation of similar work (E. S. R., 13, p. 584) carried on at the station for 4 years, numerous feeding experiments, including 51 cows and lasting 28 weeks, are reported in detail and summarized. A full account is given of the manner in which the experiments were conducted and tabulated data are presented in an appendix.

A comparison of 4, 8, and 12 lbs. of grain was made with 16 cows with results essentially the same as those obtained last year. An increase in the grain ration increased the yield of milk and butter, but not in proportion to the amount of grain fed. The slight variations observed in the quality of the milk were in favor of the medium grain ration. More milk and butter per pound of dry matter was produced on the low grain ration. From a financial standpoint the results were unfavorable to the high grain ration. "It is felt on the whole that neither the low or the high ration ranks with a medium grain ration for practical continuous dairy feeding."

The effect of adding protein and fat to standard rations was studied with 14 cows with results essentially the same as those previously reported. An excessive amount of protein did not materially increase the yield of milk, and its quality was not improved. The addition of palm oil to the ration seemed to give a permanent increase in the fat content of the milk.

The feeding value of germ-oil meal, a by-product of the glucose industry, was compared with that of mixtures of (1) cotton-seed meal, new process linseed meal, and wheat bran, and (2) wheat bran and ground oats. The germ-oil meal ration increased the yield of milk and butter 3 and 6 per cent, respectively, over the other 2 rations.

A hay and grain ration was fed with and without silage in alternating periods to 6 cows. When one-third of the hay was replaced by silage the yield of milk and butter was increased 7 per cent. The silage ration was much more profitable.

Results for 2 winters show no improvement in the quantity or quality of the milk yield from warming water from 35 to 80° F. for cows stabled in barns the average winter temperature of which was 45 to 50° F.

Tests were made of the feeding value of apples, apple pomace, and pumpkins. A substitution of apples for three-fourths of the corn silage in a ration containing in addition hay and grain lessened the yield of milk and butter 8 per cent. A similar substitution of apple pomace for silage decreased the yield of milk and butter 2 per cent. Pumpkins were substituted for silage, the results showing a decrease of 1 to 2 per cent in the yield of milk and butter. No unfavorable effects followed feeding apple pomace or pumpkins. These experiments indicate that 1 ton of corn silage has the same feeding value as 2½ tons of apples, 1½ tons of apple pomace, and 2½ tons of pumpkins.

Additional data are given concerning the experimental error involved in feeding trials. "The results of continuous feeding on a regular ration were practically uniform. If more than 2 or 3 animals are used, the experimental error inherent in the alternation method of feeding trials may be nearly or quite disregarded."

A comparison of feeding trial methods, J. L. HILLS (*Vermont Sta. Rpt. 1901*, pp. 369-375).—In the feeding experiments with low, medium, and high grain rations noted above a comparison was also made of methods of conducting feeding experiments. Different rations were fed in alternate periods to the same group of animals and continuously to different groups. The data are tabulated and discussed in detail. "So far as these trials go, they seem to affirm within limits the validity of both schemes of experimentation, provided periods 4 or 5 weeks long be used and the choice of animals be satisfactory."

The effect of feed on the quality of butter, J. L. HILLS (*Vermont Sta. Rpt. 1901*, pp. 375-377).—In connection with the feeding experiments noted above and in continuation of previous work (E. S. R., 13, p. 585) studies were made of the effect of different feeding stuffs upon the quality of butter. Feeding an excessive amount of protein did not materially affect the quality of the butter fat. Feeding palm oil in addition to a standard ration increased the melting point of the butter fat 4° C. and decreased the content of volatile fatty acids. Germ-oil meal increased the iodine number. An increase in the hardness of the butter fat lengthened the time required for churning, but decreased the loss of fat in the buttermilk. The quality of the butter was not materially affected by the different feeding stuffs.

Feeding experiments with gluten meal and gluten feed for dairy cows, H. GOLDSCHMIDT (*Ugeskr. Landm., 47 (1902), No. 9, pp. 104-111*).—Cooperative feeding experiments with milch cows for the purpose of comparing gluten meal and gluten feed with ordinary concentrated feeds are reported. According to the plan of the experiments, 3 lbs. of gluten meal or feed replaced an equal weight of the kind of grain mixtures ordinarily fed on the 14 dairy farms on which the experiments were conducted, the mixtures being made up of varying quantities of barley and oats, rape-seed cakes, sunflower-seed cakes, cotton-seed cakes, molasses bran, etc. Nine of the experiments were with gluten meal and 5 with gluten feed. The amount of grain fed ranged from 4½ to 10 lbs. per head daily. The experiments were divided into a preliminary feeding period, two experimental periods, and a post-experimental period, of 2 to 3 weeks each. The number of cows included in the experiments at the different farms varied from 6 to 40, the cows being in all cases separated into two lots, as nearly uniform as possible as regards production, time of calving, age, etc. Analyses of the milk produced do not appear to have been made, but the average daily milk yield per cow during the gluten meal feeding over and above that produced on ordinary grain mixtures amounted to 0.8 to 2.5 lbs., or, on the average, 1.45 lbs. avoirdupois, and on the gluten feed, 0.2 to 2.1 lbs., or, on the average, 0.85 lb. avoirdupois. At the prevailing prices of concentrated feeding stuffs in Denmark the results

indicate that a saving of at least \$30 per carload of feed may be effected by feeding 3 lbs. of gluten meal per head daily in the place of an equal quantity of common feed mixtures. No deleterious effects on the health or live weights of the cows were noticed during the experiments. Four pounds of gluten meal is considered a maximum allowance per day for dairy cows. It is suggested that both gluten meal and feed may also prove valuable foods in feeding horses, in amounts not to exceed 3 to 4 lbs. per head daily.—F. W. WOLL.

On feeding of dairy cattle, L. DYHRE (*Ugeskr. Landm.*, 47 (1902), No. 11, pp. 128-132).

Feeding corn stover; dehorning milch cows, C. M. CONNER (*South Carolina Sta. Bul.* 66, pp. 9).—The yields of corn stover (whole stalks after removal of the ears) and corn fodder (blades only) on several plats at the station are given and the composition of corn stover is discussed. Shredded corn stover and cotton-seed hulls fed ad libitum with a uniform grain ration were compared with 2 lots of 4 cows each in an experiment lasting 31 days. Detailed data for the experiment are given. On the corn stover ration milk was produced at a cost of 6.84 cts. per gallon and on the cotton-seed hull ration at a cost of 7.14 cts. per gallon. "Definite conclusions can not be drawn from this experiment, on account of the limited time during which it was carried on, but it shows that the corn stover has a greater feeding value than cotton-seed hulls."

The total decrease in the yield of milk of 7 cows for the 5 days following dehorning as compared with the 5 days preceding was 16.1 per cent. Three of the cows were not much affected by dehorning.

Jersey cattle in Jutland, J. LARSEN (*Ugeskr. Landm.*, 47 (1902), No. 2, pp. 17-19).—In comparing the production of Jutland and Jersey cows in a Danish herd, the latter proved superior to the domestic breed as regards the quality of the milk and the amount of butter fat produced. The Jersey cows produced at the rate of over 2 lbs. more butter per 100 lbs. of food units eaten than the Jutland cows.—F. W. WOLL.

The variation in the composition of cows' milk, H. INGLE (*Trans. Highland and Agr. Soc. Scotland*, 5. ser., 14 (1902), pp. 284-313, *dgms.* 13).—The investigations with cows on dry feed reported last year (*E. S. R.*, 13, p. 279) were repeated with cows on pasture. During 2 periods of 20 days each in August and September over 1,600 samples of milk from 19 cows were collected and analyzed. The results are presented by means of diagrams, and are discussed in connection with the data previously reported as regards the effect of period of lactation, season of the year, time and manner of milking, and food upon the composition of the milk. The quality of the milk is shown to decrease for the first 2 or 3 months of the lactation period and then to increase steadily as lactation advances. The average fat content of some 700 samples of milk obtained in March and April, 1900, was 3.86 per cent. In the present investigations samples analyzed during the first period (August 1 to August 20) showed 3.40 per cent of fat, and samples analyzed during the second period (August 20 to September 9) showed 3.46 per cent of fat—showing a lower fat content in the fall. As in the earlier investigations the cows were milked at 6 a. m. and 3 p. m. During the first period the average fat content of the morning's milk was 2.72 per cent and the evening's milk 4.09 per cent. During the second period the percentages were 2.83 and 4.09, respectively. Analyses of the mixed morning's milk showed also that the fat content may often fall below 3 per cent in the late summer or autumn where the intervals between milkings are unequal. The cows were divided into 4 lots which were fed uniformly during the first period a grain ration of 2 lbs. of decorticated cotton-seed cake. During the second period lot 1 was fed the same ration, lot 2, 4 lbs. of Chicago gluten meal, lot 3, 6 lbs. of corn meal, and lot 4, 28 lbs. of fresh brewers' grains. The yield of milk of the 4 lots during the second period, as compared with the first, decreased, respectively, 9.44, 5.69, 6.49, and 12 per

cent. The fat content increased in the case of lots 1, 2, and 4 and decreased in the case of lot 3. The results on the whole are considered as indicating that foods rich in proteids increase the yield and quality of the milk, while large quantities of carbohydrates, though slightly increasing the yield of milk, tend to diminish its quality.

Variations in cream and milk tests, A. H. WHEATON (*South Dakota Sta. Bul.* 73, pp. 19, pls. 5).—The causes of variations in the composition of milk are briefly discussed, and tables are given showing the temperature, specific gravity as determined by the Quevenne lactometer, and the fat content as determined by the Babcock test, of a large number of samples of milk as received at several creameries in the State. The author also discusses the so-called dilution separators, concluding that there is no advantage gained in their use over ordinary cans, and quoting from New York Cornell Bulletin 151 (E. S. R., 10, p. 591) in support of this view. In testing cream by the Babcock method the author recommends weighing the sample of cream. End and side views and plans of a creamery are given, and it is announced that specifications, incorporation papers, etc., will be furnished free on application to those desiring to build creameries, provided that they will safely preserve and return the same.

Killing tubercle bacilli in milk heated to a temperature of 60° C., W. HESSE (*Ztschr. Thiermed.*, 5 (1901), No. 5-6, pp. 321-325).—Theobald Smith, in experiments in the pasteurization of milk, demonstrated that the tubercle bacillus was killed by heating milk to a temperature of 60° C. for a period of from 15 to 20 minutes. The author tested these conclusions on a large scale, and a large firm of milk dealers was prevailed upon to try the experiment of heating their milk to 60° C. for 20 minutes. The milk was heated in large vessels to a temperature of 60° C., and was kept at this temperature for exactly 20 minutes, after which it was cooled as quickly as possible to a temperature of 8° C. During the time while the milk was being pasteurized it was stirred continually so as to prevent the formation of a pellicle on the surface, or the cooling of the superficial layer of milk. The author inclosed cultures of tubercle bacilli in glass tubes hermetically sealed and placed these tubes in 3 vats of milk heated at temperatures of 60, 58, and 57° C., respectively. Inoculation experiments made on guinea pigs with the material contained in these vessels showed that all tubercle bacilli which were heated to a temperature of 60° C. were destroyed, while the guinea pigs which received the other cultures heated to a temperature of 58 and 57° C., respectively, developed cases of tuberculosis of a more or less generalized nature. It is believed that the sterilization of milk is best secured with the least changes in the composition and taste of the milk by a subjection to a temperature of 60° C. for 20 minutes. Observations showed that by this treatment other organisms, including those of cholera, typhus, and diphtheria, were also killed.

On the composition of Dutch butter, J. J. L. VAN RIJN (*London: Baillière, Tindall & Cox*, 1902, pp. 48-7).—On account of the frequent charge of adulteration made against Dutch butter by foreign analysts during each fall, the Netherlands Government caused an investigation to be made of the composition of butter made during the latter months of the year. The results of analyses of 428 samples of Dutch butter obtained from various sources and known to be genuine are presented in this report. The methods of analysis employed were those used in the government laboratory in England. Of the 428 samples, 214, or 50 per cent, showed a volatile fatty acid number less than 25, the lowest limit accepted for pure butter in England, while 6 samples showed a number lower than 20. The averages by months were, September, 24.8; October, 23.7; November, 25.2; December, 26.6. When the cows were stabled in the fall and their food improved, the volatile fatty acid number increased. The abnormal composition of butter in the autumn is therefore attributed to poor food and exposure to inclement weather due to the custom of late pasturing. Conditions affecting the composition of milk and butter are discussed, and a discussion of the new Belgian butter law is appended.

Chemical and physical characteristics of fat of Norwegian creamery butter, F. H. WERENSKIÖLD, S. HALLS, and H. GREGG (*Aarsbr. Offent. Foranst. Landbr. Fremme, 1901, pp. 30*).—The investigations here reported were conducted during the years 1898–1901, to establish the variations that are apt to occur in the chemical and physical properties of butter fat from pure Norwegian creamery butter. In all 682 samples of butter from 21 creameries located in different parts of Norway were examined. The following table presents the average data obtained for each month, with maxima and minima for the different determinations:

Average results of examinations of Norwegian creamery butter.

Month.	Specific gravity (at 37.8° C.).	Refractive index (at 45° C.).	Reichert number.	Iodin number.
January.....	0.9120	39.80	31.00	33.0
February.....	.9122	39.85	31.00	32.1
March.....	.9123	39.90	30.80	32.7
April.....	.9120	40.05	30.95	33.4
May.....	.9116	40.50	29.95	35.3
June.....	.9110	41.40	28.55	39.3
July.....	.9104	41.95	28.45	39.6
August.....	.9107	41.80	28.60	39.3
September.....	.9110	41.40	29.75	38.7
October.....	.9114	40.35	30.15	34.9
November.....	.9123	39.50	30.70	30.6
December.....	.9123	39.55	30.90	31.0
Minimum.....	0.9082 (Sept.)	38.70 (Oct.)	21.10 (June)	28.2 (Nov.)
Maximum.....	.9130 (Dec.)	43.70 (June)	34.90 (Jan.)	45.1 (June)

The results show that the butter fat from the creameries investigated may assume such a composition during the spring months that according to the methods of analysis adopted it would have the same effect as an admixture of artificial butter fat; it may retain this changed character during the summer and not return to normal values again until in the fall. The results of van Rijn, Böggild, and Stein as to the increase in Reichert number at the tying in in the fall were corroborated.—F. W. WOLL.

Report of Danish butter exhibits during 1901, F. FRIIS (*Copenhagen, 1902, pp. 39*).—During the calendar year 1901, 808 different creameries exhibited butter amounting in all to 2,376 tubs. The average water content of the butter exhibited was 14.06 per cent.

A report is given of investigations conducted during 5 consecutive years (1897–1901) concerning the refractive index and volatile fatty acids of Danish creamery butter. The figures given in the following table, which have been compiled from tables in the report, represent average data for the 5 years. The total number of samples of butter fat examined during this period was 10,475.

Average results of examinations of butter fat, 1897–1901.

Month.	Refractive index (at 25° C.).	Reichert number.	Month.	Refractive index (at 25° C.).	Reichert number.
January.....	50.6	30.57	August.....	52.4	28.2
February.....	50.7	30.60	September.....	52.8	27.5
March.....	50.9	30.47	October.....	52.4	28.1
April.....	51.0	30.27	November.....	50.6	30.4
May.....	51.3	29.6	December.....	50.4	30.7
June.....	51.3	30.4			
July.....	51.8	29.4	Average for year...	51.4	29.7

The monthly variations in the refractive indexes or volatile fatty acids are repeated very regularly from year to year, and the average data for the different months

given in the table may, therefore, be considered normal figures for Danish butter at the present time. A high refractive index is in general accompanied by a low Reichert number, but this does not always hold true in single instances.

In connection with this question, information was sought as to the relation between the quality of the butter and the content of volatile fatty acids, it having been contended by some food chemists that even if a low content of volatile fatty acids is not necessarily evidence of adulteration, it shows an inferior quality and food value of the butter and this should, therefore, in some manner be subject to penalty. The data brought together in this and earlier reports of the Copenhagen experiment station (E. S. R., 12, p. 681) show that the variations found in the content of volatile fatty acids of Danish butter have nothing to do with the purity of the butter, its nutritive value, flavor, or in general, with anything that concerns the quality of the butter. In order to obtain conclusive evidence on this point, all the samples of butter received after April, 1901, scoring lowest and highest, were examined for refractive index and for volatile fatty acids, and the results are tabulated in the report. The scores of butter having the lowest and the highest refractive indexes and Reichert numbers are also given. The following summary table presents the average data thus compiled. According to the plan of judging butter adopted in the Danish butter exhibits, 15 is a perfect score.

Relation of quality of butter, refractive index, and volatile acids of butter fat.

	Cooperative creameries.			Private dairies.			All samples.	
	Score.	Reichert number.	Refractive index.	Score.	Reichert number.	Refractive index.	Score.	Reichert number.
Highest scores	12.3	29.3	51.7	10.5	28.4	51.9	11.5	28.9
Lowest scores	5.4	28.9	51.7	6.3	28.6	51.8	5.9	28.8
Highest Reichert number.	9.4	30.4	50.6	8.3	29.7	51.3	8.9	30.1
Lowest Reichert number..	9.5	27.3	52.8	8.5	27.3	52.6	9.2	27.3

The best butter contained more volatile fatty acids than the butter of the poorest grade in 15 cases out of 35, while the opposite was true in 18 cases, the volatile acid content being the same in 2 cases. While the figures in the last two lines of the table might be interpreted to show that a high content of volatile acids was found in case of lower scoring butter, the difference is most likely accidental, since the results for the single exhibits come sometimes one way and sometimes another. The author therefore concludes that there is no correlation between the quality of the butter and the volatile-acid content of the butter fat.—F. W. WOLL.

Denmark's butter exports, 1900-1901. B. BÖGGILD (*Tidsskr. Landökon.*, 1901, No. 11, pp. 515-524).—The net exports during the year 1900-1901 were 118,888,375 Danish pounds, an increase of nearly 10,000,000 lbs. over those of the preceding year, and the gross exports 165,531,812 lbs. Of this quantity nearly 158,000,000 lbs. was exported to Great Britain. The average price of the butter for the year was 98 öre per pound (23.9 cts. per pound avoirdupois), about one-sixth of a cent above the average price for 1899-1900.—F. W. WOLL.

Testing Babcock milk and cream bottles. C. H. JONES (*Vermont Sta. Rpt.* 1901, pp. 222, 223).—The method employed at the station in testing bottles is described. Having determined that the total capacity of the neck is correct by the use of 1 cc. of mercury for each 5 per cent on the scale the author determines if there are any material irregularities in the bore by means of an instrument devised by him which "consists of two brass arms sufficiently long to reach to the zero mark on the bottle scale. These are pivoted near their center and play easily back and forth. The upper end of one is securely attached to a circular brass dial, and the end of the other is so connected with a pointer, or hand, on the dial that the slightest movement of the lower end of the brass arm causes a greatly increased revolution of the

hand on the dial face. A spring on the back of the dial keeps a steady tension at the ends of the brass arms, enabling them when inserted in and drawn up the sides of the glass bottle neck to adjust themselves instantly to any variations that may occur and to manifest the same by a movement of the pointer." Bottles showing decided irregularities are further tested by filling to the zero mark with mercury and adding 0.5 cc. portions from a specially devised burette.

VETERINARY SCIENCE AND PRACTICE.

Therapeutic observations (*Ztschr. Veterinärk.*, 13 (1901), No. 5, pp. 213-234).—Experiments were tried with injections of carbolized water in the treatment of tetanus. Of 8 cases treated in this manner, 4 recovered and the other 4 died. Carbolyzed water in a 2 to 3 per cent solution was injected subcutaneously, twice per hour, in doses of 5 to 10 gm. In the treatment of tetanus with antitoxin, 9 out of 15 horses which received the antitoxin died, while 6 recovered. In some cases another form of treatment was adopted during which, in addition to the antitoxin, a serum was injected which had been obtained from a horse previously infected with tetanus. According to experiments of Kammerhof the administration of antitoxin in some cases brings about a rapidly fatal course of the disease.

Several experiments are reported in the treatment of parturient paresis with iodid of potash. Unfavorable results were obtained in only 3 cases. The remedy was applied in the way of infusions into the udder.

The same substance was also tested in the treatment of metritis, with results which left it doubtful whether recovery was entirely due to the administration of iodid of potash.

Experiments were tried with creolin in the treatment of anthrax in cattle. Creolin was given by way of the mouth and also in clysters in water. The treatment gave good results.

Detailed notes are given on the results obtained by a number of army veterinarians with colloidal silver in the treatment of morbus maculosus in horses, catarrhal fever in cattle, septic processes, phlegmonous infection, and in the treatment of wounds.

Therapeutic observations (*Ztschr. Veterinärk.*, 13 (1901), No. 6, pp. 272-291).—Reports are made on experiments with two silver preparations—citrate of silver, also known as itrol, and silver lactate, known in trade as actol. These antiseptic substances in experiments thus far made have proved to be as effective as the colloidal silver preparation of Crédé. Notes are also given on a large number of antiseptic preparations which have been used in the treatment of wounds and septic processes.

The culture of anaerobic bacteria, H. HAMMERL (*Centbl. Bakt. u. Par.*, 1. Abt., 30 (1901), No. 17, pp. 658-664).—The chief difficulty experienced in the culture of anaerobic bacteria is the production of strictly anaerobic conditions. Nearly all of the various devices which have been employed in such experiments have been defective to the extent that during some part of the experiment oxygen was allowed to enter into the atmosphere surrounding the bacteria, or into the nutrient medium. In order to prevent the access of oxygen the author recommends that an ammonium sulphid medium be placed in a glass vessel and that the neck of the vessel be closed with a loose sterilized plug of cotton from which all fat has been removed. The lower half of the cotton plug should be saturated with solution of pyrogallol acid. The upper portion of the plug should be protected with a rubber cork. Care must be exercised that the pyrogallol should not come in contact with the nutrient medium, and the cotton must be absolutely free from fat.

The dissemination of infectious diseases by insects, C. F. DAWSON (*Amer. Vet. Rev.*, 25 (1901), No. 4, pp. 266-272).—A brief review of the literature on this subject. Among the insects which are mentioned as possible carriers of disease are bedbugs, house flies, tsetse flies, mosquitoes, and cattle ticks.

Parasitically inoculated diseases, E. G. WHEELER (*Trans. Highland and Agr. Soc. Scotland*, 5. ser., 14 (1902), pp. 16-35, figs. 2).—The author briefly reviews his work on the life history of the grass tick (*Ixodes ricinus*), already noted (E. S. R., 11, pp. 891, 892). In this article especial attention is given to a comparison between louping ill and a number of other similar diseases, including Texas fever, malaria, tsetse-fly disease, surra, heartwater, and yellow fever. The author believes that louping ill is in some unexplained manner transmitted from one animal to another by means of the grass tick. It is argued that the striking similarity in the occurrence and symptoms of louping ill and other diseases which are known to be transmitted through the agency of insects substantiates this assumption.

Vermineous bronchitis in calves (*Farmers' Gaz.*, 60 (1901), No. 42, p. 763).—The symptoms of this disease are briefly described. The disease is due to the presence of *Strongylus filaria* in the bronchial tubes. In ordinary cases of the disease turpentine in spoonful doses may be administered daily in a few ounces of linseed oil. Where a considerable number of animals are infected at once they may be inclosed in a tight apartment and fumigated with sulphur. The use of chlorin gas for the same purpose is recommended as very effective, but rather more irritating and dangerous than sulphur.

The migration of the embryos of tapeworms, HOFMANN (*Berlin. Thierärztl. Wchnschr.*, 1901, No. 36, pp. 537-541, figs. 7).—From extended observations on this subject it is concluded that the oncosphere stage of tapeworms may leave the alimentary tract by means of the lymphatic vessels and efferent veins; through the veins they may reach the liver, and by means of the lymph fluid they may obtain entrance into the general circulation. They may pass through the capillaries, after remaining in that situation for some time.

The toxin of tapeworms, MASSINEO and CALAMIDA (*Jour. Méd. Vét. et Zootech.*, 5. ser., 5 (1901), Sept., pp. 537-541; trans. from *Gior. R. Soc. Accad. Vet. Ital.*, 1901, No. 30).—The authors investigated the causes of the pathological changes produced by the presence of tapeworms in the intestines of various animals. The tapeworms were crushed in a mortar and an extract was obtained without heating and was later passed through a Berkefeld filter. The species used in these experiments were *Tenia saginata*, *T. expansa bovis*, *T. alba*, *T. cucumerina*, and *T. caninus*. The filtrate obtained by treatment just described was used for inoculating guinea pigs, rabbits, and dogs. In the first series of experiments filtrate was inoculated hypodermically in doses varying from 2 to 35 cc., according to the weight of the animals. Symptoms of intoxication were produced in all cases, and 2 guinea pigs died after 24 hours. In further experiments similar results were obtained. The authors believe that the pathological changes produced in the intestines of the hosts of tapeworms are due to a secretion of toxin rather than to mechanical friction.

Sturdy or gid, F. V. THEOBALD (*Agr. Gaz. [London]*, 54 (1901), No. 1455, p. 335, figs. 2).—A description is given of the parasite which causes this disease, and the usual symptoms of the disease are mentioned. The life history and development of the parasite are described. In the prevention of this disease the author recommends that the heads of infested sheep should be destroyed in order to prevent their being eaten by dogs. Dogs which are allowed to run on sheep pastures should be treated frequently for tapeworms in order to prevent transmission of this parasite to the sheep.

Treatment of sheep scab with acaprin, H. RÆBIGER (*Monatsh. Prakt. Thierh.*, 13 (1901), No. 5, pp. 231-236).—Experiments were carried out for the purpose of testing the efficiency of this substance in destroying the scab mite. In all 550 sheep suffering from *Dermatocoptes* infestation were treated with acaprin. In May 100 ewes and 100 lambs, all shorn, were dipped in a solution of acaprin. The wool was not injured, but the dipping had no effect on the scab mites. It was also noted that the workmen were badly affected by the solution and complained of headache. Further experiments with this substance showed that by prolonging the bath and thoroughly rubbing the sheep with brushes the mites may be destroyed, but the

effect of acaprin on the workmen is severe, producing serious illness in many cases. In some cases the inhalation of the fumes of acaprin caused great irritation of the throat and a cough which persisted for several weeks. Similar symptoms were observed in some of the sheep which accidentally swallowed some of the solution while passing through the dipping vat. The high price of acaprin and its deleterious effects upon the workmen who attend to the dipping are considered as rendering the substance unfit for general use.

Prophylaxis of dourine and an account of recent discoveries concerning this disease, T. BUFFARD and G. SCHNEIDER (*Jour. Méd. Vét. et Zootech.*, 5. ser., 5 (1901), July, pp. 385-397, fig. 1).—Since the trypanosoma which causes this disease has been discovered it has become possible to make a diagnosis more quickly and to institute better measures for controlling the spread of the disease. The authors report a number of experiments during which animals were infected with the disease. It was found that at times the disease may develop without the appearance of the symptoms by which it is usually recognized. In preventing the spread of dourine the authors recommend a microscopic examination of the blood or pathological products from suspected stallions in order to make a certain and rapid diagnosis. As a further test, the blood or pathological products may be used for inoculating dogs, which are considered the most suitable animals for use in experiments in determining the nature of this disease. As soon as cases are determined, it is necessary to exclude the affected animal from breeding service.

An attempt at a classification of endoglobular hematozoa, LAVERAN (*Compt. Rend. Soc. Biol. Paris*, 53 (1901), No. 27, pp. 798-801).—The author recognizes 3 genera in this group of protozoa and characterizes them under the names *Hæmamoeba*, *Piroplasma*, and *Hæmogregarina*. A table is given showing the species which are referred to each of these genera, and the hosts in which they are found.

Mange in cattle and horses and lice on hogs, A. T. PETERS (*Nebraska Sta. Bul.* 74, pp. 27, figs. 16).—Brief historical notes are given on the origin and distribution of cattle mange in this country. It was first reported to the author from Nebraska in 1896. The disease is apparently more serious in late fall and winter than in summer, and develops the most pronounced symptoms in yearlings. The mite which causes this disease is described and notes are given on its life history.

If only a few mangy cattle are to be treated a liquid remedy may be applied by a swab, brush, or spray pump. Where large numbers of cattle are affected, however, it will be necessary to construct dipping tanks, such as are already in existence in many parts of the West. It is recommended that cattle be dipped twice in the fall and also twice in the spring, with an interval of 10 or 12 days between the 2 dippings. The substances recommended by the author for dipping cattle are chloro-naphtholeum and zenoleum. Experiments have been made with these dips on about 7,000 cattle, with favorable results. Both substances were used in a 4 per cent solution. Slightly stronger solutions may be employed. After cattle have been dipped it is recommended that they should not be allowed to lie down in infected corrals.

Brief notes are also given on other lice affecting cattle and a detailed description presented of suitable dipping vats for treatment of large herds of cattle.

Sarcoptic mange of horses has been known in the State since 1895. The symptoms of the disease are described and it is recommended that horses be treated in the same manner as cattle. Good success is reported from a single application of the dip, but in severe cases it is recommended that 2 dips be applied.

Notes are given on the lice which commonly infest hogs, especially *Hæmatopinus urinus*. Where hogs become badly infested the easiest method of freeing them of these pests is to dip the animals. It is recommended that hogs be dipped every 3 or 4 weeks, if infested with lice. Notes are given on a number of sheep dips which have been successfully used for dipping sheep and are also recommended for use on hogs.

A critical examination of the position of Dr. Koch on the subject of human tuberculosis, S. ARLOING (*Jour. Méd. Vét. et Zootech.*, 5. ser., 5 (1901), Oct., pp. 577-593).—This article is controversial in nature and the author seeks to array the many arguments which lead to conclusions contradictory to that of Koch. A report is made on experiments showing that goats, mules, cattle, and rabbits may be infected with tubercle bacilli of human origin. It is argued that the virulence of tubercle bacilli may vary to a considerable extent under different conditions and that this variation of virulence in different animals does not necessarily indicate different species of bacteria, but merely variations of the same species under different conditions of growth and development.

Report of the tuberculosis commission, C. H. COOK (*New Jersey State Bd. Agr. Rpt. 1901*, pp. 223-226).—The tuberculosis commission has continued to make examination of dairy cows which constitute the dairy herds within the State. Such examination was made in all cases where application has been made according to law so far as the appropriation permitted. During the year 1901 the total number of applications for examination was 190; the number of animals comprised in these herds, 2,512; and the number condemned, 342. The total indemnity paid for animals destroyed was \$7,260.75. The tuberculin test has also been made upon all cattle imported from other States.

Serum diagnosis in tuberculosis, G. CARRIÈRE (*Compt. Rend. Soc. Biol. Paris*, 53 (1901), No. 25, pp. 746, 747).—From numerous observations made by the author it is believed that this method is subject to some practical difficulties and requires special training for its application. It is an extremely sensitive method and gives the same results in young and old patients.

On the subject of sensibilizing substances in the serum of tuberculous patients, J. CAMUS and P. PAGNIEZ (*Compt. Rend. Soc. Biol. Paris*, 53 (1901), No. 25, pp. 734, 735).—In samples of serum obtained from tuberculous patients the presence of a sensibilizing substance causing, to some extent, the disappearance of alexin was determined. This phenomenon was not observed in every instance, but it is believed to be of general occurrence.

Tuberculin as a diagnostic of tuberculosis in cattle, J. SMITH (*Trans. Highland and Agr. Soc. Scotland*, 5. ser., 14 (1902), pp. 166-171).—On account of the number of failures of a reaction from tuberculin in cattle which were subsequently found to be tuberculous, further investigation of the subject was made by J. M. Young, who presents a report on 42 cattle which were tested with tuberculin. Of the 42 cows which were tested, 21 were found after slaughtering to be tuberculous, and of these only 17 had reacted to the test. It is recommended that in using the tuberculin test the temperature should be taken at least 4 times after inoculation, viz, at 9, 12, 15, and 18 hours after injection. In cases where the temperature appears to be gradually rising at the last period, it is recommended that it be taken subsequently, 21 hours after the inoculation.

The tubercle bacillus in feces, D. ANGLADE (*Compt. Rend. Soc. Biol. Paris*, 53 (1901), No. 28, pp. 829, 830).—According to observations by the author tubercle bacillus is almost always found in the feces, in cases where the intestines are involved in the progress of tuberculosis. Brief notes are given on a means of identification of tubercle bacillus in feces. These observations are considered of importance from a sanitary standpoint.

Lecithin in tuberculosis, H. CLAUDE and A. ZAKY (*Compt. Rend. Soc. Biol. Paris*, 53 (1901), No. 28, pp. 821-823).—Experiments with tuberculous guinea pigs and man showed that the use of lecithin does not directly check the development of tuberculosis, but that it modifies the nutritive processes favorably; under its influence the weight of the body increases, metabolic processes become more active, and the elimination of phosphorus is considerably diminished.

The action of urea on cultures of tubercle bacillus in bouillon and on tuberculous guinea pigs, RAPPIN (*Compt. Rend. Soc. Biol. Paris*, 53 (1901), No. 24, pp. 691-693).—In the experiments reported in this article the author added variable proportions of uric acid, urate of soda and urea to flasks containing from 100 to 120 gm. of the bouillon ordinarily used in the culture of tubercle bacillus. The proportions of these different substances varied between 10 cgm. and 2 gm. to 100 or 120 gm. of the bacillus. In the numerous experiments which were made the results were uniform. The action of the uric acid, even in strong doses, appears to be nil. The flasks to which this substance was added showed a growth of the tubercle bacillus equal to that of check flasks. The same results were obtained in experiments with urate of soda. The fact that the uric acid had no influence on the tubercle bacillus was at first explained by the slow solubility of this substance, but urate of soda is readily soluble. Quite different results were obtained in experiments with urea. Flasks containing tubercle bacillus to which urea, even in small quantities, was added, showed a slow and meager development as compared with check flasks. It is suggested that the action of urea in these cases was similar to that of an antiseptic.

Combating bovine tuberculosis, H. RAQUET (*L'Ing. Agr. Gembloux*, 12 (1901), No. 4, pp. 187, 188).—Brief notes on measures recently adopted in Gembloux for the eradication of tuberculosis. The author recommends thorough application of the tuberculin test in fighting this disease.

Experimental plastic spinal meningitis caused by the toxin of the tubercle bacillus, ARMAND-DELILLE (*Compt. Rend. Soc. Biol. Paris*, 53 (1901), No. 31, pp. 885-887).—A study was made of the influence of toxin obtained from an ether extract of the tubercle bacillus and inoculated into the spinal cord. The experimental animals were dogs. It was found that when the toxin was inoculated into the membranes of the spinal cord a plastic inflammation of these membranes was set up which, in its functional symptoms and anatomical lesions, resembles the course of tuberculosis. During the author's experiments with this toxin anatomical changes were produced similar to those observed by Auclair in the lungs. Further experiments are promised with a chloroform extract.

Anthrax, D. PUGH (*Farmer's Gaz.*, 60 (1901), No. 40, p. 734).—The symptoms of anthrax in horses, sheep, cattle, and pigs are described. It is recommended that as soon as an outbreak of the disease is noticed, the animals should be immediately removed from the pasture, in order to prevent its further contamination. The necessity of destroying carcasses of animals dead of anthrax is urged.

Recent work on blackleg, T. KIRT (*Monatsh. Prakt. Thierh.*, 13 (1901), No. 4, pp. 174-189, figs. 8).—The author presents a critical review of recent literature on this subject, in connection with bibliographical references to some of the important contributions.

Pathological histology and bacteriology of labial actinomycosis in cattle, Z. F. ELENEVSKI (*Arch. Vet. Nauk, St. Petersburg*, 31 (1901), Nos. 9, pp. 793-813; 10, pp. 873-896, pls. 3, figs. 2).—The author reviews the literature on this subject in great detail. Statistics were collected from various cities in Russia and other parts of Europe showing the prevalence of actinomycosis during recent years, especially since 1895. Particular attention is devoted to the study of the labial form of the disease. The proportion of actinomycosis of the lips to the total number of cases of actinomycosis in cattle was found to be as follows: In Moscow 37.9 per cent, in Tiflis 85.9 per cent, in Elisabetgrad 81.6 per cent, in Nijni Novgorod 5.5 per cent, in Ekaterinoslav 13.9. The pathological changes caused by infection of actinomycosis in the lips are described in elaborate detail. Experiments were tried with the organism, which was isolated, from actinomycotic tumors, and it was found that within 15 days after inoculation in the mucus membrane of the lower lip, a tubercle appeared and gradually increased in size until it became a large tumor at the end of 3 weeks. A careful study of the organism showed that it differed in many histolog-

ical and cultural characters from ordinary bacteria. The organism grew better upon acid media than on neutral or slightly alkaline media. The author concludes that the organism belongs to the mold fungi, rather than to bacteria proper.

Reappearance of cattle plague and the results of preventive inoculation in South Africa. A. THEILER (*Monatsh. Prakt. Thierh.*, 13 (1901), No. 4, pp. 145-161).—Cattle plague caused great losses in South Africa during the years 1896 to 1898, and as a result of this outbreak, bile and serum inoculations were applied on a large scale. The preventive inoculations of bile proved exceedingly effective and the disease was apparently eradicated. A few cattle, however, in various parts of the country were not inoculated. In May, 1891, an outbreak of the disease occurred in Basutoland and in the Orange River Colony. Many authorities have maintained that immunity produced by inoculations of bile persisted for only from 4 to 6 months. An investigation of this outbreak, however, showed that those animals which were inoculated with bile in 1897 still retained their immunity. In studying the latest outbreak it appeared that almost all cases of the disease occurred in young animals, and very few cases were observed in cattle over 4 years old. In several herds outbreaks occurred during which many calves died, but none of the older animals which had been inoculated 4 years before became infected. The author concludes that bile inoculation is to be recommended as a preventive measure, in herds where no cases of the disease have occurred, and also in infected herds. Many technical objections have been raised against the method, but it has proved itself practical and efficient, as judged by the results. The effect of this method in producing immunity has been so striking that many of the natives who at first could not be prevailed upon to allow preventive inoculation in their herds, have more recently had all their animals inoculated.

Treatment of malignant catarrhal fever of cattle with colloidal silver. TRAEGER (*Ztschr. Veterinärk.*, 13 (1901), No. 1, pp. 23-25).—In a case of this disease, as soon as the symptoms became sufficiently pronounced to enable the author to make a certain diagnosis the colloidal silver preparation was administered. The substance was injected twice per day intravenously, in doses of 50 gm. in a $\frac{1}{2}$ per cent solution. On the second day improvement was noted in the animal and ultimately complete recovery was brought about. During the whole treatment the animal received 300 gm. of the silver preparation. The injections were made partly in the jugular vein and partly in a more superficial vein.

Iodid of potash as a prophylactic treatment for parturient paralysis. A. KRÄGERUD (*Berlin. Thierärztl. Wchnschr.*, 1901, No. 40, p. 598).—The author obtained favorable results from the use of iodid of potash in the treatment of parturient paralysis, either by infusion into the udder or by intravenous injections. Experiments were made for the purpose of testing the value of this substance as a preventive of the disease, when given by way of the mouth. For this purpose cows were selected which were considered especially susceptible to the disease and were kept in stalls in which cases of the disease had frequently occurred. A few hours before parturition each cow was given 8 gm. of potassium iodid in $\frac{1}{2}$ liter of water, and the dose was repeated after from 12 to 20 hours. Of the 100 cows treated in this manner only 2 developed symptoms of the disease, so that the iodid of potash had to be given as an infusion into the udder. Several animals showed preliminary symptoms of the disease after the first administration of the iodid of potash, but recovered without serious development.

Report of the commission for combating foot-and-mouth disease (*Arch. Deut. Landw. Raths*, 25 (1901), pp. 179-230).—This report contains a detailed discussion on the presence and extent of foot-and-mouth disease in the various parts of Germany. A special report was made on the spread of the disease during the years 1886 to 1899 in various parts of the country. Numerous tables are given showing the number of cattle affected in different provinces and the extent of importation and

exportation of cattle. The commission recommends the following measures in controlling foot-and-mouth disease: Prohibition of the importation of ruminants and hogs, raw products of these animals, or other material which may serve to carry the contagion from countries which are infected with the disease. At times when no cases of the disease are known certain regulations are recommended as necessary to be observed in order to prevent as far as possible all outbreaks of the diseases. These measures include careful inspection of stock yards, slaughterhouses, stock trains, steamboats, and stock markets. It also recommended that all stalls and yards which are subject to infection from the disease should be regularly disinfected. In cases of outbreak of foot-and-mouth disease it is recommended that any delay or neglect in notifying the authorities should be punished with heavy penalty, that strict quarantine conditions should be maintained, and that none of the animals in quarantine or any of their products should be allowed to be moved from the place of quarantine until the most thorough process of disinfection has been carried out.

The intercantonal agreement concerning the enforcement of simple regulations for combating foot-and-mouth disease, J. EHRLHARDT (*Schweiz. Arch. Tierh.*, 43 (1901), Nos. 3, pp. 115-123; 4, pp. 162-173).—Regulations for the control of this disease have been formulated in 20 sections. The author gives a critical explanation of the meaning and purpose of each of these sections.

A new cure for foot-and-mouth disease, A. H. DELLSCHAFT (*Agr. Gaz.* [London], 54 (1901), No. 1456, p. 351).—The author gives an account of the treatment for this disease as recommended by Baccelli. The treatment consists in the intravenous injection of corrosive sublimate. In calves, 2 to 4 cgm. are to be administered, according to the severity of the attack; in adult cattle, from 4 to 8 cgm., according to size. The solution of corrosive sublimate should contain 75 mg. of common salt for each centigram of corrosive sublimate.

On braxy, D. J. HAMILTON (*Trans. Highland and Agr. Soc. Scotland*, 5. ser., 14 (1902), pp. 314-347, figs. 3).—This disease is especially prevalent among sheep and is identical with the disease known as bradsot in Teutonic countries. The author gives a historical review of the literature on this disease and discusses the general problems concerned with its diagnosis and nature. Braxy has a peculiar and limited distribution. It appears to affect only European sheep and is most prevalent on the West coast of Norway and of Scotland, and in Iceland. It is also prevalent on some of the small islands north of Great Britain. The number of deaths among sheep in certain seasons has been as great as 15 to 20 per cent. The symptoms are frequently not observed, since braxy usually runs its course very quickly. The breathing becomes somewhat labored and the temperature is elevated to from 105 to 108° F. It is observed that the disease is most apt to attack young animals—lambs after weaning appear to be most susceptible—while animals at 2 years of age are seldom attacked and 3-year-old sheep are almost quite exempt. The greatest prevalence of the disease is observed during the late autumn and early winter months, although occasional instances of braxy appear during the summer. Detailed descriptive notes are given on the post-mortem findings in 6 cases of natural infection of braxy. The pathological changes found in these cases agree closely with 3 other cases produced by artificial infection. Braxy bacillus was readily found in all cases and is described with reference to its various morphological and physiological characteristics. The method of natural infection is not well understood, but it is believed that the bacillus is inhaled in a dry condition. Work is being done at present for the purpose of developing an effective preventive treatment for this disease.

Acinous tumors of the gall bladder in cattle, ZELLHUBER (*Monatsh. Prakt. Tierh.*, 13 (1901), No. 2-3, pp. 97-120, pl. 1, figs. 4).—The anatomical characteristics of this disease are described in detail for 6 cases. The author concludes that the mechanical friction of the tumorous swellings of the gall bladder prevents the disappearance of the condition of inflammation and often renders this condition more

acute. In cases where the acini are numerous gall concretions may be formed which may obstruct the cystic duct and cause colic symptoms.

Investigations on the cutis of the hoofs of cattle, H. HOHMANN (*Monatsh. Prakt. Thierh.*, 13 (1901), No. 2-3, pp. 49-96, figs. 12).—On account of the numerous diseases which affect the hoofs of cattle it was considered desirable to make a further study of the anatomical structure of the hoofs of cattle. The author reviews the literature on the subject and describes the general appearance of the hoof, cutis, and subcutis in cattle. The microscopic structures, including the blood vessels and nerves which are distributed in these parts, are described in detail. A bibliography on the subject is appended.

Serum agglutination as a means for diagnosing glanders, C. O. JENSEN (*Berlin. Thierärztl. Wchnschr.*, 1901, No. 41, pp. 621-625).—The author discusses in detail the difficulties which are ordinarily met in making a rapid and certain diagnosis of glanders in suspected horses. The lack of a strictly differentiating method of staining the glanders bacillus renders its identification by ordinary bacteriological methods rather difficult. In testing animals with mallein the author considers it necessary to distinguish between animals which show only a slight elevation of temperature and in which no other general symptoms are manifested after injection with mallein; animals which show an irregular reaction, with a temperature of 39 to 40° C. of short duration and with loss of appetite and some swelling at the point of injection; and animals which show a specific reaction with a temperature of 40 to 41° C., appearing after a period of from 8 to 10 hours and persisting for from 12 to 24 hours. A brief account is also given of the method of diagnosing glanders by means of inoculating susceptible animals, such as guinea pigs, with material from suspected animals. Several experiments were made by way of testing the reliability of agglutination as a diagnostic sign of glanders; during these experiments it was found that the agglutination test is far more reliable than mallein injection. It is not urged that this method should entirely replace the use of mallein, but it is believed that the agglutination test can be judiciously used in cases where the mallein injection gives doubtful results.

Diagnosis of glanders, N. K. GADZYATSKII (*Arch. Vet. Nauk., St. Petersburg*, 31 (1901), No. 9, pp. 823, 824).—For making a definite diagnosis in suspected cases the author prefers inoculation of cats with material taken from discharges of ulcers in the nose or on other parts of the body. Where no ulceration has taken place, the submaxillary glands were removed and cats were inoculated with material from these organs. This method of diagnosis was considered very certain and does not require more than three days for a definite result.

Acute epizootic leucoencephalitis in horses, W. G. MACCALLUM and S. S. BUCKLEY (*Maryland Sta. Bul.* 80, pp. 67-76, pls. 3).—The authors made a further investigation of a disease which has been more or less prevalent for a number of years in Maryland and which has passed under a number of names, such as staggers, horse disease, and cerebro-spinal meningitis. The usual symptoms are drowsiness, imperfect vision, partial paralysis of the throat, twitching of the muscles of the shoulder, and unsteady gait. The temperature varies between 96 and 103° F. Usually the animals become more and more stupid and sometimes delirium is observed. The course varies from a few hours to a week, and is fatal in a large percentage of cases. Horses which recover exhibit defective intelligence. Post-mortem examinations were made on the brains of 4 animals which were affected with acute cases of the disease. On either side in the frontal region of the brain a softened area was observed, and was confined to the white substance. No bacteria were found in these areas. The cultures which were tried gave negative results. An inoculated rabbit remained perfectly well. When examined microscopically, affected tissues showed that greater or less changes had taken place in the nerve cells and fibers, neuroglia, blood vessels, and lymphatics. Clear hyaline masses which stained blue

were found in the small blood vessels in the affected areas. The walls of these vessels had undergone extensive inflammatory changes. Various other details of pathological changes in the affected tissue are given. Another extensive outbreak of the disease occurred in southern Maryland, during which a number of horses died. Three autopsies were made, but no macroscopic lesions were observed. When examined under a microscope, however, blood vessels in the brain substance showed inflammatory changes in certain areas. No cultures could be made with the material from these cases. A rabbit which was inoculated by material from 1 case which had been dead 48 hours died with infection of a bacillus belonging to the hog-cholera group. This bacillus requires further study, but it is not believed that it is connected with the disease.

Pneumonia and vaccination, REINLÄNDER (*Ztschr. Veterinärk.*, 13 (1901), No. 2, pp. 53-62).—A serious outbreak of pneumonia in epizootic form occurred in a number of regiments of army horses. The symptoms of the disease are described in detail and the post-mortem appearance of animals upon which anatomical examinations were made. Numerous experiments were tried in vaccinating animals for the purpose of preventing the development of pneumonia, or curing it. Of the animals which were not vaccinated 14.3 per cent became later infected with the disease, and of those which were inoculated 6.3 per cent contracted pneumonia. In considering all the experiments the author concludes that the present method of vaccination for preventing the development of pneumonia is of little value. It is believed that further investigation should be made for the isolation and identification of the micro-organism of the pneumonia of horses before better results in vaccination can be obtained.

Equine malaria, A. THEILER (*Schweiz. Arch. Tierh.*, 43 (1901), No. 6, pp. 253-280, pls. 2, fig. 1).—In studying the pathogenic organism of this disease the author noted its similarity to the organism of human malaria, but considers it a distinct species, which is described under the name *Plasmodium malariae equorum*. Notes are given on the microscopic characteristics of the parasite and on methods which are most successful in preparing and staining it. The influence of local conditions, time of year, and susceptibility of various horses to the disease are discussed. A detailed account is given of the characteristic symptoms and the method for making a certain differential diagnosis. The number of parasites in the blood is greatly diminished by the administration of quinine. It is recommended that quinine be given at least 3 times a day in doses of 6 to 10 gm. A bibliography on the subject is added to the article.

The appearance of colic in consequence of rusty barley straw, MIERSWA (*Ztschr. Veterinärk.*, 13 (1901), No. 8-9, pp. 378-380).—Several cases of colic appeared among army horses, and an investigation of the outbreak disclosed the fact that these horses had been fed on barley straw which was infected with rust of 2 species (*Puccinia graminis* and *P. rubigovera*). As soon as this forage was abandoned the outbreak of colic ceased. Brief notes are given on the therapeutic treatment which was given during the progress of the disease.

The pathogenesis of roaring in horses, THOMASSEN (*Monatsh. Prakt. Tierh.*, 13 (1901), No. 5, pp. 193-230, figs. 8).—The author gives a critical review of the large mass of literature on this subject. The anatomy of the larynx is described and the various theories which have been proposed for explaining the occurrence of this disease are discussed. A review of all the literature on this subject leads to the conclusion that the disease is still far from being well understood. It is believed that a microscopic study of those parts of the nervous system which are concerned with the disease may yield better results. Attention should be given not only to the recurrent nerve, but also to the vagus, accessory, and medulla oblongata.

Disinfection of stables with steam, KRAMELL (*Ztschr. Veterinärk.*, 13 (1901), No. 7, pp. 316, 317).—In an outbreak of pneumonia among horses an experiment was

made to determine the value of steam disinfection of stables in which the disease occurred. The steam was applied in as careful and thorough a manner as possible. As a result of these experiments it is concluded that steam is an efficient disinfectant, provided it is applied at a temperature of not lower than 100° C. In order to produce that temperature, however, in large stables the ordinary apparatus in common use is insufficient, and it is considered that this method must therefore be abandoned in the disinfection of stables.

Observations on the chicken plague which was introduced into Oldenberg from the Brunswick Chicken Exposition, L. GREVE (*Deut. Tierärztl. Wehnschr.*, 9 (1901), No. 37, pp. 373-376).—Post-mortem examination of fowls dead with this disease showed no pathological changes in the stomach. The blood vessels of the intestines were somewhat injected. Small red spots were observed on the heart and peritoneum. The bacillus of chicken cholera could not be demonstrated in the blood or other organs. Inoculation experiments with blood from the heart of a hen dead with the disease produced no infection in pigeons or white mice. Feeding experiments with infected material, however, caused the development of the disease in sparrows and pigeons. While the identity of the disease is not definitely determined, it is recommended that the same precautions be observed as are usually recommended in outbreaks of chicken cholera.

Brief statistics, M. STREBEL (*Schweiz. Arch. Tierh.*, 43 (1901), No. 5, pp. 210-220).—The author presents in a tabular form a list of the diseases which were treated in his practice during the past year. The number of cases of each disease are given and the animals affected. Brief mention is made of some of the more important diseases which are discussed by the author in the body of the article. Verminous bronchitis was observed in 43 calves and young cattle varying in age from 8 to 16 months. The animals were grazing on wet pastures. In the treatment of this disease the best results were obtained by causing the animals to inhale a mixture of 4 parts of ether and 1 part oil of turpentine. This mixture was administered 3 times per day, a spoonful being poured into the nasal cavity. The author makes a report on 9 cases of actinomycosis, 6 of which were localized in the tongue and 3 in the thyroid and laryngeal glands.

Report of the State board of health, H. MITCHELL (*New Jersey State Bd. Agr. Rpt. 1901*, pp. 229-234).—Brief notes are given on the cases of infectious diseases reported to the board of health during the year 1901. These diseases include 52 cases of glanders, 18 of tuberculosis, 4 of hydrophobia, 6 of bovine varicella, and 3 cases of supposed anthrax which were not definitely identified.

AGRICULTURAL ENGINEERING.

Irrigation department, S. FORTIER (*Montana Sta. Bul. 32*, pp. 57-71).—This is the report of the irrigation department of the station for the year ended June 30, 1901, and includes an account of observations on seepage losses from 5 irrigation canals and ditches, the duty of water for various crops in 1899, the amounts of water required by different crops in 1900, the discharge of the principal rivers of Montana in 1900, and an explanation of the importance of equitable division of water under cooperative canals.

Report on irrigation in South Africa, W. WILLCOCKS (*Agr. Jour. Cape Good Hope*, 20 (1902), Nos. 3, pp. 161-169; 4, pp. 241-249, figs. 2; 5, pp. 286-294, fig. 1; 6, pp. 344-351; 7, pp. 391-397; 8, pp. 449-455, figs. 2; 9, pp. 502-513, figs. 2, maps 2).—A discussion of conditions affecting irrigation in South Africa, and especially recommendations to the high commissioner regarding the policy to be pursued in "the recently acquired crown colonies of the Orange River and Transvaal." Proper provision by the State for irrigation, particularly the construction of storage reservoirs, is considered necessary to a normal development of the agriculture of the region, which has

remained largely pastoral and undeveloped on account of the limited amount and irregularity of the rainfall. It is maintained that rivers and torrents should be declared public domain, as has been done in Italy, and reservoirs for the storage of their waters should be built by the State, a part of the profits of the mines being utilized for that purpose, and the State being reimbursed by water rentals.

Recent developments in Punjab irrigation, S. PRESTON (*Jour. Soc. Arts*, 50 (1902), No. 2584, pp. 602-616, figs. 2).

Farmers' weirs, S. FORTIER (*Montana Sta. Bul.* 34, pp. 29, figs. 5).—A popular description of the construction and use of various devices (weirs) for measuring irrigation water, with tables for calculating the results in miners' inches.

Agricultural machines at the Paris Exposition, 1900, ALBERT and SCHILLER (*Arb. Deut. Landw. Gesell.*, 1901, No. 65, pp. 59, figs. 104).—A brief general discussion.

Second report on the highways of Maryland, H. F. REID and A. N. JOHNSON (*Maryland Geol. Survey*, 4 (1902), pp. 95-201, pls. 6, figs. 2).—This report includes an account of operations during 1900-1901, laboratory work, special road improvement, summary of road expenditures in different counties of the State, contract and specifications for two roads, and report of the Baltimore County roads engineer.

Horse and cattle barns built in 1901, E. G. SCHOLLANDER (*North Dakota Sta. Rpt.* 1901, pp. 92-98, figs. 5).—These barns are frame structures 2 stories high, standing on brick foundations. The main part of the horse barn is 45 ft. wide and 106 ft. long, with a small wing 10 ft. long and 45 ft. wide on the west side, and on the east a wing 36 ft. wide and 100 ft. long, which forms the horse stable proper. The first floor of the main structure contains a stock-judging room, harness and carriage rooms, etc. The west wing contains an office and a workshop. The east wing is equipped with stalls, racks, etc. The second floor of the main building contains attendants' rooms, feed rooms, etc. The main part of the cattle barn is 135 by 37 ft. "It holds two rows of stock facing the center, with a 5-ft. feed passage through the middle. The feed passage connects with the silo, which allows the ensilage to be thrown into a small truck and drawn through the passage way between the mangers as it is fed to the stock. On the east is a projection 10 ft. long by 32 ft. wide, containing an office, a stair footing, and a milk room. On the west is a large wing 50 ft. long by 37 ft. wide, with two rows of box stalls of different sizes, stairs, watering trough, and closets. The building has 16-ft. studding throughout." The stalls used are of the Bidwell pattern and are of different sizes. The second floor has feed bins, attendant's room, and haymows.

The silo, which is separate from the barn, "is round in form and is 24 ft. in diameter, inside measurement. The wall is made of brick, 28 ft. high and 20 in. thick, with a dead-air space in the center of it. The floor and wall are cemented with the best grade of cement. A dormer window in the silo roof serves as an intake for green corn or other material with which the pit is filled. A second dormer window on the opposite side of the roof furnishes light."

Hay and sheaf sheds, R. HENDERSON (*Trans. Highland and Agr. Soc. Scotland*, 5, ser., 14 (1902), pp. 105-147, figs. 40).—The construction and advantages of such sheds are discussed.

Compacting effect of plow teams upon the furrow, J. H. SHEPPERD (*Proc. Soc. Prom. Agr. Sci.* 1901, pp. 113, 114).—Observations with a platform scale in a barn floor showed that a horse weighing about 1,350 lbs. in walking exerted a pressure of about 640 lbs. with the hind foot and 700 lbs. with the front foot. The average surface of the feet of the horse was about 31 sq. in., the length of stride 34 in. It is estimated that the stride in pulling a plow would probably be two-thirds of this distance. On this basis it is estimated that if no portion of the ground is stepped upon a second time "the entire surface would be pressed in 5 times plowing."

Comparative experiments in cooling refrigerator cars by means of ice or ammonia, V. STORCH and H. P. LUNDE (*50. Rpt. Kgl. Vet. Landbohøjskoles Lab. Land-økon.*, Forsøg [Copenhagen], 1901, pp. 58).

MISCELLANEOUS.

Annual Report of Idaho Station, 1901 (*Idaho Sta. Rpt. 1901*, pp. 27).—This includes a report of the director on the publications and work of the station during the year, departmental reports reviewing the different lines of work at some length, and a financial statement for the fiscal year ended June 30, 1901.

Eighth Annual Report of Montana Station, 1901 (*Montana Sta. Bul. 32*, pp. 71).—This includes a financial statement for the fiscal year ended June 30, 1901; a report of the director on the work, staff, and publications of the station; a list of exchanges, and departmental reports, parts of which have already been noted from other publications (E. S. R., 13, pp. 271, 676) or are noted elsewhere in this issue. Of 201 samples of food examined by the chemist 94 were found adulterated.

Fourteenth Annual Report of New York Cornell Station, 1901 (*New York Cornell Sta. Rpt. 1901*, pp. XLVI+466).—The report proper includes the organization list, a report of the director, a summarized financial statement for the fiscal year ended June 30, 1901, and departmental reports reviewing the different lines of work during the year. Appendix I contains reprints of Bulletins 183-193 of the station on the following subjects: Sugar-beet pulp as a food for cows (E. S. R., 12, p. 878); the grape-root worm, a new grape pest in New York (E. S. R., 12, p. 974); the common European praying mantis, a new beneficial insect in America (E. S. R., 12, p. 973); the sterile fungus *Rhizoctonia* as a cause of plant diseases in America (E. S. R., 13, p. 55); the palmer worm (E. S. R., 13, p. 68); spray calendar (E. S. R., 13, p. 372); Oswego strawberries—an account of experiment with fertilizers, and records of strawberry growing, in the Oswego district (E. S. R., 13, p. 354); three unusual strawberry pests and a greenhouse pest (E. S. R., 13, p. 371); tillage experiments with potatoes (E. S. R., 13, p. 342); further experiments against the peach-tree borer (E. S. R., 13, p. 369); and studies of some shade tree and timber-destroying fungi (E. S. R., 13, p. 468). Appendix II contains a detailed financial statement for the fiscal year ended June 30, 1901. Appendix III contains reprints of Nature Study Quarterlies Nos. 6-9, Reading Lessons for Farmers Nos. 10-15, eight numbers of the Junior Naturalist Monthly issued during 1900-1901, Reading Lessons for Farmers' Wives Nos. 1 and 2, and a circular of information concerning cooperative experiments.

Director's report for 1901, W. H. JORDAN (*New York State Sta. Bul. 211*, pp. 435-450).—This is an extended review of the work of the station during the year. The more important results obtained along the different lines of investigation are enumerated.

Twelfth Annual Report of North Dakota Station, 1901 (*North Dakota Sta. Rpt. 1901*, pp. 112).—This includes a brief report of the director, departmental reports, parts of which are noted elsewhere, an account of the work at the Edgeley substation, and a financial statement for the fiscal year ended June 30, 1901.

Fourteenth Annual Report of Vermont Station, 1901 (*Vermont Sta. Rpt. 1901*, pp. 193-380+XLV).—This includes the organization list of the station, a financial statement for the fiscal year ended June 30, 1901, a report of the director containing a list of available station publications and an outline of work during the year, abstracts of Bulletins 81-87 issued during the year, and departmental reports containing in addition to summaries of the different lines of investigation miscellaneous articles abstracted elsewhere.

Organization lists of the agricultural colleges and experiment stations in the United States with a list of agricultural experiment stations in foreign countries (*U. S. Dept. Agr., Office of Experiment Stations Bul. 111*, pp. 130).—This includes the organization lists of the Office of Experiment Stations and the agricultural colleges and experiment stations in the United States with a list of station publications received during 1901; lists of the officers of the Association of American

Agricultural Colleges and Experiment Stations, the Association of Official Agricultural Chemists, the Association of Economic Entomologists, the Association of Veterinarians of Experiment Stations, and of the American Association of Farmers' Institute Workers; and a list of the agricultural experiment stations in foreign countries with a list of the publications received from such institutions during 1901.

Experiment Station Work—XX (*U. S. Dept. Agr., Farmers' Bul. 149, pp. 32, figs. 6*).—This number contains articles on the following subjects: The value of muck or peat, improved culture of potatoes, the farmer's vegetable garden, the shrinkage of farm products, transplanting and manuring muskmelons, soils for strawberries, fertilizer requirements of strawberries, plum culture, methods of growing onions, the digestibility of raw, pasteurized, and cooked milk, the dairy cow and the weather, and feed mills and windmills.

The card index of experiment station literature (*U. S. Dept. Agr., Office of Experiment Stations Circ. 47, pp. 2*).—A brief description of the card index of experiment station literature and a statement of the terms of sale.

The station bulletin, J. B. WEEMS (*Proc. Soc. Prom. Agr. Sci. 1901, pp. 75-88*).—This is a discussion on the bulletins of the experiment stations based upon replies received from editors of agricultural journals and from officers of experiment stations. The author considers that there is need of a government publication similar to the Experiment Station Record for publishing original articles by station workers.

The farmer and his education, or the farmer as an educated specialist, W. J. BEAL (*Proc. Soc. Prom. Agr. Sci. 1901, pp. 19-25*).

Subdivision of agriculture for purposes of instruction and research, E. DAVENPORT (*Proc. Soc. Prom. Agr. Sci. 1901, pp. 160-162*).

Agricultural imports and exports, 1897-1901, F. H. HITCHCOCK (*U. S. Dept. Agr., Section of Foreign Markets Circ. 24, pp. 16*).—Statistical tables are given showing in detail the agricultural imports and exports of the United States during each of the 5 fiscal years 1897-1901.

Cotton in Egypt (*U. S. Consular Rpts., 68 (1902), No. 256, pp. 43, 44*).—Statistics showing the annual production of Egyptian cotton in the last 15 years, the average price for each year, and the countries to which the staple was exported.

Sugar industry of Saxony, B. H. WARNER, JR. (*U. S. Consular Rpts., 68 (1902), No. 256, pp. 83, 84*).—A brief account of the status of the industry is given, together with statistics for the years 1882-1900, inclusive.

Clearing new land, F. WILLIAMS (*U. S. Dept. Agr., Farmers' Bul. 150, pp. 24, figs. 7*).—This bulletin deals in a popular style with the proportion of uncleared land in the United States, the land which may be profitably cleared, the cost and methods of clearing land with practical illustrations, the cultivation of new land, and crops adapted to such lands.

NOTES.

ALASKA STATIONS.—F. E. Rader and J. W. Neal have been sent to the Copper River Country to make a temporary reservation for an experiment station. It is expected that a site will be chosen, ground broken for seeding to fall grains, and a residence and barn constructed during the summer. At the close of the season Mr. Rader will return to Sitka, while Mr. Neal will remain at the new station. Reports from Kenai show favorable weather and crops doing well. At Sitka the outlook is favorable for a good harvest.

CALIFORNIA UNIVERSITY AND STATION.—Dr. Leroy Anderson, recently elected superintendent of the San Luis Obispo Polytechnic School, will continue in charge of the dairy department for the coming year. A large dairy barn is being constructed at the station. Studies of the peach worm, conducted in Placer County by W. T. Clarke, in cooperation with the county board of horticultural commissioners, are about completed. Similar cooperative work on the red spider of the orange is being conducted in Los Angeles County by C. W. Woodworth, assisted by W. H. Volck and the county board.

COLORADO COLLEGE.—J. A. Stump, assistant in physics and civil engineering, has resigned, to continue his studies. A. P. Greenacre, assistant in mechanical engineering and drawing, has also resigned. The college has adopted a plan of scholarships and fellowships. A limited number will be appointed as scholars, who will receive increased pay, and rank as fellows the second year.

CONNECTICUT STORRS COLLEGE AND STATION.—Rufus W. Stimson, professor of English literature and oratory and acting president of the college since last September, has been elected president of the college. L. A. Clinton, of Cornell University, has been appointed director and agriculturist.

CONNECTICUT STATE STATION.—Dr. G. P. Clinton, of the University of Illinois, entered upon his work as botanist of the station July 1.

FLORIDA COLLEGE AND STATION.—H. E. Stockbridge, Ph. D., agriculturist, has severed his connection with the institution.

GEORGIA STATION.—S. H. Fulton, biologist and horticulturist of the station, has resigned to accept a position in the Bureau of Plant Industry of this Department.

IOWA COLLEGE AND STATION.—Dr. W. M. Beardshear, president of the college, died at Ames August 5, 1902. Dr. Beardshear was born in Ohio, November 7, 1850. In 1864 he enlisted in the Army and served to the end of the civil war. He then entered Otterbein University, and after graduating with distinction from a classical course at that institution, in 1876, devoted two years to post-graduate work at Yale in Hebrew and Greek philosophy and theology. Leaving Yale, he engaged in ministerial work in his native State, and in 1882 accepted the presidency of Western College, at Toledo, Iowa, which he held until 1889, when he was called to Des Moines as superintendent of the city schools. Dr. Beardshear was president of the Iowa Agricultural College from 1891 until his death. A year ago he was elected president of the National Educational Association, and during the annual meeting of this organization at Minneapolis several weeks ago he suffered an attack of illness from which he did not recover. He was appointed U. S. Indian Commissioner by President McKinley in

1897. W. J. Kennedy has been made vice-director of the station, and Alfred Atkinson assistant in agronomy. A. T. Erwin, assistant in horticulture, has resigned. The part of the main building remaining after the fire of December 8, 1900, was destroyed by fire August 13, 1902. The office furniture and plant collections of the botanical department of the college and station, contained in the building, were saved. The loss is estimated at \$10,000.

MAINE STATION.—Herman H. Hanson, a graduate of the Pennsylvania State College in 1902, has been appointed assistant chemist, vice Ora W. Knight, resigned.

MASSACHUSETTS COLLEGE AND STATION.—F. A. Waugh, horticulturist of the Vermont college and station, has been elected horticulturist of the college and station to succeed S. T. Maynard. Thorne M. Carpenter, a graduate of the college, who was recently assistant chemist at the Pennsylvania Station, has been appointed assistant in the department of foods and feeding.

MICHIGAN COLLEGE AND STATION.—E. E. Bogue has been appointed professor of forestry. R. C. Kedzie, for nearly forty years at the head of the chemical department, has retired from active service in the college as professor emeritus, but remains in charge of the chemical work of the station. Robert S. Shaw of the Montana College and Station has been elected to the chair of agriculture in the college, vice H. W. Mumford, who is now connected with the Illinois College and Station. J. J. Ferguson has resigned as instructor in animal husbandry to accept a position with the Live Stock Commission at Winnipeg.

MINNESOTA UNIVERSITY AND STATION.—Andrew Boss has been promoted to associate professor of agriculture in charge of live stock. Coates C. Bull, assistant in agriculture in the University of Illinois, has been appointed assistant in agriculture. He will have charge of rural engineering and will assist in field crops. John Thompson, professor of agriculture and chemistry in the Agricultural and Mechanical College for the Colored Race, at Greensboro, N. C., has also been appointed assistant in agriculture. He will assist in field crops and farm management. J. F. Wojta, a recent graduate of the University of Wisconsin, has been appointed assistant in agriculture, with his main work in rural school agriculture. Prof. W. M. Hays has been placed in charge of the new movement to introduce agriculture into the rural schools. A bulletin nearing completion will contain about two hundred exercises and experiments. This bulletin is to be bound and furnished to each rural school. It outlines exercises which the teacher is to require of pupils, at such times as may be convenient and practicable. Each exercise includes, besides the subject and time when it can best be carried out, four divisions. Under the first heading is a statement of the object sought; under the second, the materials to be used; under the third, the plan of work; and under the fourth are notes giving important facts to the teacher. The subjects include agriculture, horticulture, cooking, sewing, domestic animals, housekeeping, laundering, agricultural chemistry, dairying, etc. The State department of public instruction has employed W. Robertson, J. F. Wojta, and J. A. Wilson to introduce the use of these exercises to the teachers in the teachers' summer schools throughout the State. Reading lessons, charts, and other helps to teaching agriculture in the rural schools are contemplated.

MISSOURI COLLEGE.—R. M. Bird, recently assistant chemist of the Mississippi college, is acting professor of agricultural chemistry.

OHIO STATION.—P. J. Parrott, until recently assistant entomologist of the New York State Station, has been appointed entomologist of the Ohio Station.

RHODE ISLAND COLLEGE.—J. H. Washburn of the college resigned August 15, 1902. Pending the appointment of a new president, H. J. Wheeler, director of the experiment station, is acting president. *Science* notes that President E. R. Nichols of the Kansas College has been elected to succeed Dr. Washburn.

SOUTH CAROLINA COLLEGE AND STATION.—H. S. Hartzog, president of the college and director of the station, has resigned to accept the presidency of the University of Arkansas, vice J. L. Buchanan, who retired on account of failing health.

SOUTH DAKOTA STATION.—Appropriations made at the last session of the legislature have enabled the station to purchase a herd of dairy cows for experimental purposes. Cross-pollination experiments with fruits and grains are being conducted at the station.

UTAH STATION.—E. G. Gowans, biologist, and J. A. Wright, horticulturist, have resigned, the former to engage in the practice of medicine, and the latter to edit the *Inter-mountain Farmer and Ranchman*, published at Salt Lake City. W. D. Beers has been made assistant irrigation engineer, and R. Stewart, assistant chemist. A vegetation house has been built at an expense of \$1,500. Experiments on the reclamation of alkali lands by means of tile drainage are being conducted near Salt Lake City, in cooperation with the Bureau of Soils. Irrigation experiments near the station are also in progress.

VERMONT UNIVERSITY AND STATION.—Cyrus G. Pringle, of Charlotte, Vt., the well-known botanical explorer and collector of Western American and Mexican plants, has transferred his herbarium to the University of Vermont and State Agricultural College, and has accepted an appointment as keeper of the herbarium of that institution. The botanical library and herbarium of C. C. Frost have also been transferred to the same institution. These collections, with some previously there, give the University the largest collection in New England, outside of Harvard University, and in quality one of the finest in the world. W. Stuart, associate horticulturist of the Indiana Station, has been appointed horticulturist, vice F. A. Waugh, resigned. B. O. White, assistant chemist of the station, has resigned.

VIRGINIA COLLEGE AND STATION.—John Spencer, D. V. S., has been elected professor of veterinary science in the college, vice E. P. Niles, resigned. J. G. Ferneyhough, D. V. S., has been appointed veterinarian of the station and assistant professor of veterinary science. Meade Ferguson, Ph. D. assistant professor of agriculture, will have charge of the classes in bacteriology. C. W. Harrison has been appointed assistant chemist, vice J. B. Huffard, resigned.

WASHINGTON COLLEGE AND STATION.—S. W. Fletcher has resigned his position as horticulturist.

WEST VIRGINIA STATION.—T. C. Johnson, formerly a fellow in botany, has been elected instructor in botany and assistant horticulturist to the station.

WISCONSIN UNIVERSITY AND STATION.—E. P. Sandsten, of the Maryland College, has been elected associate professor of horticulture to succeed E. S. Goff, whose death was recently announced. George A. Olson has been elected assistant chemist to the station.

EXPERIMENT STATIONS IN FORMOSA, JAPAN.—K. Haga, of the department of agriculture of the government of Formosa, who is now in this country, states that there are in Formosa three experiment stations under the direction of Inazo Nitobe, M. A., D. A. S., Ph. D., as follows:

At Taipeh, established 3 years ago, where experiments are conducted with rice, sugar cane, tobacco, and sweet potatoes.

At Taichu, in charge of subdirector S. Aoyagi, B. A. S., established 2 years ago, where attention is given chiefly to the growing of rice, tea, sugar cane, to silk culture, and to cattle and pigs.

At Tainan, in charge of subdirector H. Tojo, B. A. S., established 2 years ago, principally for the culture of sugar cane.

There is also a tea experiment station in Toshiyen.

AGRICULTURAL EDUCATION IN RÉUNION.—By a decree dated May 23, 1902, a committee has been appointed to formulate and install a system of agricultural education in the primary schools of the island of Réunion.

AGRICULTURAL EDUCATION IN RUSSIA.—A new agricultural school of the intermediate grade has recently been opened near the city of Pskov, Russia. There are now 8 schools of this class under the jurisdiction of the Ministry of Agriculture. The municipality of Pskov granted 850 acres of land to the school, located about 3 miles from town. Agricultural courses for women were opened in May at the Imperial Botanical Garden at St. Petersburg. These courses include horticulture and gardening, dairying, poultry raising, and beet culture. They were organized by the Society for the Promotion of Female Agricultural Education. Forty-eight students have been enrolled, most of whom will take all four of the courses. The same Society for the Promotion of Female Agricultural Education has secured the establishment of similar courses at the Mariinsk Agricultural School.

In addition to these and other means of popular agricultural education, there are held in Russia courses for teachers in primary public schools, which are conducted at agricultural schools during the period of 4 to 6 weeks; courses for educated persons other than teachers, in which the theoretical studies occupy the greater portion of the time; public readings at fairs, museums, meetings of societies, etc.; short courses for peasants and other persons interested in agriculture, lasting 2 to 3 weeks and conducted at some educational institution; and practical agricultural courses for soldiers and such detachments of the army as are located near an agricultural school.

AGRICULTURAL BUDGET OF RUSSIA FOR 1902.—The more important items for agriculture are as follows: Agricultural education, \$498,877.20; experiment stations, museums, etc., \$165,320.40; increase to the amelioration fund, \$200,000; construction of buildings, etc., \$144,000; irrigation work, \$107,200; subsidies to societies, institutions, and private persons for useful agricultural enterprises, \$90,904; reclaiming marshes and putting up of peat for fuel purposes, \$75,148; development and encouragement of village industrial handicraft, \$72,000; development and encouragement of certain industrial branches of agriculture, \$55,700; combating phylloxera and other injurious insects and animals, \$50,400; and publications, \$41,354. The appropriation for agricultural education is an increase of \$20,400 over the previous year, to cover the expense of a new agricultural middle school and some agricultural schools of lower grade.

ASSOCIATION OF OFFICIAL AGRICULTURAL CHEMISTS.—It is announced that the nineteenth annual meeting of the Association will be held in the lecture hall of Columbian University, Washington, D. C., October 2-4, 1902.

MISCELLANEOUS.—*Revue bibliographique des sciences naturelles pures et appliquées* has been discontinued. A movement is on foot to publish matter pertaining to agriculture in the *Bulletin de l'office des renseignements agricoles*.

Prof. Dr. Emil Chr. Hansen celebrated the twenty-fifth anniversary of his connection with the Carlsberg Laboratory of Copenhagen on July 1, 1902. His work on the physiology of fermentation is well known.

EXPERIMENT STATION RECORD.

VOL. XIV

OCTOBER, 1902.

No. 2.

The experiment station at Möckern, Germany, the first of its kind in the world, celebrated the fiftieth anniversary of its establishment September 20. The occasion was one for general congratulation, and is of special interest to all friends of the experiment station enterprise. The date selected for the exercises was that of the annual meeting of the German Association of Experiment Stations, which was held this year at Leipzig, only a few miles distant from Möckern. Prof. Oskar Kellner, the present director of the station, had prepared a *Festschrift*, or historical address, which was printed in advance, reviewing the incidents in the establishment of the station, its gradual development and present status, and summarizing its principal lines of work. This is a bound volume of over two hundred pages, with several plates showing the station buildings. Congratulatory addresses were made by members of the association, followed by a banquet.

The Möckern Experiment Station has had many admirers in this country, and especially in the early days of the experiment station movement it was much written about. It is therefore one of the best known of the German stations. As it marks the beginning of the experiment station as a public institution, the history of its establishment is of unusual interest.

Lawes and Gilbert in England and Boussingault in France had for several years carried on systematic and continuous field experiments, supplemented by laboratory work; and Liebig had, through his field and laboratory studies and his generalizations in science, aroused much interest in the fundamental principles underlying plant and animal nutrition. The publication of his works led to an agitation among agriculturists in Saxony, which some ten years later resulted in the establishment of the experiment station. A first step in this direction was the providing by the Saxon government of a chair of agricultural chemistry in the Forestry and Agricultural Academy at Tharand, in 1847. In the efforts to secure an experiment station which followed, the leaders were Secretary Reuning, of the General Agricultural Society, and Dr. Wilhelm Crusius, who was the president of the oldest agricultural society in Saxony (the Leipzig Economic Society, founded

in 1863) and a lessee of its farm at Möckern. Crusius was a firm believer in the importance of chemical investigation to agriculture, and had already erected a laboratory on his own account.

Through the influence of these men plans were laid for the establishment of a station, to be located on the farm of the Leipzig Economic Society and the adjoining lands of Dr. Crusius. The Saxon government committed itself to the undertaking and promised an appropriation for its maintenance, and the Leipzig Economic Society agreed to assume the expense of fitting up the first laboratory building. In October, 1850, it was announced that Dr. Emil Wolff, then an instructor in the agricultural school at Brösa, had been selected for director; and in the following January he entered upon his new duties with the practical agriculturist Bähr, formerly administrator of the society's farm, as an associate. A year and a half elapsed, however, before the State government made an appropriation for the station, and it was not until December 28, 1852, that the institution was definitely established. In the meantime it was maintained by private means, largely supplied by Dr. Crusius.

This year, accordingly, marks the fiftieth anniversary of the station as a State institution. The act of its establishment defines its purpose to be "to extend the knowledge of the practice of agriculture and the industries connected with it by means of scientific investigation, closely associated with practical experiments of various kinds, and to disseminate the useful results thus obtained." The programme laid out for it in this act covered the whole field of agricultural experimentation, but it was naturally found necessary to confine operations within a comparatively restricted field.

Wolff remained as director only three years, when he was called to the Agricultural Academy at Hohenheim, where he remained to the close of his life. He was followed by Dr. H. Ritthausen, later a prominent authority on albuminoids, who left after two years to establish a new station; and he in turn was followed by Dr. Wilhelm Knop, who remained ten years. On the latter's call to the chair of agricultural chemistry in the University of Leipzig, Dr. Gustav Kühn, a pupil of Henneberg's and at that time director of the experiment station at Brunswick, assumed the directorship. Kühn remained at the head of the station for nearly 25 years, from 1867 to 1892, when he died. The following year the present director was appointed.

Although the Möckern Station has been since 1867 primarily a station for investigation in animal physiology, it now embraces four additional divisions, each presided over by a separate officer, one for the analysis of fertilizers, another for the examination of feeding stuffs, agricultural products, waters, etc., a third for soil studies, for judging of the quality of soils, their cultural relations, laying out of estates, etc., and a fourth for vegetation experiments, to study the fer-

tilizer requirements of Saxony soils. Its working force consists of the director, 11 scientific assistants (9 chemists, 1 botanist, and 1 agronomist), several clerks, and 4 laborers.

Until 1879 the station occupied buildings furnished by the Leipzig Economic Society on its Möckern estate. In that year it was placed under the control of the State government, and an endowment made by Dr. F. Crusius (son of the founder) was used for a new building. The Government also leased the Möckern estate for a term of fifty years, so that the station was placed upon a more permanent and independent basis. It is now one of the best supported of the German stations and ranks among the foremost in its work.

The Möckern Experiment Station is to be congratulated upon its long (relatively speaking) and noteworthy career. It holds a peculiar relation to the experiment station movement, which has gradually spread from country to country. In the early days it was the guiding star. It blazed a path in a new field when few men had faith in its utility and the foundation of agricultural science was hardly laid. It has shown what an experiment station may accomplish for both the science and the practice of agriculture; and by the dignity and high character of its work it has commanded the respect of the farmer and the man of science alike. Its example has led directly to the establishment of a large number of other stations, and the sphere of its influence has extended far beyond the confines of its own country.

It is especially fortunate that the first State station should have been so successful in demonstrating its value to the public. A failure might have delayed indefinitely the spread of the movement whose beginning it marks. The fifty years which have elapsed since it entered upon its work in so meager a way have witnessed the establishment of a system of stations as State or Government institutions in practically every civilized country. These have steadily grown in strength and in importance until now they may be ranked as among the permanent institutions of civilized nations, as much as the schools and universities. They are fostered alike under the republic and under the unlimited monarchy, and are recognized by all enlightened peoples as constituting an essential element in national welfare. Rarely indeed has one been abandoned or its maintenance funds permanently diminished.

Surely no class of institutions make a better return for the money intrusted to them or reach more directly with their influence a larger proportion of the people in whose interest they are laboring.

We are called upon to record the death of Prof. Arthur Petermann, director of the Agricultural Experiment Station at Gembloux, Belgium, which occurred August 26. Professor Petermann was widely known as an agricultural chemist and investigator, and was one of the

pioneers in experiment station work in Europe. He was prominently identified with the development of the experiment station system in Belgium from its beginning, being called to Gembloux in 1872 to organize and take charge of the first station. He developed the system of analytical laboratories, of which there are now seven, and for many years was director-general of experiment stations. The Gembloux Station became the capstone of the Belgian system, being devoted to research work and determining the methods to be employed and other matters of policy relating to the analytical laboratories.

Professor Petermann was born in Dresden July 14, 1845, and graduated at the University of Göttingen. After serving as assistant in the Weende (Göttingen) and Pommritz experiment stations, he spent two years at the Nancy (France) Station as chemist. In 1872 he became director of the Gembloux Station, at present known as the Royal Institute of Chemistry and Bacteriology, and in the latter position was also professor in the Royal Agricultural Institute, with which the station is connected.

Professor Petermann's investigations covered a very wide range, but dealt more particularly with the chemistry of plant production. To a large extent they involved studies of the methods of investigation. He made numerous contributions on the methods of agricultural analysis, his method for available phosphoric acid being familiar to all agricultural chemists. He was one of the first to conduct systematic soil investigations with a view to preparing popular "agronomic" charts, showing the character of the soil, its needs, and its adaptability to different crops. He was a leading spirit and authority on all matters relating to agricultural investigation in Belgium, and the success of the State laboratories was due in large measure to his influence. Most of the directors of these laboratories were trained under him at Gembloux.

Professor Petermann was a constant contributor to the scientific serials and published several books and pamphlets. He contributed an article to this journal, published in volume five, on the Belgian system of experiment stations. His most important published work is his *Researches on Chemistry and Physiology as Applied to Agriculture* (*Recherches de chimie et de physiologie appliquées à l'agriculture*). This appeared in three volumes, and is largely a record of his agricultural investigations.

The death at Woburn, Mass., on October 1, 1902, of Mr. J. R. Dodge, for many years Statistician of this Department, removes one who, during a long life of unremitting activity, devoted his best energies to the services of agriculture and to building up the Department.

When the Department of Agriculture was but a division of the Patent Office, Mr. Dodge was already engaged in its service, but it was

not until September 4, 1863, some few months after its organization as a separate Department, that he received his appointment as a clerk. In 1867 he was commissioned as Statistician, but in addition to taking charge of the statistical work of the Department, he also served as its editor, a position for which his early experience in journalism and in the printing business especially qualified him. The early annual reports were edited by him, as were also the monthly reports, which latter, after the growth of the Department had compelled the publication of special bulletins from the several divisions, became the regular monthly reports of the Division of Statistics, the principal feature of which was the crop report, and which included a very large amount of miscellaneous and valuable statistical matter.

In his statistical work, for which he possessed special qualifications, he soon became eminent among American statisticians and held a foremost place in all statistical matters relating to agriculture.

Mr. Dodge surrendered his commission in the Department June 30, 1879, and served for some time as the chief of a division in the Tenth Census, under Gen. Francis A. Walker. He returned to the Department, resuming his former place as Statistician July 1, 1883, and held that office until he resigned, March 20, 1893. After that time Mr. Dodge devoted himself to miscellaneous writing along the line of his chosen study, contributing many valuable articles to sundry periodicals and agricultural papers, to some of which he remained an active contributor until the time of his death.

During his more than thirty years of official service he not only won the esteem and confidence of his associates, but he made his mark before the public at large as a man of rare attainments, broad views, sound judgment, and sterling integrity. He enjoyed in a marked degree the confidence of the several Commissioners and Secretaries under whom he served, and was a frequent and always intelligent adviser, not only in the line of his specialty but in many matters connected with the work of the Department. He several times represented the United States at international agricultural and statistical gatherings, the last occasion being at Budapest.

Through all he was an unassuming man, and only those who have made a study of the history and development of the Department of Agriculture can realize what a large part he took in building it up.

The late Prof. Rudolph Virchow, although preeminently an investigator in the domain of medical science and pathology, made notable contributions, at least indirectly, to the progress of agriculture. His work touched that field of applied science at various points. As the founder of modern pathological methods he exerted a profound influence on all subsequent investigation on the diseases of domestic animals, as well as of human beings. His theory of cellular pathology

has been one of the most important and fundamental factors in the development of modern medicine. He was deeply interested in the application of the teachings of science to problems of municipal sanitation and public health; and as the leading spirit of the municipal council of Berlin he instigated and supervised the introduction of a sanitary water supply and a healthful system of sewage disposal, which have made that city an object lesson to many others. "Modern Berlin is a splendid monument of his zeal in the service of humanity."

His work was not without important bearing on the physiology of human and animal nutrition, and his *Archiv für pathologische Anatomie und Physiologie*, which he established in 1847 and continued to edit to near the close of his life, contains frequent contributions on the principles underlying the metabolism and use of food nutrients.

Indeed so broad and varied was the field of Virchow's activity that it is difficult to measure his influence or to fix bounds within which it was exerted. Agricultural science may fairly claim to be one of its beneficiaries, and the methods of research which he outlined and the spirit which characterized his work will continue a guide and inspiration in this field, as well as in medical science.

CONVENTION OF ASSOCIATION OF OFFICIAL AGRICULTURAL CHEMISTS, 1902.

H. W. LAWSON,
Office of Experiment Stations.

The nineteenth annual convention of the Association of Official Agricultural Chemists was held at Columbian University, Washington, D. C., October 2-4, 1902. The meetings were presided over by the president, H. J. Wheeler, of Rhode Island. In opening the convention the president called attention to certain changes in the order of business adopted at the last annual meeting and to the recognition of the association by Congress in the appropriation act which empowers the Secretary of Agriculture, in collaboration with the association and other experts, to fix standards for food products, required in the execution of pure-food laws.

All of the referees for the year were present and submitted reports, and in addition several interesting papers were read. The change in the policy of the association, taking effect at the present convention, whereby matters not of "minor importance or of urgent necessity" are to be reported upon by committees on recommendations of referees for consideration at the next convention, apparently affected to some extent the character of the proceedings. The discussion of the reports and papers was not extended, and no very important matters were acted upon. The assignment of subjects to different committees on recommendations of referees caused some confusion and resulted in no consideration in committees during the convention of some of the reports. About 100 chemists and visitors were in attendance. Hon. James Wilson, Secretary of Agriculture, Charles W. Needham, president of Columbian University, and Charles E. Munroe, professor of chemistry in Columbian University, were present upon invitation and addressed the convention. Secretary Wilson spoke of the work of the Department along several lines, President Needham of the attraction of Washington for scientists and of the dignity and value of the work of scientific men, and Professor Munroe of the value of agreement upon methods of analysis by the association.

PHOSPHORIC ACID.

The report on phosphoric acid was read by the referee, C. H. Jones. Different methods for the determination of available phosphoric acid

in basic slag were compared. The lowest results were obtained by the ammonium citrate method and the highest by the Macfarlane method, in which the free lime is removed from the slag by means of ammonium chlorid before treatment with citric acid. The determinations ranged from 4.54 to 10.90 per cent. The referee considered it desirable to agree upon the percentage of the total phosphoric acid available in a sample of basic slag of standard composition and fineness. The advisability of continuing work on basic slag was discussed, but no action was taken.

NITROGEN.

The report of the referee on the determination of nitrogen was submitted by F. W. Morse. Comparisons were made of the neutral permanganate method as modified by Street and the alkaline permanganate method as modified by Jones for the determination of available organic nitrogen in fertilizers. The materials selected for distribution to analysts were dried blood and cotton-seed meal combined with superphosphate. Results from 12 analysts were received. In the determination of total nitrogen the weight of evidence favored a longer period of digestion than usual. Duplicate determinations of availability by any one analyst agreed well, taking each method by itself. The two methods in comparison, however, gave widely varying results, and neither was thought to give the available nitrogen. The referee recommended further study of the two methods, which was adopted. The recommendation was also adopted that in reporting analyses of complete fertilizers the amounts of nitrogen existing in the form of nitrates, organic nitrogen, and ammonium salts be so stated.

In the discussion of nitrogen determination G. W. Cavanaugh reported favorably upon the use of both mercuric oxid and potassium sulphate and upon reversing the order of adding potassium sulphid and sodium hydroxid as given in the official method. The advantage gained in the latter procedure is in adding the potassium sulphid to an alkaline solution and thereby avoiding an evolution of hydrogen sulphid. Distillation with steam was found very efficient in preventing bumping.

The report on the separation of nitrogenous bodies was read by the referee, L. L. Van Slyke. Work along this line was confined to the proteolytic products of cheese and milk and consisted in devising and testing methods of separation and estimation. Credit is given to E. B. Hart, of the New York State Station, for a large part of the work. Methods for the separation and estimation of the nitrogen compounds of cheese were described and discussed under the following headings: Obtaining sample; determination of total nitrogen; extraction of water-soluble products; determination of total water-soluble nitrogen; determination of nitrogen in the form of paranuclein, proteids

coagulable by heat in neutral solution, caseoses (albumoses), amido-acid compounds, peptones, ammonia, and unsaturated paracasein lactate. Methods for the determination of nitrogen in milk in the form of casein, albumin and syntonin, caseoses, amido-acid compounds, peptones, and ammonia were also given. The referee recommended that the methods presented be adopted as provisional methods under the head of dairy products.

The association, upon motion of Dr. Van Slyke, authorized the appointment of a committee of three as referees to take charge of the work relating to the separation of nitrogen compounds, the work to be distributed among the members of the committee on the following lines: (1) Meat proteids, (2) vegetable proteids, (3) milk and cheese proteids.

POTASH.

The report on this subject was read by the referee, H. B. McDonnell. Results from 14 analysts on the determination of potash by the Lindo-Gladding and milk-of-lime methods and a modification of the alternate method used by the referee were reported as well as determinations of moisture in potash salts. The different methods gave quite concordant results and showed a loss of potash in mixed fertilizers of about 7 per cent of the total amount present. The referee recommended further work for the purpose of getting a method of dissolving all the potash in mixed fertilizers, and also further experiments with methods for the determination of moisture in potash salts, which suggestions were adopted.

A paper by C. L. Hare on the determination of potash in fertilizers by substituting milk of lime for ammonia and ammonium oxalate as the precipitant was read by B. B. Ross. "The modification possesses several advantages over the Lindo-Gladding method. First, the precipitation of lime is immediate, and there is no delay at this point. Second, evaporation to expel ammonia salts is eliminated. Third, probable loss of potash during the evaporation is obviated. Fourth, washing the potassium platinic chlorid with alcohol and ammonium chlorid 'wash' may be performed thoroughly with greater ease and rapidity, while no larger amount of platinum is required than by the Lindo-Gladding method." The modification is not applicable to fertilizers containing ammonium salts. The milk of lime and the Lindo-Gladding methods were compared on 60 samples of fertilizers containing no organic materials, the results showing a maximum difference of 0.27 per cent in 58 determinations and less than 0.20 per cent in 46 determinations. The two methods were also compared on fertilizers containing organic matter. In 53 determinations in which the samples for both methods were ignited with sulphuric acid the extreme difference was 0.48 per cent, 41 samples showing a variation less than 0.20

per cent. In 63 determinations in which the samples for the lime method only were ignited with sulphuric acid the results showed an extreme variation of 0.29 per cent and less than 0.20 per cent in 46 comparisons. In 45 determinations without ignition the extreme variation was 0.55 per cent, nothing being claimed for the milk-of-lime method under such conditions.

SOILS.

The report on this subject was made by the referee, F. P. Veitch. The work during the year consisted in the determination of available phosphoric acid and available potash in soils and the analysis of alkali soils and crusts. The 8 samples of soil used in the phosphoric acid and potash work were obtained from 6 States and were representative of different kinds of soil. Each had a full crop and fertilizer history for a number of years. Determinations of available phosphoric acid and potash made by the referee and C. C. Moore with the N-200 hydrochloric acid method showed sufficient harmony with crop history to warrant further trial of the method. The necessity of determining available plant food to the full feeding depth of plants was recognized by the referee, but he was unable to take up this line of work during the year. A letter from Milton Whitney, Chief of the Bureau of Soils, dealing with the value and methods of mechanical analysis and the work of the Bureau in the classification of soils based upon physical examination, was read by the referee, who had been instructed by the association to consider the subject of mechanical analysis. Professor Whitney pointed out the advantages of adopting the grades already in use by the Bureau, namely, fine gravel, coarse sand, medium sand, fine sand, very fine sand, silt, and clay, calling attention to the fact that over 3,000 analyses had been published by the Bureau and that the soil survey work had been extended to 30 States. The points which received attention by the referee in the study of methods for the analysis of alkali soils were the effect of dilution upon the amount of salt dissolved and titration methods for the determination of carbonates, bicarbonates, and chlorids. "The results may be summed up as follows: The concentration of the solution materially affects the speed of solution of sulphates, particularly calcium sulphate, and it is quite evident that equilibrium has not always been reached in 24 hours. The chlorin determination is the most satisfactory and appears to be the least affected by the concentration of the solution, while equilibrium is usually reached within the 24 hours. The determination of carbonates and of bicarbonates when present in large quantities has not been very satisfactory to the referee."

Studies in nitrification were reported in a paper read by G. S. Fraps. Two kinds of tests were made, one in which nitrification was carried out in soil as it came from the field and the other in sterile soil inoc-

ulated with active soil. Under uniform conditions as regards moisture, temperature, and plant food, soils showed a variable rate of nitrification attributed to stages in the life history of the nitrifying organisms. Differences in the power of soils to induce nitrification in sterile soil provided with nitrogenous substances and kept under favorable conditions were considered dependent upon an increase in the number of organisms present and upon an increase in their activity. Variations in the comparative rate of nitrification of cotton-seed meal and ammonium sulphate in sterile soil inoculated with different soils pointed to variations in the organisms themselves. Based upon the work recorded in detail in the paper, methods were proposed for determining the relative nitrifying power of soils.

A paper on "A Quantitative Method for Determining the Acidity of Soils," by C. G. Hopkins, W. H. Knox, and J. H. Pettit, was read by Dr. Hopkins. The method, which is based upon the reaction occurring when solutions of mineral salts are added to acid soils, has been used in pot and field experiments at the Illinois Experiment Station during the past year, and "it is asserted with confidence that it can be relied upon to give trustworthy results." The addition of lime to soils in quantities indicated by the method was found to neutralize the acidity. The advantages of determining accurately the quantity of lime to apply to acid soils were pointed out. The method of determining acidity used in the Bureau of Soils was described by F. P. Veitch. The influence of soil and meteorological conditions upon the yield and character of crops was discussed by H. W. Wiley, who concluded his remarks as follows: "Agricultural chemistry, passing from having determined what the soil is and what plants are and how fertilizers can be made and applied, is now advancing to a still higher plane of investigation, to determine how the soil shall be made maximum in production and how the conditions of growth shall secure the maximum of desirable qualities."

The recommendations were adopted by the association that the N-200 hydrochloric acid method be given further trial, that samples for the determination of available phosphoric acid and potash be taken to a greater depth than at present, that virgin soils be used in investigations, that the determination of the acidity of soils be referred to the referee, and that methods for the analysis of alkali soils be further studied, with a view to ascertaining the most desirable amount of soil and the amount of water to be used in dissolving the soluble salts.

DAIRY PRODUCTS.

The referee on dairy products, G. W. Cavanaugh, reported on work done in his laboratory during the year on the determination of albumin in milk. On fresh samples the present official and provisional methods gave concordant results. On milk preserved with formalin the

results were very unsatisfactory. The percentage of albumin in milk decreased from 0.525 per cent in fresh samples to 0.157 per cent in samples preserved for 4 days with formalin. Other tests showed that formalin tends to prevent the coagulation of albumin by heat, the amount of formalin added and the time that it is in contact with the milk both affecting the coagulability. No recommendations were made. The referee was instructed to study further the effect of preservatives upon albumin in milk.

FOODS AND FEEDING STUFFS.

The work on feeding stuffs reported by the referee, C. A. Browne, jr., was practically along lines followed by preceding referees, and consisted mainly in the determination of moisture, fat, and pentosans in samples of timothy hay and distillers' grains according to the official methods and in the comparison of the official and König methods for crude fiber on both samples. Based upon results obtained by 9 analysts, the referee recommended a further study of the König method with the additional treatment of the fiber with alkali, as by the official method. The referee also recommended the substitution of Kröber's factors for calculating pentoses and pentosans for those given in the provisional method, which recommendation was adopted.

A paper by E. Gudeman, dealing with the manufacture and analysis of gluten feeds, was read by J. K. Haywood. Methods for the determination of fat and of acidity were compared. In a letter from C. L. Parsons, read by H. W. Wiley, suggestions were made concerning methods for the analysis of malt liquors.

FOOD ADULTERATIONS.

The referee on this subject, W. D. Bigelow, reported that an attempt had been made to have reports on cereal products, tea and coffee, and cocoa and chocolate, the three subjects not completed at the last meeting. Two of the reports were ready. Many of the subjects were subdivided and only parts of the subjects given attention. The referee recommended that provisional methods, embodying the minor changes suggested by the referees, be published. Acting under the advice of the executive committee the referee was authorized to make such assignments of work as he may see fit and to appoint his associate referees. The changes made in the provisional methods adopted at the last convention and published in Bulletin 65 of the Bureau of Chemistry were adopted provisionally.

SUGAR.

The report on sugar was made by the referee, G. L. Spencer, and included a brief outline of the experimental work conducted by his

associates, L. S. Munson and L. M. Tolman, a consideration of special methods used in the analysis of sugar beets and raw sugars, and recommendations of changes in the official methods, including the substitution of the German official method for Clerget's method for the determination of sucrose and the adoption of the method of direct weighing of the cuprous oxid, and of several provisional methods, one of which was the inversion at ordinary temperatures with hydrochloric acid in the proportions used in the German official method. Further work along the lines followed during the year was recommended.

Mr. Munson presented in detail the results of his investigations on methods for determining reducing sugars. The work was conducted with a view to simplifying methods and increasing the accuracy of such work. The results showed that the reduction method, in which the suboxid is weighed directly, is accurate. Encouraging results were obtained in experiments to devise a single copper solution for use under uniform conditions with all reducing sugars. Conditions modifying reduction were also studied.

Mr. Tolman read a paper giving the results of his investigations on optical methods for the determination of sucrose. In inversion at ordinary temperatures very satisfactory results were obtained in the use of hydrochloric acid in the proportions given in the German official method. Accurate results were obtained in the use of citric acid for the inversion of sucrose in the absence of acetates. Levulose was not decomposed nor its rotary power affected by this method, which was pointed out as of value in the examination of honey.

TANNIN.

The work done during the year on this subject consisted of comparisons of single and double filter papers in the determination of soluble solids in chestnut and quebracho extracts and of the distillation, Kohnstein-Simand, and charcoal methods for the determination of acids in a union liquor. Results were reported by the referee, W. H. Teas, who recommended several changes in the official methods, including an omission of the moisture determination in extracts, evaporation under identical conditions, and the use of single instead of double filter papers in the determination of soluble solids, and suggested for future work additional experiments on soluble solids, acid determinations, and on the amount of extract to be taken for analysis. Studies of a proposed modification of the charcoal method and of the correction method for the tannin absorption of the filter paper adopted by the International Association of Leather Trades Chemists were also suggested. A charcoal method for the determination of total acidity in liquors was adopted provisionally.

A letter from H. R. Proctor, referring briefly to the proceedings of the last meeting of the International Association of Leather Trades

Chemists, was read by H. W. Wiley, and the appointment of a delegate to the next meeting of this association was authorized.

INSECTICIDES AND FUNGICIDES.

The report on this subject was read by the referee, J. K. Haywood. The work was directed chiefly toward testing methods of analysis collected from various sources and published as Circular 10 of the Bureau of Chemistry. Samples were sent to a number of analysts and results were received from 9 upon Paris green and London purple, 4 upon copper carbonate, 4 upon potassium cyanid, 4 upon soda lye, 2 upon whale-oil soap, 4 upon formalin, and 3 upon tobacco extract, which, with the comments of the analysts, were reported in detail. Based upon the work, the referee recommended the adoption of method I for total arsenious oxid in Paris green, given in the circular referred to above as one of the official methods, and also the further testing of nearly all the other methods given in the circular except methods II (by weighing the residue) and III for formaldehyde, which were recommended to be dropped.

Details of several of the methods were discussed and one or two points brought up were referred to the referee for further study. H. W. Wiley suggested that every unnecessary detail be dropped from methods. J. K. Haywood spoke of the effect of free arsenious oxid in Paris green upon foliage, stating that in experiments it was observed that the presence of 7 per cent was injurious to apples and pears and 4 per cent to young peach trees, and that improperly prepared Paris green and samples in which the Paris green was in a very fine condition also injured the foliage.

ASH.

The report on this subject was submitted by the referee, G. S. Fraps. Methods for the determination of sulphur and potash in plants were further studied. Results by different analysts on corn bran and cotton-seed meal by the nitric acid method and the nitric acid method, modified by the substitution of calcium acetate for potassium nitrate, showed no satisfactory agreement. The results of the nitric acid method were considered too low. Slightly higher figures were obtained for potash by charring and extracting than by ignition with sulphuric acid. The forms in which sulphur exists in plants and the determination of sulphates were discussed, the literature along these lines being reviewed. Sulphur as sulphates was found in oats, crimson clover, cotton-seed meal, and cowpea vines, and absent in corn, green millet, timothy hay, corn silage, and peanuts. In the determination of chlorin three methods were tested, namely, ignition with calcium acetate, fusion with sodium hydroxid, and ignition with sodium carbonate. The calcium acetate method gave low results. The sodium carbonate method

gave as accurate results as the sodium hydroxid method, and being shorter and easier, was recommended for adoption.

The association recommended further testing of the fusion method for sulphur and an investigation of methods for the determination of the amount of sulphur in plants which belongs to the ash, and adopted provisionally the method of determining chlorin by ignition with sodium carbonate.

MISCELLANEOUS.

W. Frear, as chairman of the committee on pure-food standards, outlined the work of the committee during the year, which consisted in formulating definitions and standards for foods, none of which, however, were presented. The report was approved and the committee continued.

John Hamilton, secretary of the Pennsylvania State Department of Agriculture, discussed the subject of food standards with especial reference to the work being done in the inspection of foods in his State. Of 5,000 or more samples of food analyzed in two years and a half over 50 per cent were found adulterated. The more extensive testing of food preservatives was urged.

The committee on fertilizer legislation made a brief report on work done in connection with other associations, which was accepted and the committee continued.

OFFICERS AND REFEREES.

The following officers were elected: *President*, R. J. Davidson, Blacksburg, Va.; *vice-president*, M. E. Jaffa, Berkeley, Cal.; *secretary*, H. W. Wiley, Washington, D. C.; *additional members of executive committee*, C. L. Penny, Newark, Del., and A. E. Leach, Boston, Mass.

The referees as announced are as follows: *Phosphoric acid*, B. H. Hite, Morgantown, W. Va.; *nitrogen*—determination, F. W. Morse, Durham, N. H.; separation of nitrogenous bodies—cheese proteids, L. L. Van Slyke, Geneva, N. Y.; vegetable proteids, R. Harcourt, Guelph, Canada; meat proteids, W. D. Bigelow, Washington, D. C.; *potash*, H. D. Haskins, Amherst, Mass.; *soils*, F. P. Veitch, Washington, D. C.; *dairy products*, G. W. Cavanaugh, Ithaca, N. Y.; *foods and feeding stuffs*, F. D. Fuller, Geneva, N. Y.; *food adulteration*, W. D. Bigelow, Washington, D. C.; *sugar*, G. L. Spencer, Washington, D. C.; *tannin*, G. A. Kerr, Damascus, Va.; *insecticides*, J. K. Haywood, Washington, D. C.; *ash*, E. G. Runyan, Washington, D. C.

The associate referees so far announced are as follows: *Phosphoric acid*, C. B. Williams, Raleigh, N. C.; *nitrogen*—determination, E. B. Holland, Amherst, Mass.; *potash*, M. G. Donk, Tallahassee, Fla.; *soils*, C. C. Moore, Washington, D. C.; *dairy products*, G. E. Patrick, Washington, D. C.; *foods and feeding stuffs*, C. G. Hopkins, Champaign,

Ill; *food adulteration*—colors, A. S. Mitchell, Milwaukee, Wis.; saccharine products including confectionery, E. Fulmer, Pullman, Wash.; fruit products, L. S. Munson, Washington, D. C.; wine, G. E. Colby, Berkeley, Cal.; beer, H. E. Barnard, Concord, N. H.; distilled liquors, C. A. Crampton, Washington, D. C.; vinegar, W. M. Allen, Raleigh, N. C.; flavoring extracts, A. L. Winton, New Haven, Conn.; spices, R. E. Doolittle, Lansing, Mich.; baking powder and baking chemicals, F. T. Green, San Francisco, Cal.; meat and fish, M. E. Jaffa, Berkeley, Cal.; fats and oils, L. M. Tolman, Washington, D. C.; dairy products, A. E. Leach, Boston, Mass.; cereal products, A. McGill, Ottawa, Canada; infants' and invalids' foods, H. W. Wiley, Washington, D. C.; vegetables, G. W. Cavanaugh, Ithaca, N. Y.; condiments (other than spices), J. O. LaBach, Lexington, Ky.; cocoa and cocoa products, E. N. Eaton, Chicago, Ill.; tea and coffee, W. H. Ellis, Toronto, Canada; preservatives, W. D. Bigelow, Washington, D. C.; *sugar*—optical methods, L. M. Tolman, Washington, D. C.; chemical methods, L. S. Munson, Washington, D. C.; *tannin*, H. C. Reed, Stamford, Conn.; *insecticides*, J. Emory, Washington, D. C.; *ash*, F. T. Shutt, Ottawa, Canada.

The chairman of the committee on food standards is Wm. Frear, State College, Pa., and the chairman of the committee on fertilizer legislation is H. W. Wiley, Washington, D. C.

RECENT WORK IN AGRICULTURAL SCIENCE.

CHEMISTRY.

The determination of perchlorate in saltpeter, A. DUPRÉ (*Jour. Soc. Chem. Ind.*, 21 (1902), No. 12, pp. 825-827).—The method proposed is as follows: Heat 10 and 20 gm., respectively, of this salt in nickel crucibles of about 70 cc. capacity fitted with a shallow-dish-shaped, well-fitting cover, to a temperature of 545° C. for one hour. The furnace or air bath recommended for this purpose is the Gilbert modification of L. Meyer's air bath. After cooling the fused mass of 20 gm. dissolve in warm water and transfer the solution to a 200 cc. measuring flask, make up to the mark, and withdraw 25 cc. of the solution for a preliminary determination of chlorin by the Mohr method. After this preliminary test add to a fresh portion of 100 cc. of the solution an amount of standard silver solution (1 cc.=0.001 chlorin) slightly more than sufficient to precipitate all of the chlorin present (as shown by the preliminary test), add 4 cc. of strong nitric acid, and heat on sand bath to the boiling point (but avoiding ebullition) for half an hour. Cool the solution, filter, wash the precipitate thoroughly, add a little persulphate of iron to the clear filtrate, and determine the silver by titration with standard solution of ammonium sulphocyanid according to Volhard's method. Determine the chlorin by the same method in 10 gm. of the saltpeter before heating. "The difference in chlorin before and after heating is the measure of perchlorate present, provided, of course, that no other chlorin compound is present. The titration may be repeated if desired, with the 10 gm. of saltpeter, using the whole of the solution for one experiment."

The determination of total phosphoric acid in Thomas slag, C. ASCHMAN (*Bul. Assoc. Belge Chim.*, 16 (1902), pp. 140-142; *abs. in Chem. Centbl.*, 1902, II, No. 2, p. 155).—A slight modification of the author's previously described method (*E. S. R.*, 11, p. 507) is proposed.

Note on the analysis of superphosphates, J. LEGRAND (*Bul. Assoc. Belge Chim.*, 16 (1902), pp. 143, 144; *abs. in Chem. Centbl.*, 1902, II, No. 2, p. 156).—Attention is called to the fact that the cloudiness which appears in water solutions of superphosphates on standing is due to a mixture of iron and aluminum phosphates.

Determination of sulphuric acid in soils, C. B. WILLIAMS (*Jour. Amer. Chem. Soc.*, 24 (1902), No. 7, pp. 658-661).—A series of determinations of sulphuric acid in soils by the method of the Association of Official Agricultural Chemists, and by a modification of the same method in which the iron and alumina were first removed by precipitation with barium sulphate, are reported, which show that much higher results are obtained by the modified method. This is apparently due to solution of barium sulphate by either the ferric chlorid or aluminum chlorid or by both.

A lime test for soils rich in lime and marls, M. PASSON (*Deut. Landw. Presse*, 29 (1902), No. 68, p. 562).—A description, with explanation of method of use, of the Passon apparatus, which has already been noted (*E. S. R.*, 13, p. 319).

The determination of ammonia in waters, O. EMMERLING (*Ber. Deut. Chem. Gesell.*, 35 (1902), p. 2291; *abs. in Chem. Ztg.*, 26 (1902), No. 68, *Repert.*, p. 214; *Chem. Centbl.*, 1902, II, No. 4, p. 298).—The ordinary method of direct determination of ammonia by means of Nessler's reagent is condemned as inaccurate in presence of

protein compounds. In such cases ammonia is best determined in the distillate obtained after the addition of lead hydroxid.

The solubility of dicalcium phosphate in pure water, A. RINDELL (*Compt. Rend. Acad. Sci. Paris*, 134 (1902), No. 2, pp. 112-114).—In a previous article the author showed that dicalcium phosphate was dissolved with decomposition at ordinary temperatures. By repeated treatment with fresh portions of water he succeeded in completely changing a certain quantity of this phosphate into tricalcium phosphate. Schloesing has shown that it may be dissolved without decomposition. Further experiments by the author, reported in this article, confirm his previous conclusions and show that considerable time is required to establish the equilibrium of saturation. With less than 10 gm. of phosphoric acid per liter of water, 252 hours were required for saturation.

Comparative nitrogen determinations by the method of the German Association of Experiment Stations and the Gunning-Atterberg modification of the Kjeldahl method, O. KELLNER (*Landw. Vers. Stat.*, 57 (1902), No. 3-4, pp. 297-304).—Comparative tests by several cooperating laboratories are reported which show that this modification of the Kjeldahl method is as reliable as the method previously used by the German association. The method is as follows: Heat 1 to 2 gm. of substance with 20 cc. of nitrogen-free concentrated sulphuric acid with the addition of about 1 gm. of mercury until the substance is dissolved (this requires about 15 minutes), then add 15 to 18 gm. of potassium sulphate and heat again, continuing the digestion for 15 minutes after a colorless solution has been obtained. Allow to stand 10 minutes, then dilute with water. With substances which do not foam the potassium sulphate may be added at the beginning of the operation.

A criticism of the official method for the estimation of nitrogen in nitrates, C. A. MOOERS (*Univ. Tennessee Record*, 5 (1902), No. 4, pp. 263-265).—Attention is called to the omission of any directions as to the time to be allowed for the solution of the nitrates before adding the thiosulphate in the Gunning modification of the Kjeldahl method. Determinations are reported which indicate that quick solution may be obtained without sacrifice of accuracy by adding from 1 to 2 cc. of water to the fertilizer mixture and allowing it to stand 5 or 10 minutes before the addition of acids. It was also found that by the careful application of heat the nitrate could be dissolved in the acids in 1 or 2 minutes without appreciable loss of nitrogen.

Some experiments with the Kjeldahl method of nitrogen estimation, H. D. LAW (*Jour. Soc. Chem. Ind.*, 21 (1902), No. 12, pp. 847, 848).—Determinations of nitrogen with and without the use of permanganate are reported to determine the correctness of Nihoul's¹ conclusion that the amount of nitrogen obtained depends largely on the duration of the time of heating after the solution has become clear. The conclusion is reached that "the amount of nitrogen obtained does not increase after a clear solution has been obtained, but until this stage is reached results are always too low." With the use of an oxygen carrier the time of heating is much reduced and the results obtained are less variable.

A source of error from the use of mercury in the Kjeldahl estimation of nitrogen, C. A. MOOERS (*Univ. Tennessee Record*, 5 (1902), No. 4, pp. 262, 263).—Attention is called to a marked absorption of ammonia in the condenser of the Kjeldahl apparatus, probably by the mercury carried over into the coils along with paraffin. Analytical data reported indicate that the error from this cause may be considerable, especially if block-tin condensing coils are used. Glass condensing coils or straight tubes are considered cheaper and in other respects preferable to block tin.

The application of Kjeldahl's method of estimating nitrogen in the tannery as a means of controlling the tanning and finishing of sole leather, J. G. PARKER (*Jour. Soc. Chem. Ind.*, 21 (1902), No. 12, pp. 838-842).

¹ Bourse aux Cuirs de Liège, September, 1901.

An easily made and safe dephlegmator for Kjeldahl distillations, W. J. LOVETT (*Jour. Soc. Chem. Ind.*, 21 (1902), No. 12, pp. 849, 850, fig. 1).

Fixing nitrogen from the air, T. C. MARTIN (*Amer. Mo. Rev. of Reviews*, 26 (1902), No. 3, pp. 338-342, figs. 6).—A brief account of the process devised and installed at Niagara by C. S. Bradley and D. R. Lovejoy for oxidizing the nitrogen of the air by means of direct-current arcs. It is stated that by this process 70 per cent nitric acid can be produced at a cost of a little less than 1.6 cts. per pound for energy, using a current generated by Niagara water power at \$20 per kilowatt.

Report on general work in the chemical laboratory, C. A. GOESSMANN (*Massachusetts Sta. Rpt.* 1901, pp. 104-107).—This includes a list of miscellaneous materials sent to the station for analysis during the year, and notes on wood ashes, comparing the quality of samples examined during 1900 and 1901.

The potash and phosphoric acid content of the ash of leaves of various kinds of potatoes rich in starch, J. SEISL and E. GROSS (*Ztschr. Landw. Versuchsw. Oesterr.*, 5 (1902), p. 62; *abs. in Chem. Zig.*, 26 (1902), No. 64, *Repert.*, p. 202).—It was found that the leaves of potatoes rich in starch contained more potash and phosphoric acid than those poor in this substance, and this was true regardless of the fertilizing and stage of growth.

Compilation of analyses of fruits, garden crops, and insecticides, H. D. HASKINS (*Massachusetts Sta. Rpt.* 1901, pp. 132-147).—Tables are given which show the percentages and relative proportions of the fertilizing constituents of fruits and garden crops, based mainly upon analyses made at the Massachusetts Agricultural College and Experiment Station; also the average composition of various insecticides examined at the same place.

Laboratory apparatus, P. N. RAIKOW (*Chem. Zig.*, 26 (1902), No. 63, pp. 732-734, figs. 6).—Descriptions are given of filters for hot and cold filtration, wash and absorption flasks for gases, burettes, etc.

Note on a convenient apparatus for the chemical and bacteriological examination of the atmosphere, W. CHATAWAY and F. M. WHARTON (*Analyst*, 27 (1902), No. 317, pp. 243-245).

BOTANY.

Influence of the elementary plant foods on plant growth, A. N. PEARSON (*Dept. Agr. Victoria*, 1901, June, pp. 14, pl. 1, *dgms.* 2).—An account is given of experiments with wheat plants grown in the absence of nitrogen, phosphorus, sulphur, chlorine, iron, lime, magnesium, potassium, and sodium, in porcelain pots filled with sand that had been washed and ignited, the different pots being arranged in series. Each series contained one pot in which all the plant elements were supplied, accompanied by pots in which single elements were omitted. One of the interesting facts brought out in the experiments was the peculiar thin, wiry stems and narrow, straight leaves produced where nitrogen was omitted from the plant food. Where potash was deficient, the plants were characterized by short, weak stems and narrow, pendent leaves. Subsequent to the principal investigation the author conducted an experiment with sand taken from a hill and placed in pots. The untreated soil produced plants of an unmistakably nitrogen-starved type, while soil to which nitrogen had been added produced plants showing a deficiency in the potash.

Investigations on the nutrition of plants by amids, L. LUTZ (*Bul. Soc. Bot. France*, 48 (1901), No. 7, pp. 325-334).—Experiments are reported in the nutrition of a number of species of algæ and fungi, different forms of amids being added to the culture solutions in which the plants were grown. The amids tested were formamid, acetamid, propionamid, butyramid, benzamid, salicylamid, asparagin, urea, oxamid, succinamid, and acetanilid. It was found that the amids of the fatty acid series were readily assimilable, while those belonging to the aromatic group could not be success-

fully used in the nutrition of plants. In every case where there was a production of ammonia in the cultures the fermentation was due to the entrance of secondary organisms. Where there was an absolute absence of micro-organisms the fungi were able to develop without the formation of ammonia, depending upon the amids present in the solution. The soluble ferments secreted by *Aspergillus niger*, *A. repens*, and *Penicillium glaucum* were incapable of transforming the amids to ammonium salts.

The electrical conductivity of plant juices, F. DE F. HEALD (*Abs. in Science*, n. ser., 15 (1902), No. 377, p. 457).—By using the methods of physical chemistry the author investigated the conductivity of the juice expressed from the leaves, stems, and roots of beets, potatoes, onions, radish, cucumbers, purslane, water lilies, and rough pigweed. Ash determinations were also made for the juices used, and the ash redissolved in distilled water and diluted to the original volume of the juice from which it was obtained. The specific conductivity was determined for the ash solutions. It was found that plant juices are comparatively good conductors, the conductivity being due in a large measure to the dissolved mineral substances, the organic compounds playing a minor part. The conductivity of juice obtained from the roots of plants is always less than that of the juice obtained from the subaerial parts of the plant. The specific conductivity generally increases progressively from the root upward, although in some cases the sap from the stem has a higher conductivity than that from the leaves. In most cases the specific conductivity may be taken as a rough measure of the relative amount of ash present in the different parts of the plant.

The sensory area of the roots of land plants, F. C. NEWCOMBE (*Abs. in Science*, n. ser., 15 (1902), No. 377, pp. 454, 455).—The sensitiveness to external stimuli on the part of roots of land plants has generally been considered as confined to the apex and elongating zone. In nearly all species this would be confined to the first 10 mm. of the apex. In studying the phenomena of rheotropism the author found that the region of the root posterior to the elongating zone is sensitive. To determine the location of the sensory tissue, various parts of the root were shielded from the flow of water by inclosure in glass tubes. The roots of radish, white mustard, buckwheat, sunflower, and popcorn gave rheotropic curves when stimulated at a distance of 10 to 15 mm. from the limit of the elongating zone.

The significance of transpiration, C. R. BARNES (*Abs. in Science*, n. ser., 15 (1902), No. 377, p. 460).—In this paper the author seeks to present a new point of view regarding transpiration. Ordinarily the purpose of transpiration is held to be a double one: First, to cause the influx to the leaves of a large amount of water, thereby supplying the leaves with a sufficient amount of mineral salts; and second, to concentrate the extremely dilute solutions and thus get rid of the surplus water. The author claims that the amount of salts absorbed is dependent upon the living cortex of the rootlets and the mesophyll of the leaves. If the cortex is freely permeable, equilibrium in the distribution of any salt will occur without evaporation from the aerial parts. If, then, evaporation concentrates the solution, the higher diffusion tension of the salt will tend to drive it to those regions where the diffusion tension is lower. This tendency, therefore, would operate against the further supply of that material to the leaves. If the cortical layers of the roots be not freely permeable, the amount absorbed is regulated wholly by protoplasmic activity and is not directly affected by outside supply. The phenomena of selective absorption show that transpiration does not determine the amount of salts absorbed. Wet cell walls exposed to the atmosphere are indispensable for the solution of the necessary gases, the plant being unable to render waterproof the cell walls so long as gas absorption is necessary. Transpiration is, therefore, considered as unavoidable, although in itself a constant menace to the life and activity of the plant. Advantage is doubtless taken of the xylem bundles to facilitate the movement of substances held in solution, but the author claims there is no reason to think that this is essential. In addition to the above, attention is called to the fact that transpiration has also

become a protective factor to plants grown in the open, their temperature being kept within reasonable bounds in this way.

The influence of metallic poisons on respiration, E. B. COPELAND (*Abstr. in Science*, n. ser., 15 (1903), No. 377, p. 454).—Experiments are reported with *Elodea*, *Callitriche*, a crucifer, fish, and frog larvæ, in which copper, zinc, cadmium, silver, and mercury were used as stimulants. It was shown that the respiration may be stimulated by a small fraction of a fatal concentration of these metals. With increasing concentration the evolution of carbon dioxid becomes accelerated, sometimes reaching 25 times that of the normal. The evolution of carbon dioxid continues undiminished after plasmolysis is suspended by the poison. It was found that copper and zinc may cause a considerable evolution of carbon dioxid from specimens of *Elodea* that have been boiled.

Cyanogenesis in plants, W. R. DUNSTAN and T. A. HENRY (*Proc. Roy. Soc. [London]*, 70 (1903), No. 461, pp. 153, 154).—The authors have investigated the nature of the poison contained in young plants of *Sorghum vulgare*. This plant, under the name of guinea corn, durra, etc., is extensively cultivated in tropical countries as a food grain. The young plants have in a number of instances, especially in Egypt, proved fatal to animals, and the authors show that when crushed with water the young plant produces prussic acid. The acid does not appear to exist in a free state, but is produced by the action of the hydrolytic enzym, which is apparently identical with the emulsin of bitter almonds, on a cyanogenetic glucosid, which has been named dhurrin. Dhurrin is said to differ from the amygdalin of bitter almonds and the lotusin of *Lotus arabicus* in being derived from dextrose and not from maltose. The poisonous properties of young plants do not seem to be in any way present in the seeds or older plants. The authors intend to make an investigation of the general problems raised by the occurrence of cyanogenetic glucosids in plants.

A preliminary study of the germination of the spores of *Agaricus campestris* and other Basidiomycetous fungi, MARGARET C. FERGUSON (*U. S. Dept. Agr., Bureau of Plant Industry Bul.* 16, pp. 43, pls. 3).—A report is given of preliminary studies on the germination of the spores of Basidiomycetous fungi, the principal species used being *Agaricus campestris*. The methods of investigation are described and experimental results given in detail. The effect of various agents on germination is shown, and the author reports having found that the germination of spores of *Agaricus campestris* is favored under cultural conditions if a few of the spores are germinated or if a small portion of the mycelium of the fungus be introduced into the culture. The growth resulting in either case will cause the germination of nearly all the spores in the culture, provided the conditions are such as not to be detrimental to it. A historical résumé is given of investigations along the same line, and a brief bibliography completes the report.

Cell nuclei in some cases of parasitism or intercellular symbiosis, R. CHODAT (*Extr. from Compt. Rend. Cong. Internat. Bot. Paris, 1900*, pp. 10).—The constant presence of many parasites, especially in some of the higher plants, has been taken to be a form of symbiosis and not as parasitism. The author has made a study of the apparent association between fungi and a number of plants to determine the effect of the presence of the organism on the cell and particularly upon the nucleus. In his studies he found that the parasite of *Hippophaë rhamnoides* acts toward that plant in a similar manner as does the organism causing the club root of cabbage. It is a true parasite and destroys the nucleus of the cell. In turn the parasite may be absorbed by the host plant. The fungus parasite occurring as mycorrhiza in certain orchids in the beginning acts as a true parasite, but never to the destruction of the cell nucleus. After having passed a certain stage the plant seems to be able to restore the attacked cells and no permanent injury is inflicted. In the case of leguminous plants the bacterial parasite seems to be present in a true symbiosis, the host toler-

ating the micro-organism without injury to the nucleus, although in *Ornithopus* the nucleus was somewhat enlarged.

The root tubercles of bur clover and of some other leguminous plants, G. J. PEIRCE (*Proc. California Acad. Sci.*, 3. ser., *Bot.*, 2 (1902), No. 10, pp. 295-328, pl. 1).—While examining some sections of root tubercles of the bur clover (*Medicago denticulata*), the author was struck by the great difference between cells containing bacteria and those in which there were none. This led to a careful microscopic study of the root tubercles of the bur clover and other leguminous plants to ascertain if possible the real relations of the tubercular organisms to the cells in which they are found. After describing in detail the method of procedure, the author considers the origin and morphology of the root tubercles, their form, distribution, and structure.

Summarizing his results, the author found that bacteria which form root tubercles on leguminous plants are usually slowly motile in artificial cultures, although this proves nothing for their movement through the soil. The proportion of root hairs affected in the case of the bur clover was about 1:1,000. If the bacteria are in contact or close proximity with the young root hairs many infections may occur simultaneously. The root tubercle bacteria enter and infect a root hair by softening or dissolving a portion of the cell wall. There is no evidence whatever that they enter through broken root hairs. The infection thread grows fairly straight through the cortical parenchyma from the root hair to the layer of cells next the outside of the central cylinder of the root. Tubercles are formed only as a result of the stimulating action of the bacteria, and are originated endogenously from the same layer as that which gives rise to lateral roots, hence morphologically they are lateral roots greatly modified by the influence which caused their formation. The growth of the root tubercle is apical and there is little if any secondary growth in thickness. Root tubercles are usually largest and most numerous near the surface of the soil, and it is probable that perennial leguminous plants form few if any tubercles after their roots have penetrated deeply into the soil.

The presence of bacteria in the cells of a tubercle prevents those cells from forming starch. The affected cells are usually larger than normal ones, due to the increased pressure and to the greater irritation. The bacteria cause the degeneration and almost complete destruction of the nuclei of the cells in which they occur. The infection strands grow definitely toward the daughter cells formed by the meristem, and seem to grow toward the nuclei, which they appear to penetrate. Infected cells soon lose their power of division, but not of growth. The presence of the bacteria in the cells of the tubercle is injurious to the cells, the relation being one of true parasitism on the part of the bacteria. The presence of intercellular spaces in the root makes it unnecessary to assume that the bacteria live anaerobically, as has been assumed by some investigators.

In conclusion, the author states that it is difficult to understand how the leguminous plant as a whole can profit by an association which is injurious and finally destructive to the cells in which the bacteria occur.

On the development of root tubercles of leguminous plants, E. LAURENT (*Compt. Rend. Acad. Sci. Paris*, 133 (1901), No. 26, pp. 1241-1243; reprinted in *Prog. Agr. et Vit.* (Éd. L'Est), 23 (1902), No. 13, pp. 387, 388).—Since 1897 the author has been studying the effect of certain fertilizers on the production of root tubercles upon the roots of leguminous plants. The plats have each year received the same fertilizer and have been grown with the same crop successively. One plat was manured with a nitrogenous fertilizer, a second with potash, a third with superphosphate, a fourth with lime, and a fifth with sodium chlorid. The plants experimented with were peas, hairy vetch, common vetches, and lupines. One object of the experiments was to determine whether by continuous cultivation under similar conditions the plants would acquire characteristics resistant to parasites or other biological changes. In

1897 the peas grown on the plat receiving ammonium sulphate produced few tubercles upon their roots, and these were scattered upon the lateral rootlets. Those plants grown on plats receiving potash fertilizers produced abundant tubercles, which were aggregated close to the tap root, and similar results were obtained with superphosphates. Under the influence of large amounts of lime the tubercles were less abundant, but their volume was greatly increased, many of them attaining a diameter of 10 mm. The action of the sodium chlorid seems to be toward the formation of a few small tubercles.

Each year the seed have been saved from each plat separately and reseeded upon the same, the experiment being carried on continually. In 1901 the peas gathered from the plat which had constantly received nitrogenous fertilizers seemed to have lost their ability to form root tubercles in that soil. When seeded in ordinary soil, however, they readily produced root tubercles, showing that after 5 years there had been no important biological change in the plants. For the other plats, seeds harvested year after year and planted again showed no important differences. The action of the hairy vetch and the cultivated vetch did not differ materially from that shown by the peas. With the yellow lupine, however, the results are somewhat different. The well-known action of lime upon this plant was plainly shown in the plats which received that fertilizer. Comparisons were made with beans of several varieties. In the case of the beans, nitrogenous fertilizers seem to stimulate the formation of root tubercles, while tending to restrain their development with the other leguminous species studied. The addition of superphosphate tends to stimulate the production of tubercles upon peas, hairy vetch, common vetch, and particularly on the yellow lupine, but it has a contrary effect with beans.

METEOROLOGY—CLIMATOLOGY.

Eclipse meteorology and allied problems, F. H. BIGELOW (*U. S. Dept. Agr., Weather Bureau Bul. 1, pp. 166, pls. 3, figs. 24, charts 16*).—This is a report of observations during the total solar eclipse of May 28, 1900, on the effect of the moon's shadow on the earth's atmosphere. It is based upon the records of an expedition to Newberry, S. C.; upon the special meteorological observations at 62 Weather Bureau stations located within 500 miles of the center of the track of totality; upon a considerable number of voluntary observations made within the belt of the umbra, in accordance with instructions from the Weather Bureau; and upon a study of various problems in solar and terrestrial meteorology. "As the outcome of this work there have been made special studies, (1) on the apparatus planned to obtain a large-image picture of the inner corona, while yet employing a telescope of comparatively short focus; (2) on the shadow band phenomena, which appear to be due to meteorological conditions exclusively, and are not to be associated with diffraction on the edge of the moon, and (3) on the variations of the pressure, temperature, vapor tension, and wind caused by the passage of the shadow cone, together with a computation on the number of calories of heat absorbed per kilogram of air."

Meteorological observations, J. E. OSTRANDER, H. L. BODFISH, and S. C. BACON (*Massachusetts Sta. Met. Buls. 160, 161, 162, pp. 4 each*).—Summaries of observations on pressure, temperature, humidity, precipitation, wind, sunshine, cloudiness, and casual phenomena during April, May, and June. The data are briefly discussed in general notes on the weather of each month.

Report of the department of meteorology and meteorological summary, C. H. PETTEE (*New Hampshire Sta. Bul. 87, pp. 130-133*).—A brief report is given of the operations of this department of the station during the year, accompanied by a monthly and an annual summary of observations on temperature, precipitation,

snow fall, cloudiness, and direction of wind during the fiscal year ended June 30, 1901, with averages for each month from July 1, 1895, to June 30, 1901, inclusive. The annual summary of these observations is as follows: Temperature (degrees F.)—1900-1901, 45.9; 1895-1901, 45.3; precipitation (in.)—1900-1901, 41.03; 1895-1901, 44.36; snow fall (in.)—1900-1901, 35; 1895-1901, 57.65; number of days on which there was 0.01 in. precipitation—1900-1901, 98; 1895-1901, 100; prevailing direction of wind—1900-1901, northwest; clear days—1900-1901, 135.

Meteorological observations, W. T. ELLIS, R. ROBERTSON, S. A. BEDFORD, A. MACKAY, and T. A. SHARPE (*Canada Expt. Farms Rpts. 1901*, pp. 60, 61, 335-337, 455, 512, 558).—A record of the continuation of observations of previous years (E. S. R., 13, p. 228).

Meteorological chart of the Great Lakes, A. J. HENRY and N. B. CONGER (*U. S. Dept. Agr., Weather Bureau, Meteorological Chart of the Great Lakes, 1902, No. 1, pp. 26, charts 2*).—This is a summary of data relating to the weather during the season of navigation; precipitation in the Lake region, winter of 1901-2; ice during winter of 1901 and 1902; opening of general navigation, season of 1902; wrecks and casualties from January 1 to April 30, 1902; Lake region storm of April 25-26, 1902; a new service by the Weather Bureau (predictions of high north to east winds at Buffalo to raise the ice blockade), and the display of storm warnings on the Great Lakes.

Wind velocity and fluctuations of water levels on Lake Erie, A. J. HENRY (*U. S. Dept. Agr., Weather Bureau Bul. J, pp. 22, charts 25*).—"This report deals with the character and frequency of the storm winds that prevail on Lake Erie, the changes in water level produced by them, and the possibility of predicting the occurrence of the most pronounced changes in level at the eastern end of the lake."

A year of weather and trade in the United States, R. DE C. WARD (*Pop. Sci. Mo., 61 (1902), No. 5, pp. 439-448*).—The conclusion reached by the author from his study of this subject is that "as the result of the experience of many years, trade is in a condition of such very close and delicate adjustment to the average weather of any particular month, or even week, that 'seasonable,' i. e., normal weather, other things being equal, usually means 'seasonable' trade. . . . When meteorological conditions are unseasonable, trade at once reflects the change, and suffers. Trade is, however, subject to many and widely varying controls; hence the problem of the particular controls which affect it in any one week is a very complex one, and the key is not always, or sometimes even at all, to be found in local weather conditions."

Composition of Barbados rainfall (*Rpt. Agr. Work, Imp. Dept. Agr. West Indies, 1899-1901, p. 2*).—The total amount and the chlorin and nitrogen (total and as ammonia and nitrates) in the rainfall at Dodds Botanic Station for each month from December, 1899, to May, 1901, inclusive, are reported.

Rainfall at the Variety Experiment Stations from December, 1899, to May, 1901 (*Rpt. Agr. Work, Imp. Dept. Agr. West Indies, 1899-1901, pp. 142, 143*).—The number of rainy days and number of inches of rainfall for each month during this period are reported for 11 places in Barbados.

A study on the climate of Tunis, G. GINESTOUS (*Bul. Dir. Agr. et Com. [Tunis], 7 (1902), No. 24, pp. 251-363, figs. 4, charts 4*).—This is the third communication (E. S. R., 14, p. 16) on this subject and summarizes the available meteorological data for the three summer months, June, July, and August.

Ten years' observations on the influence of the weather on the yield of sugar beets and on the so-called second growth of beets (*Deut. Landw. Presse, 29 (1902), Nos. 53, pp. 452, 453; 54, p. 460*).—A brief discussion based mainly on Rimpaur's observations and applicable to German weather conditions.

The gases of the atmosphere, H. F. KELLER (*Jour. Franklin Inst., 153 (1902), No. 6, pp. 419-430; 154 (1902), No. 1, pp. 47-57*).

WATER—SOILS.

The significance of phosphates in natural waters, A. G. WOODMAN (*Jour. Amer. Chem. Soc.*, 24 (1902), No. 8, pp. 735-743).—It is claimed that the determination of phosphoric acid in natural waters "by reason of the conversion of organic phosphorus compounds into phosphates through the processes of decay is one which might reasonably be expected to throw considerable light on the question of the pollution of [such] waters." The author has used with success a modification of J. West-Knights' method, evaporating 50 cc. of the water and 3 cc. of nitric acid (sp. gr. 1.07) to dryness on a water bath, and heating the residue in a water oven for 2 hours. The dry residue is taken up in 50 cc. of cold distilled water, 4 cc. of ammonium molybdate (50 gm. per liter), and 2 cc. of nitric acid added, and the color compared with standards made by diluting varying quantities of a standard phosphate solution (1 cc. = 0.0001 gm. phosphorus pentoxid) to 50 cc., and adding the reagents as above. Blank determinations on the distilled water are advised.

Determinations in a large number of samples of water are reported, together with data obtained by the ordinary sanitary analysis of water. These data show that "the amount of phosphate and its variation seem to follow the same general line as the other mineral constituents which either accompany the polluting material or are produced by its decay, especially the nitrates and the chlorids. It is not, however, so delicate an indicator as these. . . . The results obtained by the colorimetric method would seem to indicate that the limit of 0.5 part of phosphorus pentoxid in a million, as given by Hehner for unpolluted waters, is rather low. A safer amount would be 1 part, although the average would doubtless be lower than this."

Artesian waters and irrigation, W. G. COX (*Agr. Jour. Cape Good Hope*, 20 (1902), No. 11, pp. 612-618).—This article gives data relating to artesian borings in Queensland, with a discussion of the influence of artesian irrigation on the agriculture of that region.

Well waters from farm homesteads, F. T. SHUTT (*Canada Expt. Farms Rpts.* 1901, pp. 193-196).—Analyses of 64 samples of water with reference to sanitary condition are reported.

Some excessively saline Indian well waters, J. W. LEATHER (*Jour. Chem. Soc. [London]*, 81 (1902), No. 476, I, pp. 387-392).—Analyses of a number of such waters are reported and their use in irrigation is briefly discussed.

The examination of water from some typhoid-polluted wells, S. RIDEAL (*Analyst*, 27 (1902), No. 317, pp. 245-247).

The temperature of the soil, D. T. MACDOUGAL (*Jour. New York Bot. Gard.*, 3 (1902), No. 31, pp. 125-131, figs. 3).—A description is given of a thermograph devised by Prof. W. Hallock, of Columbia University, for making a continuous record of the temperature of the soil at any desired depth. "The essential features of the Hallock thermograph are as follows: The thermal element of the instrument consists of a copper bulb or globe 11 cm. in diameter, with a strengthening equatorial ridge, filled with commercial kerosene. A short section of copper tubing with a heavy wall is soldered to an opening in one pole of the globe, and the free end of the heavy tube receives a small copper tube with an external diameter of about 4 mm., a bore of 1 mm., and of any desired length. The tube is also filled with petroleum. The free end of the small tube is connected with a chamber consisting of a pair of corrugated brass disks 8 cm. in diameter, with the edges soldered together. The chamber is seated on a metal block fastened to the base of a recording apparatus and the tube connects with the chamber through an opening in the metal block. An opening is made in the upper side of the first chamber and a second chamber of the same kind is sol-

¹Analyst, 5 (1880), p. 197.

dered to it, the interior of the two chambers being thus connected. The pair of corrugated chambers are filled with petroleum as convenient during the course of construction, and care is taken to exclude all air from the bulb, tube, and chambers. As the temperature in the bulb is made to rise it expands, and as both it and the small tube have fairly rigid walls, the total expansion of the liquid is made to press outwardly the walls of the chambers with corrugated walls, which expand and contract after the manner of a bellows. An upright post is fixed to the upper wall of the pair of chambers, and it may be lengthened or shortened in making the necessary adjustments. This post connects with a short arm 4 cm. in length, running to an axis held in bearings between two upright standards. A second arm 17 cm. long, carrying a pen, is attached to this axis and extends to an upright recording cylinder revolved by clockwork. The cylinder carries double-ruled paper and occupies a week in a single revolution. The instrument is now adjusted so that the pen bears against the point on the paper indicative of the same temperature as that of the bulb as determined by a mercurial thermometer, and it is ready for use. At the end of a week the paper, bearing a continuous tracing of the temperature for that time, is removed and another put in its place."

Capillary studies and filtration of clay from soil solutions, L. J. BRIGGS and M. H. LAPHAM (*U. S. Dept. Agr., Bureau of Soils Bul. 19, pp. 40, figs. 5*).—This includes studies of the influence of dissolved salts on the capillary rise of soil waters, the capillary movement of water in dry and moist soils, and filtration of suspended clay from soil solutions.

Influence of dissolved salts on the capillary rise of soil waters (pp. 5-18, figs. 3).—This is a technical paper which discusses the factors modifying capillary action, describes the methods and apparatus used in studying the effect of certain salts found in alkali (sodium chlorid, sulphate, and carbonate) on this action, and explains the significance of the results obtained. The following conclusions are drawn: "(1) Dissolved salts in general do not increase the capillary rise of soil waters. (2) Neutral salts in dilute solution have practically no influence on the extent of capillary action. (3) Concentrated or saturated solutions of all salts materially diminish capillary activity. (4) This effect appears to be due—(a) To the increased density of the solution, which more than offsets the increased surface tension, and—(b) To the resistance of a film to a tangential shearing stress, which retards capillary action and offers in addition a permanent resistance to the movement of the solution through thin films, thus increasing the angle of contact, or—(c) To an increase in the tension of the liquid-solid surface, as the concentration is increased. (5) Sodium carbonate differs from neutral salts, the capillary rise being considerably greater than for neutral solutions of equal concentration. (6) This may be due in part to the saponification of traces of grease on the surface of the soil grains through the hydrolysis of the sodium carbonate, thus furnishing clean surfaces for capillary action. (7) The same effect should consequently be observed with all salts which undergo an alkaline hydrolysis, viz, potassium and sodium carbonates, borates, phosphates, etc. (8) This action is characterized in the soil tubes by indistinctness of the upper boundary of the capillary column."

The capillary movement of water in dry and moist soils (pp. 19-30, fig. 1).—This is a technical account of the methods used and the results obtained in investigations on this subject. From the latter the following conclusions are drawn: "(1) The extent of capillary action in a soil under field conditions is not represented by the capillary rise of water in the air-dried soil. (2) The extent of capillary action may, however, be found by determining the limiting height through which capillary movement will take place in a moist soil. (3) If a general relation can be established between the capillary rise of water in dry and in moist soils, then the capillary rise in air-dried soils may be used as a basis for investigating the behavior of the soils under field conditions, and possesses the advantage of greater simplicity. If no

definite relation can be found, then the determinations of the capillary rise in dry soils are without value. (4) It is consequently important that investigators in this line should determine the limit of capillary movement in moist soils in which they are interested, both to obtain reliable data regarding the extent of capillary action and to determine the ratio of capillary action in dry and moist soil. (5) The true limit of capillary movement may be determined by finding the limiting height of a soil column from the upper surface of which evaporation proceeds at a finite, continuous, and approximately uniform rate, the supply being obtained from a reservoir at the base of the column. The rate of evaporation may be determined directly by weighing the system, or less accurately by measuring the height of the water in the reservoir. (6) For Sea Island soil we have found the capillary rise in dry soil to be only 37 cm., while the limiting value of capillary movement in a vertical column of moist soil is not less than 165 cm., or 4.5 times as great. (7) The rate at which water can be supplied at a given point by capillary action through soil columns of various heights is of fundamental importance when the plant is dependent upon capillary movement for its water supply. This determination can readily be made by the methods described."

Filtration of suspended clay from soil solutions (pp. 31-40, fig. 1).—The difficulty of securing satisfactory filtration of solutions containing suspended clay obtained in soil analysis is pointed out, and a light, portable apparatus, consisting essentially of an unglazed porcelain filter tube connected with a filter pump, which has been devised and used with success in the Bureau of Soils, is described.

Contribution to the study of the solution of phosphoric acid in the soil solutions, G. PATUREL (*Ann. Agron.*, 28 (1902), No. 8, pp. 385-398).—From the results of studies of soils of different kinds, with and without the addition of superphosphates, following in the main the method proposed by Schloesing (E. S. R., 11, p. 821), the author concludes that the generally accepted view that the greater activity of superphosphate as a fertilizer is due to the fact that the phosphoric acid is widely diffused in the soil and precipitated in a fine state of division, which renders it easily assimilable by plants, is not true in all cases, especially in light, sandy soils poor in lime and having little absorptive power for the superphosphate. He found that in such soils a portion of the superphosphate added was still soluble after the lapse of several months. The results confirm those reported by Schloesing in indicating that plants take up all of their phosphoric acid in soluble form, and that the soil solutions play an important rôle in supplying this soluble phosphoric acid for the use of the plant.

On a method of determining the heat generated when soils are moistened, A. MITSCHERLICH (*Landw. Jahrb.*, 31 (1902), No. 4, pp. 577-604, figs. 5).—In continuation of a previous article (E. S. R., 13, p. 833) the author describes a new drying apparatus for use in his method based on the heat generated on moistening soils (*Benetzungswärme*) and reports a large number of experiments on different kinds of soil to test the accuracy of the method.

Soil survey in Salt River Valley, T. H. MEANS (*Arizona Sta. Bul.* 40, pp. 287-330, pls. 4, figs. 8, maps 3).—A reprint from the report on field operations of the Division of Soils of this Department for 1900 (E. S. R., 13, p. 924).

Soil investigations, F. T. SHUTT (*Canada Expt. Farms Rpts.* 1901, pp. 140-152).—Miscellaneous investigations are reported, including chemical analyses (total and available constituents) of 2 samples of soils from British Columbia, 2 from Ontario, 5 from Nova Scotia, and 1 from Prince Edward Island, with suggestions as to their fertilizer requirements and treatment. Examinations of several soils with reference to available lime and a study of the relation of cover crops and cultivation to soil moisture are also reported. The observed losses of water from the soil were much larger in that under crop (clover) than in that which had been cultivated.

The sampling of soils, J. W. LEATHER (*Jour. Chem. Soc. [London]*, 81 (1902), No.

476, I, pp. 883-887).—Analyses of a number of samples of soils are reported which were made to test the accuracy of the auger method of sampling soils. The results were not conclusive.

Soil cultivation, J. H. GRISDALE (*Canada Expt. Farms Rpts. 1901, pp. 295-298*).—A brief discussion of cultivation as a means of improving the physical condition of soils.

Summer fallows, A. MACKAY (*Canada Expt. Farms Rpts. 1901, pp. 505-507*).—A brief discussion of methods of summer fallowing and of the advantages of the practice.

FERTILIZERS.

The cowpea and the velvet bean as fertilizers, J. F. DUGGAR (*Alabama College Sta. Bul. 120, pp. 123-179, figs. 3*).—"This bulletin records the results of more than 50 experiments conducted at Auburn during the past 5 years, to ascertain the effects of cowpeas and velvet beans in the improvement of the soil. The amount of soil improvement has been determined by the increase in the yields of cotton, corn, oats, wheat, and sorghum, grown as first, second, third, or fourth crops after the stubble and roots of cowpeas or velvet beans, or after vines, stubble, and roots of these plants have been plowed under. The basis for determining this increase has been the yield of each crop on plats where no leguminous plant has recently grown." Different varieties of cowpeas differ considerably in fertilizing value. In these experiments the average amount of nitrogen supplied by the whole crop was 70.2 lbs. per acre; by the stubble, roots, and fallen leaves, 19.75 lbs., or 28 per cent of the whole. Velvet beans and cowpeas were of about equal value as soil improvers. The percentage increase of the following crops when the vines were plowed under averaged 63 per cent in case of cotton and 87 per cent in case of sorghum.

"When the vines of the cowpea or velvet bean were utilized as hay and only the roots and stubble employed as fertilizer, the increase in the yield per acre of the crop immediately succeeding the stubble was as follows:" Cotton, 18 per cent; corn, 32 per cent; oats, 334 per cent; wheat, 215 per cent; sorghum hay, 57 per cent. "The largest percentage increase from either the vines or stubble of cowpeas or velvet beans was made by wheat and fall-sown oats, probably because these best prevented the washing away or leaching out of the fertilizing material in the stubble or vines of the legumes. . . . The value of the increased product resulting from the use of the entire legume for fertilizer was greater with cotton and sorghum than with corn, oats, or wheat. . . . Comparing the fertilizing effect of the vines with that of the stubble of the cowpea and the velvet bean, the excess in the next crop in favor of the vines averaged as follows:" Corn, 49 per cent; sorghum hay, 9 per cent; cotton, 40 per cent.

"With oats and wheat the vines of these summer legumes were not superior to the stubble when the small grains were sown immediately after the legumes matured.

"The fertilizing effect of the stubble of cowpeas or velvet beans was very transitory on sandy land, the average increase in the second crop of corn after the stubble being only 1.34 bushels per acre, or 12 per cent, as compared with the yield of a plat that had not borne legumes.

"The fertilizing effect of the vines of cowpeas and velvet beans was less transitory than that of the stubble, and the increase was 24 to 54 per cent in the second crop, 14 per cent in the third crop (oats), and the favorable effect was even perceptible in the fourth crop (sorghum) grown in the same year as the third. . . .

"On the other hand, on very light soil the fertilizing effects of both stubble and vines had practically disappeared within 12 months after the plowing in of the legumes."

Fertilizer experiments on moor soils, results of experiments by the

Swedish Moor-Culture Association, 1887-1899, H. VON FEILITZEN (*Jour. Landw.*, 50 (1902), No. 1, pp. 77-90, pls. 3; *Deut. Landw. Presse*, 29 (1902), Nos. 48, p. 413, figs. 2; 49, pp. 420, 421, fig. 1).—A summary of the results of the experiments carried out by C. von Feilitzen, former director of the Swedish Moor-Culture Association, which have been published in book form. The Swedish moor soils are as a rule poor in potash, and thus it was found that both the yield and quality of crop was improved by applications of potash fertilizers. The soils are also poor in phosphoric acid and are benefited by applications of phosphates. The crude phosphates were of little benefit, but those containing citrate-soluble and water-soluble phosphoric acid were of equal value. The phosphates shortened the period of growth. Soluble nitrogenous fertilizers were decidedly beneficial, but lengthened the period of growth. Manure gave good results, but this is attributed to the soluble nitrogen present or to the fermentation set up by the manure in the soil, which makes the nitrogen present more available.

Pot experiments on the action of lime and magnesia in burnt lime and marl, R. ULBRICHT (*Landw. Vers. Stat.*, 57 (1902), No. 1-2, pp. 103-166).—This is a detailed account of pot experiments with barley supplementing experiments previously reported (*E. S. R.*, 11, p. 1023). As in the previous experiments referred to, the lime fertilizers in all amounts used as a rule increased the yield to a marked extent. The weight of grain, however, was in every case reduced by applications of lime and marl in February. The tillering of the grain was invariably increased by the use of lime and magnesia fertilizers. Heavy applications of lime with small magnesia content promoted all phases of growth, but of straw more than of grain. In this case also the weight of the grain was lighter. Heavy applications of magnesia lime reduced yield of grain and straw.

On the dependence of the maximum yield on a definite quantitative relation between lime and magnesia in soils, O. LOEW (*Landw. Jahrb.*, 31 (1902), No. 4, pp. 561-576).—A discussion of this subject based mainly upon the results of investigations by the author and D. W. May (*E. S. R.*, 13, p. 630) and T. Furuta and K. Aso (*E. S. R.*, 14, p. 14), which show a definite relation between the amounts of lime and magnesia and the maximum growth of plants.

On the fertilizing value of peat ashes, J. BOES (*Ztschr. Oeffentl. Chem.*, 8 (1902), pp. 150, 151).—This article discusses briefly the variation in the chemical composition of such ashes.

Nitrate of soda, potassium perchlorate, and crops, L. GRANDEAU (*Jour. Agr. Prat.*, n. ser., 4 (1902), No. 34, pp. 242-244).—This is a review of various investigations on this subject from which the following conclusions are drawn: Nitrates contain an element (potassium perchlorate) which has until recently been ignored. This perchlorate is very unequally distributed in the nitrate and is very variable in amount. High percentage nitrates as a rule contain only small amounts of perchlorate.

A new use for potash salts in agriculture, F. LUCKE (*Chem. Ztg.*, 26 (1902), No. 50, *Reper.*, p. 175).—A brief note on a new manure preservative known as Utilit, a by-product of the potash industry, which contains free sulphuric and phosphoric acids and various combinations of potash.

Investigations on the influence of soil moisture on the action of phosphoric acid in bone meal, Thomas slag, and superphosphate, C. VON SEELHORST (*Jour. Landw.*, 50 (1902), No. 2, pp. 167-174).—The results of pot experiments which are reported show that the moisture content of the soil was without effect on the action of the phosphoric acid of bone meal. On the other hand, the action of the phosphoric acid of Thomas slag and superphosphate was influenced to a considerable extent by the water content of the soil, being favored by an increased water content.

The comparative value of different phosphates, D. PRIANISHENIKOV (*Ann. Agron.*, 28 (1902), No. 7, pp. 356-367).—A translation of an article already noted (*E. S. R.*, 13, p. 934).

Phosphate discovery in New Zealand (*Amer. Fert.*, 17 (1902), No. 3, pp. 15, 16, figs. 5).

Bureau of fertilizers, R. E. ROSE ET AL. (*Florida Dept. Agr. Mo. Bul.*, 12 (1902), No. 77, pp. 11-24).—The results of fertilizer inspection during the season of 1901-2 are reported, with suggestions to purchasers, and notes on certain special fertilizing materials.

Report on official inspection of commercial fertilizers and agricultural chemicals during the season of 1901, C. A. GOESSMANN (*Massachusetts Sta. Rpt. 1901*, pp. 91-103).—This report includes a comparison of the quality of the fertilizers examined during 1900 and 1901, the trade values of fertilizing materials during the same years with an explanation of the use of these data in calculating the approximate value of a fertilizer, a table showing the average composition of fertilizers examined during 1901, and a list of brands of fertilizers licensed for sale under the provisions of the State law during the year.

Compilation of analyses of agricultural chemicals, refuse salts, ashes, lime compounds, refuse substances, guanos, phosphates, and animal excrements, H. D. HASKINS (*Massachusetts Sta. Rpt. 1901*, pp. 108-131).—This compilation includes the maxima, minima, and averages of all analyses made at the Massachusetts Agricultural College and Experiment Station during the period from 1868 to 1901. The data are given in percentages and pounds per ton.

Inspection of fertilizers in 1901, F. W. MORSE (*New Hampshire Sta. Bul.* 88, pp. 11).—Analyses of 106 samples of fertilizers collected under the supervision of the secretary of the State board of agriculture are reported, together with analyses of wood ashes and miscellaneous fertilizing materials, including fish scrap, glue "stick," ground bone, tankage, and nitrate of potash.

Analysis of commercial fertilizers (*South Carolina Sta. Bul.* 70, pp. 24).—This bulletin reports analyses and valuations of 186 samples of fertilizers collected during the season of 1901-2, accompanied by notes on the nature and sources of phosphoric acid, nitrogen, and potash used in fertilizers and on valuation, and the laws and regulations governing the sale of commercial fertilizers in the State.

Fertilizers, F. T. SHUTT (*Canada Expt. Farms Rpts. 1901*, pp. 152-160).—Analyses are reported of miscellaneous materials, including muck, mud, marl, limestone, Thomas slag, wood ashes, tannery waste, and seaweeds (rockweed and eelgrass).

FIELD CROPS.

Field experiments with farm crops, W. SAUNDERS, W. T. MACOUN, F. T. SHUTT, J. H. GRIDDALE, R. ROBERTSON, W. S. BLAIR, S. A. BEDFORD, A. MACKAY, and T. A. SHARPE (*Canada Expt. Farms Rpts. 1901*, pp. 7-58, 113-120, 125-127, 167-183, 298-311, 337-356, 391, 392, 395-421, 457-482, 516-533).—This is the annual report for 1901 of the Central Experimental Farm for Canada and Ottawa and the branch farms for the Maritime Provinces, Manitoba, the Northwest Territories, and British Columbia. The results of variety tests with the different crops in 1901, excepting winter wheat, have been noted from a previous bulletin (*E. S. R.*, 13, p. 838).

Wheat.—Of 22 varieties of winter wheat tested at Ottawa, Gold Coin, Dawson Golden Chaff, Early Red Clawson, Reliable, and Jones Winter Fife headed the list.

Spring wheat at the Manitoba farm yielded best when sown at the rate of 6 pks. per acre. At Ottawa the best yield was from seeding 2 to 2½ bu. per acre on sandy loam and 1 to 1½ bu. on clay loam. Mixtures of wheat and flax and wheat and rape were grown in Manitoba. A mixture of 7 pks. of wheat and 1 pk. of flax per acre yielded 21 bu. and 20 lbs., as compared with a yield of 28 bu. and 40 lbs. per acre where 7 pks. of wheat were sown alone. A mixture of 7 pks. of wheat and 2 lbs. of rape per acre produced 25 bu. and 40 lbs., while the wheat sown without the rape gave a yield of 28 bu. and 40 lbs. The yields of wheat on summer fallow and

unplowed stubble land were practically the same. In a fertilizer test the best results were obtained from an application of 200 lbs. of nitrate of soda per acre, one-half being applied when the grain was 2 in. high and the rest when it was 6 in. high. The results from selected and unselected seed varied greatly among the different varieties, but on an average the unselected seed produced 9 lbs. more per acre than the selected seed.

At the Northwest Territories farm Preston produced the largest yield. Here a comparative test of selected (hand-picked), well-cleaned, and small seed resulted in favor of the well-cleaned seed. In a fertilizer test the best yields were obtained from 200 lbs. of muriate of potash per acre on 1 plat and the use of 200 lbs. of superphosphate, 100 lbs. of muriate of potash, and 100 lbs. of nitrate of soda on another. Both plats yielded at the rate of 65 bu. and 20 lbs. per acre. The results from different methods of soil preparation showed that wheat grown in a rotation test produced the heaviest yield.

At the British Columbia farm sowing $2\frac{1}{2}$ and 3 bu. of seed per acre produced the most grain, but it was found that thick sowing weakened the straw and shortened the heads. In this experiment the grain on the thickly sown plats lodged.

Oats.—In a field test of a number of varieties on the Manitoba and Northwest Territories farms Abundance headed the list in yield. At the latter place selected, well-cleaned, and small seed yielded 130 bu. and 20 lbs., 122 bu. and 12 lbs., and 120 bu. and 20 lbs. per acre, respectively. In general, better yields were obtained on fallow than on prairie sod turned back with the plow. In the fertilizer test at the British Columbia farm an application of 200 lbs. of superphosphate and 100 lbs. each of muriate of potash and nitrate of soda per acre produced the heaviest yield. The use of 3 bu. of seed per acre proved most economical. At Ottawa sowing at the rate of 2 to 3 bu. per acre gave the largest crops on either sandy or clay loam soils.

Barley.—The yield from selected seed on the Manitoba farm was 1 bu. and 32 lbs. per acre more than the yield from unselected seed. The variety Beaver stood first, with a yield of 55 bu. and 15 lbs. per acre. In British Columbia the results from using different quantities of seed were in favor of sowing 3 bu. per acre. At Ottawa $2\frac{1}{2}$ to $3\frac{1}{2}$ bu. of seed per acre gave the best yields on either sandy or clay loam soils.

Peas.—At the Manitoba farm a mixture of 2 bu. of peas and 2 pks. of oats per acre yielded 57 bu. and 20 lbs., as compared with 46 bu. and 20 lbs. from a mixture of 2 bu. of peas and 1 pk. of oats. In sowing peas alone 2 and $2\frac{1}{2}$ bu. of seed per acre gave a yield of 33 bu. and 40 lbs., and 3 bu. of seed a yield of 32 bu. and 20 lbs. At the British Columbia farm yields ranging from 90 bu. and 40 lbs. to 106 bu. and 20 lbs. per acre were obtained on soil which had received 200 lbs. of nitrate of soda the year before.

Corn.—The results of an experiment in drilling corn in rows 21, 28, 35, and 42 in. apart in the Maritime Provinces were in favor of the 28-in. rows, while in Manitoba, the Northwest Territories, and British Columbia the 21-in. rows gave the heaviest average crops. Special fertilizer experiments in Maritime Provinces resulted in the best returns from 20 tons of green manure, the yield being $22\frac{1}{2}$ tons per acre, and the next best from applications of 30 tons of manure, and of 15 tons of manure with 250 lbs. of commercial fertilizers, the yield being $18\frac{1}{2}$ tons per acre in each case.

Roots.—At Ottawa turnips, mangels, carrots, and sugar beets were sown on May 8 and 22 and harvested on October 14 and 28. For turnips and mangels the advantage was with the earlier sowing and the later harvesting. The results obtained with carrots and sugar beets show that early sowing increased the crop, but the late harvesting gave a smaller yield than the early harvesting. In the Maritime Provinces 15 tons of manure and 250 lbs. of commercial fertilizers per acre gave the best yield. Manure was much more effective on the root crops than commercial fertilizers.

Analyses of sugar beets from the Northwest Territories, Manitoba, and Prince Edward Island are reported, samples from the Northwest Territories indicating an excellent quality.

Potatoes.—At Ottawa the best average results were obtained by planting the sets 14 in. apart in the row, as compared with 10, 16, and 18 in., the average results at 12 in. being nearly as good. Planting 1 in. deep gave the best results, but a depth of 4 in. is recommended to prevent the sets being disturbed by cultivation. Planting on May 30 gave better yields for both early and late varieties than later planting, and the average yields for 4 successive years are also in favor of planting the latter part of May. Spraying with Bordeaux mixture for the prevention of blight and rot proved profitable. Special experiments with fertilizers in the Maritime Provinces showed that manure increased the yield of potatoes to a larger extent than other fertilizers. A test of 8 early varieties is also reported from this farm.

Millet.—At Ottawa Cat-tail, Pearl, White Round Extra French, and Moha Hungarian, in the order named, produced the heaviest crops among 9 varieties, the yields of hay ranging from 5 tons and 240 lbs. to 8 tons and 1,280 lbs. per acre. On the Manitoba farm Japanese millet yielded 3 tons and 1,400 lbs. and Common 2 tons and 1,760 lbs. of hay per acre; and in the Northwest Territories Italian, Cat-tail, Hungarian, and Japanese gave better yields than White Round Extra French, German, or Pearl.

Soy beans—Horse beans.—These crops at Ottawa produced the best yield in the 28-in. rows, while in the Northwest Territories the yield of soy beans was in favor of the 21-in. rows, and of horse beans the 35-in. rows.

Tobacco.—Plat tests of 46 varieties were made at Ottawa. Of 6 varieties grown on large areas, Connecticut Seed Leaf gave the largest yield, 2,192 lbs. of dry leaves per acre.

Buckwheat.—Of 5 varieties tested in the Maritime Provinces, Silver Hull yielded the most grain and straw, and in a field test produced 84 bu. on 5 acres. At the Manitoba farm volunteer crops of Japanese, Silver Hull, and Gray produced over 28, 32, and 35 bu. per acre, respectively.

Flax.—Growing flax and wheat in a mixture has been mentioned above under wheat. Sowing 40 lbs. of flax per acre in Manitoba gave the best total yield, as compared with sowing 30 or 20 lbs. per acre. In the Northwest Territories flax was sown at the rate of 40 and 80 lbs. per acre on May 15, 22, and 29. For the earliest date the yield of seed was in favor of the lighter seeding, but for the other dates the yield was in favor of the heavier seeding. The difference in yield varied from 1 bu. and 26 lbs. to 2 bu. per acre. White flax was tested, but the straw did not grow over 6 in. high, and very little seed formed, although the season was very favorable for ordinary flax.

Spelt.—This grain was compared with wheat, oats, and barley in Manitoba, the yield of grain being largely in its favor. The heaviest crop was obtained from drilling at the rate of $1\frac{1}{2}$ bu. per acre, the yield being 46 bu. Summer fallow produced a larger crop of spelt than unplowed stubble land. In the Northwest Territories a yield of 58 bu. and 20 lbs. per acre was obtained.

Sunflowers.—One and one-half tons of heads per acre were obtained from Mammoth Russian sunflowers at the Manitoba farm, while in the Northwest Territories this variety sown May 22 was frozen September 17 and did not mature.

Rape.—The results of growing rape and wheat in a mixture have been given above under wheat. In the Northwest Territories Dwarf Essex, Broad Leaved, and Dwarf Victoria yielded over 41, 41, and 31 tons per acre, respectively. In British Columbia Dwarf Essex was a failure.

Miscellaneous.—A number of experiments in addition to those already mentioned are reported by the Central farm. In a test with mixed roots and mixed roots and vegetables the largest yield was obtained from a mixture of mangels, carrots, and turnips, and the smallest yield from a mixture of carrots, cabbages, and tomatoes. A report on the influence of previous crops on growing grain shows that oats and barley gave the best yield after horse beans, as compared with flax, grain, and soy beans. Clover as

a green manure for oats increased the yield of grain nearly 10 per cent and the yield of straw over 35 per cent. In the case of corn the clover plats gave an increase of 40 per cent in yield of green fodder, and with potatoes the increase in yield was more than 8 per cent. Among different applications of fertilizers, 400 lbs. of Thomas slag per acre was most effective on clover and also produced the largest yield of hay from awnless brome grass. Special fertilizer experiments have been in progress at Ottawa for 12 years with 21 different applications, including barnyard manure and commercial fertilizers. The crops grown in this connection are wheat, oats, barley, corn, mangels, and turnips. The results for the season and the average results for the entire period are shown in tables. It was found in these experiments that fresh barnyard manure has an equal crop-producing power to rotted manure. It has been shown that fresh manure loses about 60 per cent of its weight while rotting. These experiments further indicate that untreated mineral phosphate and sulphate of iron are of no value as fertilizers. Common salt proved a valuable fertilizer for barley, but was much less effective when applied to spring wheat and oats. Gypsum was of some value as a fertilizer for barley but of very little service for wheat or oats.

The yields of clover and alfalfa from 2 and 4 cuttings were compared, and the composition of the different cuttings determined. Four cuttings of clover produced 258 lbs. of dry matter or 104 lbs. of crude protein more per acre than 2 cuttings. The difference in weight of crop per acre was 2,065 lbs. In the case of alfalfa 4 cuttings produced 61 lbs. more of crude protein per acre than 2 cuttings, but the weight of dry matter per acre was in favor of 2 cuttings by 48 lbs. The difference in weight of crop per acre was 1,210 lbs. in favor of 4 cuttings.

Analyses of clover, clover silage, corn, and corn silage are given, the silage being taken from different parts of the silo. The results with clover "point to a greater degree of fermentation and consequently greater loss of feeding elements in the center than at the bottom of the silo. Weight for weight, this silage is not of an equal feeding value with clover."

In rotation experiments in Manitoba now in progress for 3 years, it was found that annual leguminous crops were a more effective green manure than red clover.

The itemized cost of growing oats, barley, peas, clover hay, corn, mangels, turnips, carrots, sugar beets, rape, and pumpkins, and of making clover silage is reported.

Cooperative experiments in agriculture (*Ontario Agr. and Expt. Union Rpt. 1901, pp. 9-24*).—This report on the cooperative experimental work of the Agricultural and Experimental Union of Ontario was presented at the twenty-third annual meeting of the organization. The results with grain, root, and forage crops for 1901 are shown in brief tabular statements, and the results for several years for each particular crop are briefly considered. In addition to the report a discussion on the work of the members is given. The varieties giving the best yields in 1901 were Siberian oats, Manshury barley, Black Hulless barley, Goose wheat, Japanese buckwheat, Early Britain peas, Early Yellow soy bean, North Star Yellow Dent corn, and Dawson Golden Chaff winter wheat.

Report of the agriculturists, W. P. BROOKS and H. M. THOMSON (*Massachusetts Sta. Rpt. 1901, pp. 11-56*).—This report presents the results for 1901 of fertilizer, soil, and variety tests, with different field and garden crops, in progress for a series of years. (E. S. R., 13, p. 332).

In the comparison of barnyard manure, nitrate of soda, dried blood, and sulphate of ammonia as sources of nitrogen, soy beans were grown in 1901, the yields obtained ranking the different fertilizers in the order mentioned. The average results since 1890, with a variety of crops, place them in the following order: Nitrate of soda, barnyard manure, sulphate of ammonia, and dried blood.

Common red clover, Mammoth red clover, alsike clover, and cabbage were grown this season in the muriate and high-grade sulphate of potash tests. The best yields of hay were with the sulphate, and the average results for several years also favor

the use of this form for clovers. The difference in its favor appeared to be greater in proportion as the rainfall was abundant. The yield of cabbage was 33,680 lbs. per acre on the muriate plats and 30,600 lbs. on the sulphate plats.

The results with garden crops were similar to the average results of previous years. Regarding the effectiveness of nitrate of soda as 100 per cent, dried blood and sulphate of ammonia stood at 92.7 and 54.8 per cent, respectively, for the early crops (including onions, lettuce, beets, peas, and strawberries), and at 98.7 and 77.5 per cent, respectively, for the late crops (including cabbage, turnips, and celery). A comparison of muriate and sulphate of potash for these crops was in favor of the sulphate for the early and the muriate for the late crops.

The different phosphates applied on the basis of equal cost ranked in relative value as follows: Phosphatic slag, South Carolina rock, Mona guano, dissolved boneblack, Florida rock phosphate. Oats were grown in connection with this test in 1901.

In the test of different phosphates used on the basis of equal quantities of "actual" phosphoric acid, continued for several years, the results in 1901 with onions showed them to rank in the following order: Raw bone, phosphatic slag, South Carolina rock, apatite, dissolved bone meal, dissolved boneblack, Tennessee phosphate, acid phosphate, steamed bone meal, Florida phosphate. The results confirmed the conclusions of the previous year.

Different potash salts were compared as fertilizers for wheat and corn, but the results were inconclusive. The authors call attention to the proportionately large yields obtained from the use of muriate and nitrate of potash. Good yields were obtained from the use of carbonate and silicate of potash, which is considered as indicating a high grade of availability for these forms.

The aggregate yields per acre of the varieties of silage corn grown in the test with potash salts were as follows: Eureka, 47,960 lbs.; Boston Market, 38,200 lbs.; Leaming Field, 34,520 lbs., and Rural Thoroughbred, 36,150 lbs. The characters of the different varieties are briefly noted. In actual food value ensilage from Leaming Field was superior. The disadvantages of growing excessively late varieties of ensilage corn are enumerated.

Soil tests were continued this year with grass and onions. In the tests with grass nitrate of soda alone gave a considerable increase in crop, but much the best yield was obtained where it was applied with potash and dissolved boneblack. The results also show a close dependence of clover upon a liberal supply of potash, and establish the possibility of growing profitable hay crops with the use of fertilizers only. It is further concluded that for grass mixtures containing clover a combination of potash and an available phosphate is a profitable application. The results of the tests with onions were exactly similar in kind to those of the previous year, but the yield on the limed soil showed a falling off. The need of lime was shown where muriate of potash and nitrate of soda were applied and where muriate of potash was used alone. Dissolved boneblack contains a considerable proportion of land plaster, and where this substance was used the need of lime was not so apparent. As in the previous year, the use of dissolved boneblack greatly promoted the perfect ripening of the crop, and the use of either this or acid phosphate is recommended for soils on which onions failed to ripen properly. Potash in combination with lime gave a much better crop than either of the other fertilizers alone under similar conditions.

Experiments have been in progress since 1890 to illustrate the relative value of applying manure alone and with potash. Where manure alone was used, 6 cords per acre were applied, and where used in conjunction with potash, the application consisted of 4 cords of manure and 160 lbs. of potash per acre. This season these applications produced corn crops practically equal in value, while the hay crops were slightly larger on the manured plats, but the increase, as compared with the manure and potash plat, was produced at a cost greater than its value. The plats on which

a special corn fertilizer is compared with an application richer in potash were in grass during the last season. Considering the results obtained up to date, "it is anticipated that the superiority of the mixture of fertilizers containing the larger quantity of potash will become more evident from year to year."

The experiment in manuring grass lands in rotation with wood ashes, ground bone and muriate of potash, and barnyard manure was continued upon the same basis as in the previous year. The yields for the season ranged from about $3\frac{1}{4}$ to $3\frac{3}{4}$ tons of hay per acre. These yields, as well as the average yields for the entire series of years, were decidedly profitable.

An application of 150 lbs. of nitrate of soda per acre on Kentucky blue grass and timothy sod increased the yield of rowen 571 and 259 lbs. per acre, respectively. The cost of increase was $\frac{1}{2}$ ct. per pound for the Kentucky blue grass and $1\frac{1}{2}$ cts. per pound for the timothy. These results showed a profit only in the case of the Kentucky blue grass.

The experiment in hauling barnyard manure and spreading it in autumn or winter, and in hauling it at that time into large piles to be scattered immediately before plowing in the spring was continued, and the results indicated that on lands sloping moderately, the spring application is preferable.

Culture tests with alfalfa are reported. The yields were small and the authors believe its success doubtful on the average soils of the State.

Mand Wonder forage crop and Brazilian millet appeared identical in every way with Pearl millet.

Stock ranges of northwestern California, J. B. DAVY (*U. S. Dept. Agr., Bureau of Plant Industry Bul. 12, pp. 81, pls. 8, figs. 4, maps 3*).—This bulletin contains an account of northwestern California, its physiography and climate, and especially its forage conditions. For the purpose of discussion the region is divided into the interior plateau region, the coast bluff belt, and the redwood belt, and each division is treated separately.

Brief discussions are given on the temperature, water supply, soils, and agricultural products of the interior plateau region, including the mountain valleys and upland ranges, the open summer or annual ranges, the prairies, the woodland or winter range, the chaparral, and subalpine meadows. The forage plants occurring under these different conditions are enumerated and their value noted. The prevalent weeds occurring throughout the region are also discussed. About 50 years ago, when the Sherwood Valley was first settled, *Danthonia californica* was the favorite, most nutritious, and most abundant forage plant. At present it is scarce. *Bromus racemosus commutatus*, *B. hordeaceus glabrescens*, and *Holcus lanatus* have become naturalized and prevail in place of the former native plants. Other naturalized species, but less common than those mentioned, are soft chess (*Bromus hordeaceus*), silvery hair grass (*Aira caryophylla*), small barley grass (*Hordeum maritimum gussoneanum*), and rat-tail fescue (*Festuca myuros ciliata* and *F. myuros schiroides*). Broncho grass (*Bromus maximus gussoni*), which is occasionally found, is considered of no value and as being a troublesome weed. Redtop (*Agrostis alba*) and timothy (*Phleum pratense*), introduced as forage plants, have almost entirely disappeared from the wild meadows and pastures of the mountain valleys. The native grasses found in the meadows are tufted hair grass (*Deschampsia cespitosa*), slender hair grass (*D. elongata*), agrostis (*A. exarata microphylla*), meadow barley grass (*Hordeum nodosum*), danthonia (*Danthonia californica*), prairie June grass (*Koeleria cristata*), and California fescue (*Festuca californica*). Blue canary grass (*Phalaris amethystina*) is found along the edge of the redwood forests, and a species of *Pleuripogon*, *Panicularia fluitans*, and slough grass (*Beckmannia erucaeformis*) are found in the streams and swamps. Of the native clovers, *Trifolium dichotomum*, *T. microdon*, *T. barbigerum*, *T. bifidum decipiens*, *T. microcephalum*, *T. wormskjoldii*, *T. variegatum*, and *T. tridentatum* are quite common, while *T. depauperatum* and *T. longipes* occur only sparingly.

Bull clover (*T. wormskjoldii*), the most valuable among them as a forage plant, is also used as food by the Indians.

In the Sherwood Valley about 3 tons of hay per acre is considered an average yield, and it is estimated that about 50 head of cattle can usually be pastured for about 5 months on 100 acres of valley pasture. In the recommendations for the improvement of pasture and meadow the author mentions the following species as most likely to be successful: Orchard grass (*Dactylis glomerata*), reed fescue (*Festuca arundinacea*), many-flowered millet grass (*Oryzopsis miliacea*), tall oat grass (*Arrhenatherum elatius*), awnless brome grass (*Bromus inermis*), red fescue (*Festuca rubra*), rescue grass (*Bromus willdenowii*), timothy (*Phleum pratense*), meadow foxtail (*Alopecurus pratensis*), creeping bent or florin (*Agrostis alba stolonifera*), Italian ray grass (*Lolium italicum*), red clover (*Trifolium pratense*), perennial white clover (*T. repens*), and alsike clover (*T. hybridum*).

On the open summer or annual ranges which occupy the slopes and summits of the plateau ridges and mountains, rat-tail fescue, small barley grass, and soft chess were found prevalent. In addition to these grasses alfalfa and wild clovers chiefly compose the range feed. The only perennial grasses found on dry open hillsides were Lemmon bunch grass (*Stipa lemmoni*), California melic grass (*Melica californica*), a variety of red fescue (*Festuca rubra*), a variety of sheep fescue (*F. ovina*), danthonia (*Danthonia californica*), *Sitanion villosum*, *Elymus angustifolius*, and one or two species of Poa. In describing the woodland or winter range the prevalent trees, underbrush, and herbaceous plants are enumerated, and orchard grass, tall oat grass, wood meadow grass (*Poa nemoralis*), and reed fescue (*Festuca arundinacea*) are recommended for trial. In the chaparral or low thickets covering dry, stony ground *Melica californica*, *M. harfordii*, *Stipa lemmoni*, *Sitanion multisetum*, *S. planifolium*, *Elymus glaucus*, *Bromus carinatus*, and species of Poa and Festuca are the most common. The forage plants other than grasses occurring in these places are *Lotus americanus* and *Ceanothus integrifolius*. Judging from the plants growing in protected places the author concludes that the primitive forage plants were the bunch grasses comprising Danthonias, Stipas, Melicas, Poas, and perennial Festucas, with annual and perennial clovers, wild pea vines, and wild sunflowers.

The discussion of the coast bluff belt treats of the mesa lands, white-ash prairies, bottom lands, and sand dunes separately, and mentions the most important species of plants represented in the flora of each region. The subject of sand-binding plants is discussed at some length.

In the redwood belt the grasses are reported as scarce and the few common species are *Bromus laevipes*, *Melica bromoides*, *Savastana macrophylla*, *Trisetum canescens*, and *Deschampsia elongata*.

In addition to notes on poisonous plants and fungus parasites, the following fodder crops cultivated in northwestern California are described: Beach grass (*Ammophila arenaria*), bur clover (*Medicago denticulata*), black medic (*M. lupulina*), blue grama (*Bouteloua oligostachya*), buffalo grass (*Bulbils dactyloides*), California lotus or Dakota vetch (*Lotus americanus* or *Hosackia purshiana*), creeping bent (*Agrostis alba stolonifera*), diss (*Ampelodesmos tenax*), field peas (*Pisum arvense*), hard fescue (*Festuca duriuscula*), Johnson grass (*Andropogon sorghum halepensis*), hairy vetch (*Vicia villosa*), knot grass (*Paspalum distichum*), meadow foxtail (*Alopecurus pratensis*), orchard grass (*Dactylis glomerata*), ray grass (*Lolium* spp.), Italian ray grass (*L. italicum*), English perennial ray grass (*L. perenne*), Australian ray grass (*L. perenne tenue*), many-flowered ray grass (*L. multiflorum*), red clover (*Trifolium pratense*), red fescue (*Festuca rubra*), redtop (*Agrostis alba*), reed fescue (*Festuca arundinacea*), sheep fescue (*F. ovina*), awnless brome grass (*Bromus inermis*), tall oat grass (*Arrhenatherum elatius*), timothy (*Phleum pratense*), vetch (*Vicia sativa*), and white clover (*Trifolium repens*).

Forage conditions on the northern border of the Great Basin, D. GRIFFITHS

(U. S. Dept. Agr., Bureau of Plant Industry Bul. 15, pp. 60, pls. 16, map 1).—This bulletin is a report upon investigations made in 1901 in the region between Winnemucca, Nev., and Ontario, Oreg. A description of the region is given and the precipitation for 1900 and 1901 recorded. The soils of the section are briefly discussed and 50 soil samples taken at different places are described. Partial analyses of these soil samples furnished by the Bureau of Soils of this Department are tabulated.

Grease wood (*Sarcobatus vermiculatus*) and alkali saccaton (*Sporobolus airoides*) were found growing on soils containing 4 and $4\frac{1}{2}$ per cent of soluble white alkali, and salt grass (*Distichlis spicata*) on soils with 3 per cent of soluble black alkali. Utah saltbush (*Atriplex truncata*), small cord grass (*Spartina gracilis*), alkali grass (*Puccinellia airoides*), and prairie bulrush (*Scirpus campestris*) grew on land containing from 0.50 to 0.70 per cent of black alkali. The growth of black sage (*Artemisia tridentata*) is considered an indication of good soil.

The method of handling stock on the ranges of that region and the condition of the ranges are discussed at some length. The species of grasses considered as furnishing the largest quantity of feed are Buckley blue grass (*Poa buckleyiana*), Wheeler blue grass (*P. wheeleri*), and bunch wheat grass (*Agropyron spicatum*). Black sage, grease wood, spiny saltbush (*Atriplex confertifolia*), and hop sage (*Grayia spinosa*) are not eaten enough by stock to be injured by overstocking, but red sage (*Kochia americana*), bud sage (*Artemisia spinescens*), and white sage (*Eurotia lanata*) suffer considerably from this cause. It was noticed how overstocking injures the open grassy areas by exposing the roots of the grasses to the sun and by facilitating the loss of moisture from the unprotected soil. Several areas of pure sheep fescue (*Festuca orina*) from 3 to 60 acres in extent were found completely ruined, and the author concludes from his observations that the process of recuperation will be exceedingly slow. It was observed that cinquefoil (*Dasiphora fruticosa*), willows, poplar (*Populus tremuloides*), wild choke cherry (*Prunus emarginatus*), and Indian currant (*Symphoricarpos oreophilus*) furnish an important part of the forage supply.

The hay crops of the region are discussed and the methods of handling hay on a large scale are described. The grasses considered the best native hay crops of the region are wild wheat or blue stem (*Elymus triticoides*) and bunch blue grass (*Poa laxigata*). The following forage plants were common on some of the hay land areas: Sedges (*Carex lanuginosa*, *C. douglasii*, and *C. nebraskensis*), salt grass (*Distichlis spicata*), redbud (*Agrostis alba*), alkali saccaton (*Sporobolus airoides*), squirrel tail (*Hordeum jubatum*), wild barley (*Hordeum nodosum*), orchard barley (*Sitanion longifolium*), wild wheat (*Elymus triticoides*), giant rye grass (*E. condensatus*), slender wheat grass (*Agropyron tenerum*), bunch blue grass (*Poa laxigata*), steel grass (*Sporobolus depauperatus*), slough grass (*Beckmannia erucaformis*), beard grass (*Polypogon monspeliensis*), creeping spike-rush (*Eleocharis palustris*), rush (*Juncus balticus*), prairie bulrush (*Scirpus campestris*), tule (*S. lacustris*), clover (*Trifolium involueratum*), seaside arrow grass (*Triglochin maritima*), and cat-tail (*Typha latifolia*). The successful introduction of redbud and timothy into the region is reported. *Psoralea purshii*, *Dalea kingii*, *Tetradymia comosa*, and moss are briefly considered for their value as sand-binding plants.

Lists of the more common weeds and the more important native forage plants, together with brief descriptions of their habits and distribution, are given. The poisoning of stock due to eating larkspur and wild parsnip is also noted.

Experiments in range improvement in central Texas, H. L. BENTLEY (U. S. Dept. Agr., Bureau of Plant Industry Bul. 13, pp. 72, pls. 2, figs. 6).—The work and results of experimental range improvement in central Texas, carried on for 3 successive years, are reported at some length. The history of each year's work is reviewed separately. The experiments were conducted on a section of land divided into a number of portions, each portion receiving a different treatment. Plat tests with grasses and forage crops were made in a grass garden in connection with this work.

From the first year's work it was concluded that cultivating pastures with disk and iron-tooth harrows, especially in the semiarid regions of the State, was profitable, and that pastures in that region should be rested during the seasons when the grass seeds mature and fall to the ground. These conclusions were confirmed by later results.

The outcome of the second year's work demonstrated the availability of alfalfa, sulla, sainfoin, vetches, several varieties of cowpeas, velvet bean, soy bean, teosinte, and several varieties of sorghum for annual or temporary pastures and for hay purposes. The results further showed that the seeds of grama and mesquite grasses and of wild timothy, cotton top, Canadian rye, and everlasting grass can be utilized to good advantage for permanent pasture purposes. In addition to the above results it was also definitely shown that the ranges may be improved by judicious resting of the pastures, cultivating the sod, and sowing the seeds of hardy native and improved grasses.

During the third year from 80 to 85 head of mixed cattle were pastured on the land. This was about one head to every $7\frac{1}{2}$ acres, as compared with a capacity as estimated by experts of one head to every 16 acres at the time the experiments were begun. All the pastures were not grazed at the same time, as each portion of the pasture land was given periods of rest in regular succession. During these resting periods the different pastures carried double the number of stock recommended. "As one result of this systematic resting, the grasses in each pasture were, to a greater or less extent, permitted to mature seeds, which, falling to the ground, increased the number of grass roots and in that way added materially to the capacity of the range for supporting stock."

The author believes that the sustaining capacity of the range can be increased in connection with pasturing stock provided the number of cattle is never too large and each part of the range is given its regular period of rest. "It was practicable April 1, 1901, to place as many as 100 head of mixed cattle on the 640 acres included in the grass and forage plant station near Abilene, and hold them thereon during the succeeding 12 months without giving them other feed than they could get for themselves. But that could not be done with the 640 acres thrown into one pasture and the 100 head of cattle allowed during the 12 months to range at will over the entire pasture."

The cost of the range improvement work did not average 25 cents per acre per year. The author considers the outlay and the resulting increase in pasture capacity and shows the profitableness of the work.

As a result of experimental work a list of grasses and forage plants well adapted, to the climatic and soil conditions of central Texas is given. Each species is briefly described and its behavior in culture tests at the station grass garden and elsewhere in that region is reported. The list includes the following: *Grasses*—barnyard grass (*Panicum crus-galli*), Bermuda grass (*Cynodon dactylon*), buffalo grass (*Bulbils dactyloides*), bushy blue stem (*Andropogon nutans*), Colorado grass (*Panicum texanum*), cotton top grass (*P. lachnanthum*), crab grass (*P. sanguinale*), curly mesquite (*Hilaria cenchroides*), everlasting grass (*Eriochloa punctata*), grama grass (*Tripsacum dactyloides*), black grama (*Hilaria mutica*), blue grama (*Bouteloua oligostachya*), side oats grama (*B. curtipendula*), Johnson grass (*Andropogon halepensis*), knot grass (*Paspalum distichum*), little blue stem (*Andropogon scoparius* and *A. torreyanus*), the millets, needle grass (*Aristida fasciculata*), rescue grass (*Bromus unioloides*), smooth brome grass, (*Bromus inermis*), the sorghums, Texas blue grass (*Poa arachnifera*), white top grasses (*Triodia albenscens*), wild rye (*Elymus canadensis*), wild timothy (*Muhlenbergia racemosa*), teosinte (*Euchlaena luxurians*), and common oats and wheat; *legumes*—alfalfa or lucern (*Medicago sativa*), Turkestan alfalfa (*M. sativa turkestanica*), oasis alfalfa, Florida beggarweed (*Desmodium tortuosum*), alsike clover (*Trifolium hybridum*), bur clover (*Medicago maculata*, *M. denticulata*), mammoth clover (*Trifolium medium*), red

clover (*T. pratense*), Russian red clover (*T. pratense pallida*), sweet clover (*Melilotus alba*), white clover (*Trifolium repens*), cowpea (*Vigna catjang*), field pea, gram or chick pea (*Cicer arietinum*), Metcalf bean (*Phaseolus retusus*), soy bean (*Glycine hispida*), sulla (*Hedysarum coronarium*), velvet bean (*Mucuna utilis*), spring vetch (*Vicia sativa*), hairy vetch (*V. villosa*), sainfoin (*Onobrychis sativa*), and peanuts (*Arachis hypogaea*).

Rape, saltbushes, sweet potatoes, and fallow weed are reported as having given more or less satisfactory results.

Grasses and leguminous crops for the Arkansas Valley, H. H. GRIFFIN (*Colorado Sta. Bul. 68, pp. 1-11*).—Brief notes are given, with cultural directions, on a number of grasses and leguminous crops adapted to the Arkansas Valley. The plants discussed are orchard grass, tall meadow fescue, tall meadow oat grass, Kentucky blue grass, redtop, timothy, serradella, red clover, cowpea, field pea, soy bean, and hairy vetch. Notes on when to sow grass seed and on fall seeding of alfalfa are also given.

Grass seeding on irrigated land, W. JONES (*Amer. Agr. (mid. ed.), 69 (1902), No. 3, p. 82*).—A brief note on methods of sowing alfalfa, timothy, redtop, and broom grass seed on irrigated lands in Wyoming.

Awnless brome grass, J. FLETCHER (*Canada Expt. Farms Rpts. 1901, pp. 261, 262*).—The value of the awnless brome grass (*Bromus inermis*) for the more or less arid regions of the Northwest is shown, and the results of an experiment with this grass in the Calgary district are given. In this experiment 8 acres were seeded with this grass in 1897, and in 1900 the hay and seed sold from this area amounted to \$413.50.

Notes on summer forage crops, J. B. LINDSEY (*Massachusetts Sta. Rpt. 1901, pp. 169, 170*).—Brief notes are given on wheat and winter vetch, corn and cowpeas, and barnyard millet as forage crops. Earlier observations along this line were published in Bulletin 72 of the station (E. S. R., 13, p. 176).

The improvement of cereals during the last ten years, N. H. NILSSON (*K. Landt. Akad. Handl. Tidskr., 40 (1901), No. 3, pp. 149-162*).—A historical sketch of methods of seed improvement of cereals, with special reference to the work done in this line by the author at the Svalöf Seed Improvement Station at Svalöf, Sweden (E. S. R., 13, p. 814). Since 1892 the author has followed pedigree culture, i. e., selection for propagation of individual parent plants possessing especially desirable characteristics. Each year the finest and most typically and harmonically developed plant is selected from the pedigree plat for the mother plant to be grown the following year. The seed of the other plants in the pedigree plats is sown in the so-called control plats, where the variety is examined qualitatively and its cultural value determined in a preliminary manner. If the variety proves promising, it is grown in such quantities as to permit of careful comparative tests on a large scale, and if these also give good results, it is handed over to a private company for a more extended culture and its consequent disposal to farmers. In these culture tests the variety is watched closely, so that only fixed and really superior varieties are sent out. In the years that have passed since this method of seed improvement was adopted by the Svalöf station the following 17 new varieties of cereals and legumes have been bred by the station and given to the seed trade: Svalöf Top Squarehead wheat, Svalöf Grenadier wheat, Svalöf Princess barley, Svalöf Swan Neck barley, Svalöf Extra Squarehead wheat, Svalöf Black Bell oats, Svalöf Black Grand Mogul oats, Svalöf Whiting oats, Svalöf Improved Sweet vetch, Svalöf Improved Gray vetch, Svalöf White Round vetch, Svalöf Spring Pearl wheat, Svalöf "Gute" barley, Svalöf Giant Six-rowed barley, Svalöf Hannchen barley, Svalöf "Ris" wheat, and Svalöf "Bore" wheat. These are all fixed and characteristic varieties, and several of them have found general distribution among Swedish farmers and have proved as valuable as expected. In addition, several hundred new varieties bred at Svalöf are still under trial, and many of them are very promising.

The author maintains that the older, so-called methodical system of plant breeding has not and can not accomplish what has been expected of it. Selection in groups, no matter if regulated by the most exact methods, can but rarely lead to fixed characteristics, i. e., to true improvement, and never to well-characterized, wholly new varieties. The breeding of agricultural plants must be built on nature's own laws of heredity and variation, which, among other things, point to the single living plant individual as the only true unit with which we have to reckon and to work. The work of plant breeding must be planned in a scientific manner and be founded on purely botanical characteristics, which, on the one hand, constitute the most certain guides to the detection of essential and hereditary qualities in the mother plants, and, on the other hand, endow the new varieties thus bred with the dignity of independent botanical species, raised above a modifying influence of changing conditions of climate and soil. Special, well-equipped, scientific, and practical institutions are required for the advancement of agricultural plant production, which, taking the existing crops of the country or of a geographical plant zone as a basis, must breed new, improved races adapted to the needs of the different regions and different requirements. The work of maintaining the standard of these varieties by means of systematic selection falls to the farmer and the seedsman.—F. W. WOLL.

Types of green and yellow rye and dark and light colored Squarehead wheat grown under field conditions, M. FISCHER (*Fühling's Landw. Ztg.*, 50 (1901), Nos. 19, pp. 684-692; 20, pp. 727-734; *abs. in Centbl. Agr. Chem.*, 31 (1902), No. 4, p. 258).—A difference in the development of the plants from green and yellow grains of rye was plainly shown, although the seed was of a common origin. The plants resulting from the yellow grains required, in addition to an application of nitrogenous fertilizers given in the fall, a heavier application of phosphoric acid than the plants grown from the green-colored seed. The special characteristic of the plants from the green grains was their greater hardness. In the test with breeding types of Squarehead wheat the dark-colored seed represented the hard and glassy grains, and the light-colored seed the soft and mealy wheat. The principal result from this test was that the plants from the light-colored grains showed the greatest hardness.

Alfalfa pasture in Argentina, B. W. SNOW (*Amer. Agr. (mid. ed.)*, 69 (1902), No. 3, p. 82).—A brief description of alfalfa pasture in Argentina, and a comparison of the results with pasturing on native grasses. It is stated that over 4 acres of natural pasture are required to sustain one animal, while less than 1 acre of alfalfa pasture produces the same result.

Breeding pure forms of Bohemian barley, J. NOLČ (*Deut. Landw. Presse*, 29 (1902), Nos. 28, pp. 239, 240, figs. 3; 29, p. 248, figs. 2).—This article is a detailed description of the method of originating new forms of barley as practiced in a commercial way.

Hungarian and Virginia dent corn varieties, L. KIESSLING (*Deut. Landw. Presse*, 29 (1902), No. 1, p. 4).—A comparison of these varieties shows that Hungarian dent corn is earlier than the Virginia, but not so productive.

A chemical study of the Sea Island cotton seed, F. S. SHIVER (*South Carolina Sta. Bul.* 68, pp. 90, fig. 1).—As distinguished from the Upland varieties the Sea Island cotton has a small black seed, which is almost entirely denuded of lint in the process of ginning. Two varieties of Sea Island cotton seed were studied extensively as to their composition with reference to fertilizing and food constituents, and the results compared with data for Upland and Egyptian seed. On an average the seed of the finest Sea Island cotton weighed 0.0971 gm. and that of the coarsest, 0.0966 gm. On an average the kernels constituted 59.58 per cent, and the hulls 40.42 per cent of the seed. Taking the average of three mills, the yield of oil was 42.6 gal. per ton, or 75.8 per cent of the total oil present. At 23.6° C. the refractive index of the oil examined was 1.4718, the saponification equivalent, 215. The average composition of the seed and its parts is given as follows:

Average composition (food constituents) of Sea Island cotton seed and its products.

	Water.	Protein.	Fat.	Nitrogen-free extract.	Crude fiber.	Ash.
	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>
Cotton seed.....	8.05	20.96	19.71	31.44	15.31	4.53
Cotton-seed kernels.....	6.47	34.00	34.65	^a 16.80	2.31	5.77

Insoluble matter.....	.037	.050	.051	.939	.14	.063

^a In air-dry material.

The difficulty of securing all of the phosphoric acid present in Sea Island seed by ordinary treatment with nitric and hydrochloric acids indicated the presence of some organic form of phosphorus, such as glycerol-phosphoric acid or lecithin. A number of determinations of the latter substance were made, showing 0.66 per cent in the seed and 0.94 in the meal, an amount too small to influence to any appreciable extent the determination of phosphoric acid. It is concluded that part of the latter is in the form of meta and pyro phosphoric acid, as shown by Hardin to be the case in upland cotton-seed meal (*E. S. R.*, 4, p. 901), and only a small part in the ortho form.

Hop culture in Belgium, L. BÉTHUNE (*Jour. Soc. Cent. Agr., Belg.*, 49 (1902), No. 4, pp. 147-167).—An article discussing the condition of the Belgian hop industry.

Potatoes grown under straw (*Amer. Agr. (mid. ed.)*, 69 (1902), No. 4, p. 124).—A brief note on how prize potatoes were grown by this method.

Report on ramie, E. DAZEY (*Bul. Agr. Algérie et Tunisie*, 8 (1903), No. 1, pp. 24-32).—This report treats of the culture of ramie in Algeria and its preparation for industrial purposes.

The rice industry of Louisiana and Texas, A. E. HEBERT (*Tradesman*, 46 (1902), No. 9 (23. annual), pp. 113-115, figs. 2).—A general account of the industry in these two States.

Pennsylvania sugar beets in 1901, W. FREAR and W. T. CARTER (*Pennsylvania Sta. Bul.* 59, pp. 8).—The composition of 31 samples of sugar beets grown in Elk County in 1901 and the yields per acre from 22 plats are reported. The average percentage of sugar in the cleaned and decrownd beets was 16 per cent and the average coefficient of purity 83.8 per cent. The average yield of topped beets on 22 plats was at the rate of 13.52 tons per acre. The weather conditions were less favorable than

usual to the yield of beets, but favored a high sugar content. The manner of conducting the test and the conditions connected with it are described.

The sugar-beet industry, H. W. WILEY (*Ontario Agr. and Expt. Union Rpt. 1901*, pp. 33-42, figs. 2).—A paper on the sugar-beet industry, presented at the twenty-third annual meeting of the Ontario Agricultural and Experimental Union. A discussion of the paper is also given.

The influence of nitrogen, potash, and phosphoric acid on the sugar beet, (*Bul. Assoc. Chim. Sucr. et Distill.*, 19 (1902), No. 9, p. 1130).—A summary is given of the results of experiments by Wilfarth, which lead to the conclusion that sugar beets require a complete fertilizer and that manuring with nitrogenous fertilizers alone does not give the good results generally attributed to them in practice.

Growing Sumatra tobacco under shade in the Connecticut Valley, M. WHITNEY (*U. S. Dept. Agr., Bureau of Soils Bul. 20*, pp. 31, pls. 7, figs. 2).—This bulletin contains a detailed statement of the growing of Sumatra tobacco under shade in the Connecticut Valley during the season of 1901. Preparation of the seed bed, selection of the land, erection and cost of the shade, and the cultivation and preparation of the crop are described, and suggestions as to the important points to be sought in the culture of wrapper leaf are given.

The area covered in this work aggregated 41 acres, of which 35.88 acres were Sumatra and the rest Connecticut Havana. The average total cost of the shade per acre was \$286.70. The cost of fertilizers ranged from \$10.51 to \$64 per acre, with an average of \$45.31. The cost of cultivation, including the preparation of the seed bed or the purchase of the plants where no seed bed was constructed, is estimated at between \$34.21 and \$73.28 per acre, with an average of \$47.94. The cost of harvesting, including the priming, stringing, hanging, and taking down and tying the tobacco, is estimated at an average of \$137.93 per acre. The fermentation, sizing, assorting, and baling was estimated to have cost an average of \$139.29 per acre. "The total cost of the crop, including the shade, fertilizers, cultivation, harvesting [fermentation, sizing, assorting, and baling], as nearly as this could be determined from the accounts kept by the farmers and by the Department agents, varied from \$613.42 to \$849.55 per acre, or an average of \$657.17." The total yield of Sumatra tobacco was 51,308 lbs., or an average of 1,430 lbs. of cured tobacco per acre. Of this crop about 71 per cent was wrappers, 16 per cent seconds, and 13 per cent trash. The Connecticut Havana seed grown under shade produced an average of 1,367 lbs. per acre. The cost of Sumatra tobacco, barn-cured and including the whole cost of the shade, fertilizers, cultivation, and harvesting, is estimated at a little over 36 cts. per pound, or at 32.2 cts. per pound if one-fifth of the cost of the framework is charged against the crop. "The cost of the finished product, including cost of warehouse work and allowing for the loss in this stage of the work, is estimated at 51½ cts. per pound, including the total cost of the shade, or 47.6 cts. per pound charging one-fifth only of the cost of the framework." The author assumes that the framework will last 5 years. During the summer of 1901 a portion of this crop of Sumatra tobacco was sold at an average price of \$1.91 per pound, prices ranging from \$1.40 to \$2.50 per pound.

Tobacco culture in Haiti (*U. S. Consular Rpts.*, 58 (1902), No. 256, pp. 116, 117).—A brief account of the culture of tobacco in Haiti, with notes on curing and preparing the product and its use in cigar manufacture.

The wheat industry in the Philippines (*Amer. Thresherman*, 4 (1902), No. 8, pp. 623, figs. 9).—This article treats of the native threshing and milling devices.

Variety tests with winter wheat, A. SEMPOLOVSKI (*Deut. Landw. Presse*, 29 (1902), No. 31, pp. 263, 264).—The varieties tested are briefly described and the yields of straw and grain recorded.

HORTICULTURE.

Report of the South Haven Substation for 1901, S. H. FULTON (*Michigan Sta. Bul. 194, pp. 31-72*).—This is the regular annual report on the fruits, vegetables, and nuts growing at the South Haven Substation, and is similar in character to those of previous years (*E. S. R.*, 13, p. 349). The data for 1901 include tabulations on the yield, quality, etc., and descriptive notes in some instances, of 50 varieties of raspberries, 26 of blackberries, 18 of currants, 15 of gooseberries, 21 of cherries, 84 of peaches, 40 of pears, 12 of plums, 60 of grapes, 9 of quinces, 81 of apples, 12 of crab-apples, and several varieties of chestnuts, filberts, pecans, almonds, walnuts, and watermelons. The season was rather unfavorable for all sorts of fruits except peaches. The varieties recommended in most instances are practically the same as those of previous years.

In some experiments in spraying peach trees with copper sulphate solutions of varying strengths for leaf curl it was found that "trees sprayed early with 1 lb. of copper sulphate to 100 gal. of water showed no more curl than trees sprayed at the same time with 1 lb. of copper sulphate to 20 gal. of water." Like results were obtained when 1 lb. of copper sulphate was used to 200 gal. of water. In the test of fall and winter pruning of peach trees *v.* spring pruning, no difference could be noted in the crops of the following season.

Of the pears grown, Bartlett, Bloodgood, Elizabeth, and Giffard are recommended for summer use; Bose, Anjou, Duchess, Howell, Keiffer, Seckel, and Sheldon for autumn; and Dana Hovey and Winter Nelis for winter.

Of the nuts tested Paragon is considered one of the most valuable chestnuts grown at the station. Cosford and Kentish Cob filberts are considered valuable plants for ornamental purposes; they have fruited sparsely at the station. The Japan walnut (*Juglans sieboldii*) grows thriftily at the station and produces annually full crops of nuts. Pecan seedlings from Iowa, planted at the station in 1890, have grown vigorously but produced no fruit. Three-year-old hard-shelled almonds have made a strong and healthy growth, produced some flowers but no fruit. English walnuts have made a failure at the station, though the trees grow slowly.

Eighty-seven varieties of watermelons were tested at the station, the seed of which was obtained from the U. S. Department of Agriculture. Some notes are given on the results obtained, but no recommendations made.

Notes on vegetables, L. R. TAFT and M. L. DEAN (*Michigan Sta. Bul. 196, pp. 87-112*).—Notes on the following vegetables grown at the station in 1901 are recorded: Eight varieties of green-podded snap beans, 8 of dwarf wax beans, 4 of English dwarf beans, 3 of pole beans, 2 of bush Lima beans, 1 of the ordinary white pea bean, 18 of early cabbage, 7 of medium cabbage, 6 of late cabbage, 3 of red cabbage, 5 of kale, 3 of kohlrabi, 5 of Brussels sprouts, 5 of cauliflower, 1 of Chinese cabbage, 34 of lettuce, 32 of peas, 19 of sweet corn, 118 of potatoes, and 84 of tomatoes. Tabulations as to date of maturity, yield, etc., are usually given, and descriptions of the more promising varieties in most instances.

Of the loose, open, crinkled varieties of early maturing lettuce, Hamilton Market and Early Curled Simpson are stated as desirable, though Grand Rapids is most largely grown for forcing purposes. Among the larger kinds of lettuce Leviathan, Maximum, and New York are considered good sorts. Giant Glacier, Golden Queen, and Crystal Palace are stated as choice varieties in the same class with Cream Butter.

Of the early market garden peas Scorcher, Prolific Early Market, and Earliest of All are considered valuable varieties, but not equal in quality to Gradus or Thomas Laxton. The latter are nearly as early as the other varieties, but more care must be taken to delay sowing them until the ground has become warm. Of the midseason or main crop varieties, Hosford Market Garden, Master, and American Wonder are

among the better sorts. Stratagem and Champion of England are stated as standard late varieties, while Monarch and Blue Imperial are among the more promising of the new sorts.

In the potato test, 43 varieties were early and 75 late potatoes. Of the early potatoes, Michigan, yielding 219.29 bu. per acre, was the leading white variety. Other good early varieties were Acme, Andes, and Cole. Daughter of Rose, a second early variety, yielded 274.71 bu. per acre. Carman No. 1 and No. 3 and Sir Walter Raleigh are stated as desirable late varieties.

Fruits, vegetables, flowers, and ornamental shrubs at the experimental farms in Canada, W. T. MACOUN, W. S. BLAIR, S. A. BEDFORD, A. MACKAY, and T. A. SHARPE (*Canada Expt. Farms Rpts. 1901*, pp. 87-108, 112, 113, 120-125, 132-135, 369-391, 429-452, 482-505, 533-558, pls. 2).—Separate reports are given on the fruits, vegetables, flowers, and ornamental shrubs grown at the Central station in Ottawa and at the branch stations in Manitoba, Maritime Provinces, Northwest Territories, and British Columbia. These reports are largely in continuation of those for previous years (E. S. R., 13, p. 243). The data recorded consist largely of the results obtained in tests of varieties of orchard fruits, grapes, raspberries, strawberries, gooseberries, currants, rhubarb, and of the more prominent garden vegetables, such as peas, beans, onions, cabbage, cauliflower, tomatoes, sweet corn, beets, melons, cucumbers, squashes, pumpkins, lettuce, Brussels sprouts, etc. Lists are given in a number of instances of the most suitable varieties of vegetables for farmers' gardens. Tests are also reported on the hardiness and suitability to the various districts of a large number of ornamental shrubs, hedge plants, and annual and perennial flowers.

In an experiment with corn at the Maritime Station the effect of removing the suckers from the corn plant in hastening maturity was studied. The data given indicate that no apparent advantage was gained by removing the suckers. In general, the varieties of Americana and Nigra plums have given the best results at the different stations. Descriptive notes are given in some instances on some of the orchard fruits and vegetables grown.

Celery tests on American Gardening trial grounds (*Amer. Gard.*, 23 (1902), No. 378, p. 185, fig. 1).—In these tests Major Clarke has proved by far the best red variety of celery grown. One of the best green varieties of celery was Evans Triumph. Winter Queen has proved itself the best of all winter celeries for 2 seasons. It is a strong plant with good heart and of excellent flavor, and has surpassed all others in keeping properties.

Growing melons at Rockyford, D. V. BURRELL (*Amer. Agr. (mid. ed.)*, 69 (1902), No. 16, p. 558).—Methods observed at Rockyford, Colo., in growing muskmelons are described.

Onion beginnings; seeding, packing, and shipping, H. L. WELLS (*Sunset Mag.*, 8 (1902), No. 3, pp. 123-127, figs. 7).—Brief description of California methods of growing and harvesting onions and onion seed. It is stated that about a half million pounds of onion seed were grown in California in 1901.

Forcing rhubarb in the field (*Amer. Gard.*, 23 (1902), No. 3, p. 23).—Methods of forcing rhubarb by means of frames and stable manure are given. The frames may be made of open-ended boxes or barrels sawed off at the proper height. These should be placed over the hills and held in place by stakes and surrounded by manure. Over the frames window sash or heavy oiled "plant bed" or "protecting" cloth may be used. In the fall, before the ground is frozen, beds intended for early spring forcing should be plowed or deeply cultivated, and the ground about the plants thoroughly spaded. Thus prepared from 800 to 1,000 lbs. of complete commercial fertilizers per acre should be evenly scattered about each hill. When forcing begins a further application of $\frac{1}{2}$ to $\frac{3}{4}$ lb. of nitrate of soda per plant should be placed about the hill and thoroughly worked in, taking care not to get any considerable quantity over the crown. The manure on the outside of the frames should be piled

up level and thoroughly packed down. If the rows are wide apart it need not occupy the whole space between them. It is considered best to be a little liberal and round up the spaces a few inches above the level of the edge of the frames. Immediately after the manure is put in place the glass should be closed down and kept so, no matter how high the temperature may go, until the rhubarb crown bud appears above the surface. Then the same attention must be given to airing as with the ordinary hotbed. Toward spring, when the days are getting longer and the sun hotter, the use of cloth frames or straw mats is advised in preference to glass, since the latter induces a weak and spindling growth.

Fertilizer tests on tomatoes, H. A. HUSTON (*Indiana Sta. Bul. 92, pp. 107-115*).—This bulletin presents briefly some statistics on the canned tomato industry of this country, and gives the results of some field experiments with fertilizers for tomatoes. The experiments were carried out during the seasons of 1899 and 1900 on moderately heavy clay loam that would naturally yield about 24 bu. of wheat or 50 bu. of corn per acre. The fertilizer formula followed in the main was that recommended by Voorhees, viz, nitrogen 4.7 per cent, phosphoric acid 7.2 per cent, and potash 12 per cent, applied at the rate of 500 lbs. per acre; and was composed of muriate of potash, nitrate of soda, azotin, and acid phosphate. This mixture cost about \$32 per ton. On some plats one or more of the fertilizers was omitted, and the amounts applied on the different plats also varied. Barnyard manure applied on clover sod at the rate of 12 to 15 2-horse loads per acre formed one plat in 1900.

The best results were obtained by using a complete fertilizer in liberal amounts. The use of nitrogen alone, either in the form of nitrate or organic nitrogen, was unprofitable. The yield on the barnyard manure plat was the largest obtained with any of the fertilizers. This fertilizer had a tendency to delay and prolong the ripening period, but the total yield was very nearly double that obtained from any other plat.

On the whole, the use of the commercial fertilizers considerably increased the yields and hastened the maturity of the crop. The results also indicate that on lands of the type used where clover is grown in the rotation, a fertilizer made up of 3 per cent nitrogen, 7 per cent available phosphoric acid, and 12 per cent potash would more nearly meet the requirements of the tomato crop than the Voorhees formula and would be about \$5 per ton cheaper. Earlier experiments at the station indicate that sulphate of potash gives a better quality of early tomatoes than the muriate.

The statistics included in the bulletin show that Indiana is the second State in the Union in the production of canned tomatoes, the average yearly output for the last 5 years being 697,200 cases. Each case contains 24 cans, holding 3 lbs. each. Maryland stands first in the production of canned tomatoes, with a yearly average of 1,840,000 cases.

Successful culture of tomatoes for canning, E. J. DIRICKSON (*Amer. Agr. (mid. ed.), 69 (1902), No. 14, p. 491*).—The method observed by the author in growing from 50 to 80 acres of tomatoes each season is given. The varieties Ignotum, Trophy, and Favorite are the varieties used, and all considered equally good.

Mushroom culture in France, J. K. GOWDY (*U. S. Consular Rpts., 68 (1902), No. 259, pp. 537-541*).—A popular article describing in detail the culture of mushrooms as observed by growers in the abandoned mines about Paris. In this work the cost of mushroom culture is estimated as follows: Manure, 10 cts.; labor, 20 cts.; rent, 2 cts.; total, 32 cts. The receipts per square yard are 6 lbs. mushrooms, 90 cts.; spent manure, 5 cts.; total, 95 cts. It is believed that if proper means were used to destroy the insects affecting the mushrooms the receipts per square yard might be increased to \$2.

Culture of the edible mushroom *Tricholoma nudum*, J. COSTANTIN and L. MATRUCHOT (*Rev. Gén. Bot., 13 (1901), No. 155, pp. 449-475, pl. 1, figs. 4*).—The culture of the spawn and the production of mushrooms therefrom have been studied,

together with the parasites and anomalous growths affecting this plant. The cultures have been made in caves, greenhouses, open gardens, and forests, also in sterilized tubes. As a medium in which to grow, beech, poplar, maple, and oak leaves have been used, also spent tan bark, manure, etc. The results secured, both in the production of spawn in these media and in the growth of the mushrooms above ground, are reported at length and in detail. They show that spawn can be obtained in abundance by seeding spores in pure cultures. In commercial work spawn has been very successfully grown in heaps of beech or oak leaves or in spent tan bark. With poplar leaves, on the other hand, the mycelium developed very poorly. The fruiting of *T. nudum* has been successfully accomplished in heaps of tan bark and beech leaves, less often in oak leaves. With the special manures used in growing cultivated mushrooms no fructification was obtained, though the spawn developed. The duration of the period of incubation of the spawn, that is, from the time the spawn is seeded until the appearance of the mushrooms above ground, has been on the average 10 to 12 months. In caves the harvest has lasted 2 to 3 months and a less time in the open air. The spawn seems to be of a perennial nature, and in one experiment fructified three years in succession. As compared with cultivated mushrooms, the returns from *T. nudum* are inferior; on the other hand, the medium of culture is cheaper and the preparation of special manures is not required, the mycelium is vigorous, the mushroom may be cultivated out of doors and in forests, and is much more hardy than the cultivated mushrooms.

Experiments in grafting. H. LINDEMUTH (*Gartenflora*, 51 (1902), No. 1, pp. 12-15).—When *Solanum erythrocarpum* was grafted on *S. lycopersicum* June 29, it grew so luxuriantly that by July 9 it was ready to be transferred from pots to the open field. At first the graft did not grow quite as rapidly as ungrafted plants, but later overtook and surpassed them in luxuriance, attaining a total height of 1.48 meters. Other plants that have grown exceptionally well when grafted on strong growing stocks have been *Physalis* on potatoes, *Arabis albida* on cole, and *Solanum auriculatum* on *S. tuberosum*. It is believed that grafting on strong growing stock is only at the beginning of its importance.

Wallflower was grafted on red cabbage August 1, wintered in a cold house, and planted out the following summer. Both grew. The cabbage sent out sprouts and formed a solid head weighing 800 gm. At the time of writing the wallflower had formed buds. *Abutilon thompsoni* grafted on *Althaea narbonensis* made a strong growth, much beyond its usual season. *Petunia hybrida* has been grafted on potato stalks, but with unfavorable results. The best stock found for *Petunia* has been *Nicotiana glauca*. Two plants of *Abutilon thompsoni*, grafted on *Sida napaea* stocks 25 cm. long and treated in the same manner, developed 3 stems each. The leaves on one plant were intensely variegated in color, while on the other they remained green. No explanation of the effect could be given.

Influence of stock on scion. L. H. PAMMEL (*Amer. Gard.*, 23 (1902), No. 372, p. 86).—An instance is cited of the use of the frost plum seedlings as stock for the Wellington plum, a variety similar to the De Soto. The fruit produced was nearly worthless and similar to the frost plum. De Soto plums grafted on De Soto produced fruit on a dozen trees that was very different from the De Soto in size, color, and quality.

Influence of the hardness of wood in grafting cider apples. E. LEROUX (*Jour. Soc. Nat. Hort. France*, 4. ser., 3 (1902), Jan., pp. 48-66, fig. 1).—A general discussion is given of the influence of the hardness or density of wood in grafting cider apples, and 200 varieties of these apples are arranged alphabetically and classified as to the relative hardness of the wood of each variety. The numerous observations along this line which have been made by the author have led to the following conclusions: (1) In the culture of cider apples varieties with tender wood can be most successfully grafted on stocks having tender wood, or varieties with hard wood on stocks having hard wood; (2) success follows only rarely when a variety with

tender wood is grafted on a stock having hard wood; (3) success seldom or never follows when a variety with hard wood is grafted on a stock with tender wood. These principles are believed to apply to other orchard fruits as well as to apples.

The home fruit garden: Preparation and care, L. C. CORBETT (*U. S. Dept. Agr., Farmers' Bul. 154, pp. 20, figs. 6*).—A popular discussion of the planting out and care of a home fruit garden, including orchard and small fruits. Plans are given showing the position of the different fruits in the garden, and of a combined fruit and vegetable garden.

Canning of fruits and vegetables, G. C. BUTZ (*Pennsylvania State Dept. Agr. Bul. 91, pp. 57, figs. 8*).—This is a popular presentation of the subject of canning fruits and vegetables on a commercial scale. Some statistics of the canning industry are given, together with notes on the historical development of canning, location of canning factories, capital required in starting a factory, and the machinery necessary. The methods observed in canning tomatoes, corn, peas, beans, squash, pumpkins, and various fruits are noted in some detail. The bulletin also contains a bibliography of the publications concerning the canning of vegetables and fruits; a list of the supply houses and manufacturers of canning-factory machinery and materials; list of canned goods brokers; list of the canning factories of the United States, and dimensions of the standard-sized cans and boxes for fruits and vegetables.

The orange in southern California, J. W. JEFFREY (*California Cult., 18 (1902), No. 2, pp. 17, 29, fig. 1*).—A handy condensed summary of the extent of the orange industry and of cultural methods in southern California.

Orange conference (*Bul. Bot. Dept. Jamaica, 9 (1902), No. 1-2, pp. 1-25*).—A reprint of the papers presented at the orange conference held under the auspices of the board of agriculture December 4, 1901. The subjects of varieties, situations for orchards, propagation and treatment in orchards, irrigation, insects and diseases affecting, with notes on natural and artificial remedies, are considered.

Report on cooperative experiments with small fruits, H. L. HUTT (*Ontario Agr. and Expt. Union Rpt. 1901, pp. 24-31*).—The form of contract entered into between the Union and cooperative experimenters is given, together with the cultural instructions sent to experimenters with each of the following crops: Strawberries, raspberries, black raspberries, blackberries, currants, and gooseberries. A brief summary of reports sent in on the growth of these fruits secured by experimenters in different districts is included.

Strawberry notes for 1901, L. R. TAFT and M. L. DEAN (*Michigan Sta. Bul. 195, pp. 75-85*).—Notes and tabulated data in continuation of those reported for previous years (*E. S. R., 13, p. 456*) are recorded for 170 varieties of strawberries. The tabulation includes the usual data on blooming and ripening period, vigor, hardness, productiveness, size, form, color, quality, and firmness of the strawberries. In place of some of the older early varieties of strawberries, such as Michel Early or Beder Wood, the authors suggest the use of Excelsior, Stone Early, or Mayflower, which seem to have some superior characteristics. Valuable large berries of high quality are Marshall, Wm. Belt, and Sample. For market berries where quality is desired, Excelsior for early, followed by Warfield, Haverland, Clyde, Sample, Wm. Belt, and Bubach, are recommended.

A preliminary note on the enzym in tea, M. K. BAMBER and H. WRIGHT (*Indian Gard. and Plant., 10 (1902), No. 9, pp. 152-154*).—A discussion of the nature of enzymes in tea and of their use in tea manufacture.

Cultivation of pepper in the Bombay Presidency, J. MOLLISON (*Agr. Ledger, 1901, No. 3, pp. 33-40*).—This article deals mainly with analyses of the pepper plant and typical soils on which pepper is grown, made with a view to determining the best system of manuring for this plant.

Congress for the hybridization of the grape, L. J. GRANDVOINET (*Prog. Agr. et Vit. (Éd. L'Est), 22 (1901), Nos. 50, pp. 709-714; 51, pp. 743-745; 52, pp. 771-774*;

23 (1902), No. 2, pp. 46-51).—Herewith is given a summarized account of the papers and reports presented to the hybridization congress for grapes, held at Lyons from November 15 to 17, 1901. At this congress direct producers were advised for temperate or cold regions, where the attacks of phylloxera are of less importance than in the middle or warmer portions of France. These plants are quite resistant to winter freezing and give very satisfactory harvests. They are especially advised in planting parcels of ground of mediocre value, where neither much attention nor manure can be given to them. Wines made from grapes grown in these positions are very satisfactory for household purposes, and are made at considerably less expense than with grafted vines. The number of new hybrid direct producers within recent years is considered of sufficient importance to call the attention of viticulturists to a study of their merits. While the resistance of these new hybrids to phylloxera is not absolute, it is considered superior to older sorts and grafted plants, and sufficient for the center, southeast, and northeast portions of France.

Table of comparative merits of grapes, T. S. HUBBARD (*Amer. Gard.*, 28 (1902), No. 378, p. 186).—A scale of points showing the comparative size of berry and cluster, quality for table use, earliness in ripening, hardness of bud and cane, health of foliage, vigor of growth, productiveness, shipping and keeping quality, and compactness of cluster is given for 62 varieties of grapes grown in the grape belt of western New York.

Bench grafting resistant vines, B. BRUCK (*Pacific Rural Press*, 63 (1902), No. 9, p. 152).—Account of method, cost, and results. It is shown to be cheaper and to give more satisfactory results than vineyard grafting.

Direct producers, RAVEZ, BONNET, BOUFFARD, DUPONT, and REY (*Ann. École Nat. Agr. Montpellier, n. ser.*, 1 (1902), No. 3-4, pp. 195-309).—Brief notes on the characteristics of a large number of varieties of direct producers grown at the school, accompanied by analyses of the must and wine in each case.

Tests of commercial fertilizers on vines, E. CHUARD and C. DUSSERRE (*Chron. Agr. Canton Vaud*, 15 (1902), No. 2, pp. 38-45).—Herewith are recorded the results of experiments with commercial fertilizers as a supplement to barnyard manure for grapes. The experiments bring out the fact that instead of the exclusive use of barnyard manure, which is expensive, may be substituted in part commercial fertilizers. The experiment shows that about as good results are obtained when only half the usual amount of barnyard manure is employed and this supplemented by superphosphate or Thomas slag, sulphate of potash, and a moderate annual application of nitrate of soda. The quantity of the latter should be reduced with vigorous growing vines, while on other soils it may be increased to 400 kg. per hectare per year.

Phosphoric acid and wines, G. PATUREL (*Ann. Agron.*, 28 (1902), No. 1, pp. 5-30).—The author reviews the work of other investigators on the composition of fruit and vines of grapes and of wines, and reports the results of his own studies on the relation of the phosphoric acid in soils and grapes to the quality of the wine produced, and on the influence of methods of fertilizing and fermentation on the proportion of phosphoric acid found in the wine. These researches show that the grape takes a very small amount of phosphoric acid from the soil, much less than of potash and nitrogen. A vineyard requires from 7 to 15 kg. of phosphoric acid per hectare annually. The larger part of this is returned to the soil in the leaves, prunings, and marc. That removed in the wine and thus lost to the soil does not exceed 3 kg. per hectare, but in spite of the small amount required, it has been noted that phosphatic fertilizers very frequently produce beneficial results as regards maturity and quality of the grapes and their resistance to cryptogamic diseases. The work of Müntz has shown that there is a relation between the phosphoric acid content and the quality of wines of different origin. The author has found the same relation, although much less marked, in different wines of the same region. His examina-

tion of the wines of Beaujolais and Mâconnais showed an absolute correlation between the richness of the wines in phosphatic substances and their commercial value based on quality. Almost all of the phosphoric acid of red wines is derived from the juice of the grapes in which this substance occurs in solution. The solid parts (stems, seeds, and skins) yield only insignificant amounts of phosphates to the wine except when subjected to fermentation. These results indicate the desirability of increasing the phosphoric acid content of wines. This may be done by three methods, (1) the use of phosphates in the wine vat, (2) modifications of the process of vinification, especially a more prolonged contact of the marc with the fermenting wine, and (3) the use of phosphatic fertilizers.

Manuring vines, E. H. RAINFORD (*Queensland Agr. Jour.*, 10 (1902), No. 3, pp. 187-190).—A compiled article showing the necessity for manuring vines and the best fertilizers to apply on different soils.

Grafting and budding walnuts (*California Cult.*, 18 (1902), No. 4, p. 53).—Directions are given for successfully grafting and budding walnuts.

Etherizing lilacs for early forcing, F. HARMS (*Müller's Deut. Gart. Ztg.*, 17 (1902), No. 1, pp. 8-11, figs. 3).—The author describes in some detail methods of etherizing plants (*E. S. R.*, 12, p. 243), and gives some results obtained by himself in forcing lilacs which had been etherized. When the lilacs were etherized for 48 hours and afterwards placed in the forcing house, they started into growth 3 to 4 days later and were in full bloom in 25 days. Plants not etherized did not bloom for 8 to 10 days later.

The effect of ether in forcing plants (*Amer. Florist*, 18 (1902), No. 720, pp. 319-321, figs. 4; *Gardening*, 10 (1902), No. 230, p. 213, figs. 4).—This report is abstracted from *Le Jardin*, and summarizes the results of experiments in the ether forcing of plants at an experiment station in Dresden. Etherized lilacs were brought into full bloom within 18 days after bringing in the house. Treated shrubs forced early flowered much more freely, and were 8 to 10 days earlier than untreated. In general, etherized plants were found to force at a much lower temperature than those not treated. *Azalea mollis* and the viburnums have responded readily to the treatment. Less success has been obtained with *Prunus triloba*, Deutzia, and roses. Forty per cent of etherized lily of the valley plants flowered, when placed in heat, November 21, at 75° F., while but 2 per cent of untreated plants flowered under the same conditions. The effect of the ether in forcing becomes less marked as the flowering season of the plant in question approaches. It is, therefore, considered of greatest value in November and December.

Ether forcing of plants, A. MAUMENE (*Amer. Gard.*, 23 (1902), No. 381, pp. 338, 339, fig. 1; *abs. from La Nature*).—The object and methods of etherizing plants are discussed. In the forcing of shrubs it is stated that it is absolutely necessary that vegetation should be completely arrested and the plants brought to a period of repose. When the fumes of ether envelop the branches of the shrub they accelerate vegetation, cause the leaves to wither, and ultimately arrest growth, the same as the first frosts of autumn. After treatment the plants may be immediately placed in the forcing house. The European experiments have shown that etherization is of most use when applied from July to the first of September. Etherization should take place in closed compartments having a temperature of not less than 17 to 18° C. About 400 gm. are considered sufficient for a cubic meter of air. The time of exposure to the fumes of the ether should be about 50 hours.

Watering with hot water (*Amer. Gard.*, 23 (1902), No. 370, pp. 53, 54).—The value of drenching plants that have become sickly with water having a temperature of 125 to 130° F. is noted. Sufficient water should be used to carry off any acidity of the soil that may be present. In addition, it is suggested that fertilizers be used at the same time in the rejuvenation of the plants. In the article good results are reported with such plants as Clivia, palms, Ficus, Begonia, Aspidistra, Primula, and Dracena.

Methods and results of sterilization, G. E. STONE (*Amer. Florist*, 18 (1902), No. 718, pp. 194-196).—Besides the value of sterilized soils in preventing certain diseases in the greenhouse, it has also been found of practical value in increasing the growth of the crop. The paper discusses in considerable detail the present use and methods of sterilizing soil in the greenhouse.

A new spring flowering iris (*Amer. Gard.*, 23 (1902), No. 373, pp. 104, 105).—An account is given of a new race of hybrid Alpine irises, which commence blossoming in early spring and continue until the end of April or first of May. The race was originated by W. J. Caparn, of England, an amateur gardener. The range of color in the new race runs from pure white selfs through the various shades of yellow and blue. The race is also valuable for forcing.

Growing water lilies from seed, G. B. MOULDER (*Amer. Gard.*, 23 (1902), No. 378, p. 191, fig. 1).—Methods observed in growing the different species of water lilies from seed are given.

The hybridization of orchids and their culture from seed, A. HEFKA (*Möller's Deut. Gart. Ztg.*, 17 (1902), No. 1, pp. 4-7, figs. 6).—A discussion is given of the principles to be observed in the hybridization of orchids to secure desirable qualities in the hybrids, and of the method of growing orchids from seed. The author was most successful in growing the seed on cut moss placed in low, flat pots with large holes in them so that water could be absorbed from below. The seed is never sprinkled or watered from above. The seed should be sown at about the time the mother plant usually starts into growth, or otherwise they are apt to remain dormant for a much longer period. The first roots usually appear in from 3 to 6 months after seeding, and as soon as 2 leaves are formed the plants are ready for transplanting to pots or baskets. Good illustrations are given, showing the growth of seedling orchids in pots.

Winter protection for tea roses (*Amer. Gard.*, 23 (1902), No. 381, pp. 239, 240).—Tea roses were kept in perfect condition in cold frames or when enveloped in straw or straw bundles. Twenty-five per cent of the plants died when protected over winter with dry leaves only. When protected with dry leaves and earth about 10 per cent died. With no other covering than strawy manure about 50 per cent of the plants died.

Fertilizers for sweet peas (*Amer. Gard.*, 23 (1902), No. 378, p. 188).—A comparison was made between muriate of potash combined with mineral superphosphate of lime and with sulphate of ammonia for sweet peas. The sulphate of ammonia was applied in solution at the rate of 2 oz. to 4 gal. of water. The result from the use of the sulphate of ammonia was a much closer jointed and firmer growth than with muriate of potash, but the plants did not bloom as freely nor were the blooms as large. The color of the flowers, however, was equally good, and they lasted much longer when cut and also when left on the haulm.

FORESTRY.

A working plan for forest lands near Pine Bluff, Arkansas, F. E. OLMSTED (*U. S. Dept. Agr., Bureau of Forestry Bul. 32*, pp. 48, pls. 9, figs. 9).—This bulletin contains a detailed working plan for a forest tract made in cooperation between the Bureau of Forestry of this Department and the owners of the timber land, Sawyer and Austin Lumber Company. The tract of land comprises 105,000 acres, about 5 per cent of which is bare of merchantable timber. The forest is divided into 3 types of forest growth: Pine ridge, which embraces 65 per cent; pine flat, 20 per cent; and hardwood bottom lands, 15 per cent. The principal species of trees are the short-leaved pine, loblolly pine, cow oak, white oak, white ash, and several species of hickory. These different species are described and silvicultural notes given regard-

ing them. A careful estimate of the entire tract shows that it may be worked as a sustained annual yield of 14,500,000 ft. per year. The present capacity of the mills erected by the company is 40,000,000 bd. ft. per year, and in order to keep them at their full capacity it would be necessary to increase their area by 170,000 acres of forest land similar to the tract reported upon. A brief summary of the rules laid down for lumbering limits the cutting of pine to 14 in. on the stump and hardwoods 20 in. A certain number of pine trees over 14 in. on the stump are to be left standing for seed purposes, and wherever practicable the hardwoods on the pine lands are to be cut off. All pine trees 18 in. or over in diameter are to be sawn not higher than 18 in. from the ground, and those below this diameter at 12 in., and care is to be used in felling that as little damage as practicable be done to the young growth.

Massachusetts forestry, W. R. SESSIONS (*Massachusetts State Bd. Agr. Rpt. 1901, pp. 322-330*).—Some suggestions are given for future action for the reforestation of the cheap lands of the State. On account of the uncertain income to be derived from forest production the author believes that the State should take up the matter, and not leave it for private enterprise. One of the important features in connection with reforestation of the State is the protection of the water power and water supply by furnishing a mature forest cover for the hills from which the streams receive their supply of water. It is believed that a large part of the wooded land, waste, and semiwaste land of the State should be purchased and controlled by the State government. Many of these lands can be purchased at a comparatively low valuation, and if the results should prove financially successful, the revenue would necessarily go to the State, reducing the taxes in the various localities.

Report of the superintendent of forestry for Canada, E. STEWART (*Rpt. Dept. Interior Canada, 1901, pt. 8, pp. 25, pls. 7*).—This report gives the details of the work of the office of the superintendent of forestry, in which the development of tree planting in the Northwest Territories is shown, and the details of the operations conducted in various parts of the Dominion are indicated. Notes are given on forest protection from fire, and brief descriptions given of the timber reserves in Canada. Those described are the Riding Mountain reserve, Spruce Woods reserve, Turtle Mountain reserve, Moose Mountain reserve, the Foothills reserve, Rocky Mountain Park, and the railway belt in British Columbia, which consists of a territory about 500 miles in length by 40 in width along the main line of the Canadian Pacific Railway. An account of the tree planting which has been conducted in the plains region is given, and a plan of cooperation for government tree planting is outlined. In addition, the reports of the assistant superintendent, forest inspectors, and forest rangers are given in the appendix.

Annual report of the director of forestry of the Province of Ontario, 1900-1901, T. SOUTHWORTH (*Rpt. Dir. Forestry, Ontario, 1900-01, pp. 53*).—This report contains an account of the condition and management of the forest reserves in Ontario, together with an appendix on the production of tannin in the same province. The subject of the cutting off of the timber in the older portions of the province has received considerable attention and has been investigated through the aid of the latest obtainable statistics. An analysis of these returns shows that the proportion of wooded land in most localities is steadily decreasing. The necessity of correcting this process of deforestation is evident, but the steps to be pursued to prevent it are not apparent. A compilation of the legislation enacted in many of the States of the United States for the encouragement of tree culture and forest maintenance is given as a suggestion for legislative action to remedy the evils of deforestation.

Management of the farmer's wood lot, W. N. HURT (*Rpt. Dir. Forestry, Ontario, 1900-01, pp. 54-62, figs. 6*).—A description of the average farmer's wood lot is given, which consists usually of mature trees, trees past maturity, prematurely developed trees, healthy growing trees, coppice and seedlings, and stump and wasteland. Methods of replanting are discussed, and the methods of reproduction of different species

are shown. The methods of seeding and planting the different varieties of trees are described, and different kinds of trees are recommended for the different conditions of soil, exposure, etc. The kinds of trees recommended for planting are white pine, chestnut, elm, hickory, basswood, ash, maple, white oak, cedar, and black walnut. The value of mixed plantations is shown, and the necessity for trimming and thinning pointed out.

Experiments in tree planting on Sable Island, W. SAUNDERS (*Canada Expt. Farms Rpts. 1901, pp. 62-77, pl. 1*).—Sable Island, which lies off the coast of Nova Scotia, is about 21 miles long and about a mile across. The island formerly was much larger in extent but being of a sandy nature is gradually being washed away by the action of the winds and waves. There are no trees found on it and the gradual wasting away of the island has led to the consideration of the possibility of establishing tree growth there and thus fixing the soil. In 1900 the author was requested to investigate the subject of foresting this island, and taking advantage of his presence in Europe, visits were made to a number of regions in France where forest operations had been conducted in sandy land. As a result of his investigations, a selection of trees and shrubs, which were thought to be adapted to the purpose, was made, and 81,345 plants, representing 25 varieties of evergreens and 79 of deciduous trees and shrubs, were secured and sent to the island. The planting operations were conducted in the summer of 1901, the details of which are given. At the end of the season a report was made on the condition of the trees and seedlings, from which it appears that a protracted drought killed many of the weaker plants and the high winds, which occurred toward the end of September, caused the leaves on many of the deciduous trees to wilt and appear as though scorched by fire. All the evergreens, with the exception of the white pine, seemed to have done quite well. The experiment thus far has covered too brief a period to permit the forming of a very definite opinion as to the ultimate success of tree planting on Sable Island.

Forest belts, W. T. MACORN (*Canada Expt. Farms Rpts. 1901, pp. 127-132*).—The forest planting at the Central Experimental Farm has been made in belts along the northern and western boundaries, that on the western boundary being 165 ft. wide and the northern 65 ft., the total length being a little less than 2 miles. The total number of trees planted is 23,300. The plantings were made to gain information regarding the growth of the best timber trees when grown on different kinds of soil and at different distances. The first trees have been planted 13 years, and the results obtained warrant the extensive planting of timber trees under similar conditions. The best results were obtained where the trees were planted 5 ft. apart each way. Such trees have clean trunks and will produce the best timber. A table is given in which the average height and diameter of the different varieties of trees are stated, together with the growth during the season covered by the report. Black walnut, butternut, white elm, and Norway spruce have not made satisfactory growth owing to the unsuitability of the soil and other causes. Notes are given on the plantings that have been made in the arboretum and botanic gardens. There are now living in the arboretum more than 4,200 specimens of trees and shrubs which have been obtained from many sources.

Notes on the arboretum, S. A. BEDFORD (*Canada Expt. Farms Rpts. 1901, pp. 438-442*).—A report is given of the arboretum maintained at the Manitoba branch station. No additions were made during the season covered by the report, but notes are given on the hardiness of trees and shrubs previously planted.

Trees and shrubs, A. MACKAY (*Canada Expt. Farms Rpts. 1901, pp. 493-498*).—The condition of the trees and shrubs which had been planted at the substation in the Northwest Territories is said to be very satisfactory. During the past 12 years the demand for trees and shrubs from the experimental farm has been much greater than the supply, and the demand has steadily increased, especially from the southern portion of the Territories. Notes are given of a list of species and varieties under test, in which their relative hardiness is shown.

The hardy catalpa, H. F. ROBERTS (*Kansas Sta. Bul. 108*, pp. 99-140, pls. 31).—The author has brought together such information as is available to show the economic value of the hardy catalpa (*Catalpa speciosa*) for Western planting. Although 2 forms of catalpa have been known as indigenous to the United States for a long time, it was not until the latter half of the nineteenth century that the two were considered as specifically distinct. The systematic relationships of the hardy and other species of catalpa are discussed at some length, after which notes are given on the durability of the timber of the hardy species. Evidence is presented which shows that for posts, railroad ties, telegraph poles, etc., the timber exhibits great durability in contact with the earth. In planting catalpa the seed should be sown in seed beds and afterwards transplanted to the permanent plantation. In the earlier plantings the trees were set at a distance of 4 by 4 ft., the idea being by close planting to cause the trees to become naturally pruned and force the growth into a straight trunk. The catalpa differs, however, from other forest trees in that its dead limbs are not readily dropped. In order to secure clean, smooth trunks, systematic pruning is necessary, which should be begun when the trees are 5 or 6 years old, and the limbs should be cut off to a distance of 5 or 6 ft. from the ground. The proper distance for planting is rather imperfectly known, and the results of a number of artificial plantations are given. The rate of increase in diameter of catalpa trees varies according to soil, water supply, and distance of planting. Trees planted at a distance of 4 by 8 ft. in the interior of plantations increase about $\frac{1}{2}$ in. per year in diameter after about 10 or 12 years. The thinning processes should be begun after the trees have been planted 8 or 10 years by the removal of half the trees. In general, the proper time for cutting should be during the months of August and September. This will prevent the return to the trunk of the soluble food in the leaves which would furnish nutriment for bacteria and fungi.

The cost and profit of catalpa growing, based upon results obtained in a number of plantations, are given, from which it appears that a net profit of about \$20 per acre for the first 10 years can be obtained, leaving the products still standing in the plantation worth about \$400 per acre. The value of catalpa for railroad ties is discussed at considerable length and the results of a number of tests conducted by railroads are given. Several commercial catalpa plantations are described which have been made since 1870.

The catalpa plantations at the agricultural college, A. DICKENS and G. O. GREENE (*Kansas Sta. Bul. 108*, pp. 141-145, pls. 8).—An account is given of the plantings of catalpa at the Kansas Agricultural College which have been made since 1872. Very encouraging results have been obtained, and on very poor soil the catalpa has made a paying crop. On good soil the growth was proportionately better. In from 7 to 10 years growth of suitable size for posts was produced, and in 20 to 25 years sufficient size for lumber or other purposes. The best distance for planting appears to be 5 to 6 ft. apart in rows 8 ft. distant. Clean cultivation should be given the trees for several years and pruning should be resorted to to produce straight, desirable growth. The trees are easily raised, readily transplanted, grow rapidly, and endure extremes of drought, heat, and cold.

The western red cedar, W. M. BOMBERGER (*Proc. Iowa Park and Forestry Assoc.*, 1 (1901), pp. 17, 18).—The western red cedar (*Juniperus scopulorum*) is said to require considerable heat and withstand drought to a remarkable extent. On this account it is considered one of the most valuable of evergreen trees for growth on the elevated plains country of Iowa, Minnesota, Dakota, Nebraska, Kansas, Oklahoma, and Colorado. Two common forms are briefly described; one, which is indigenous along the Platte River in Nebraska, is considered best for general planting; the other form native in the Rocky Mountains is characterized by the glaucous color of its foliage, and is better adapted for ornamental plantings.

A forestry plantation after thirty years, E. REEVES (*Proc. Iowa Park and Forestry Assoc.*, 1 (1901), pp. 21-24).—An account is given of a plantation made in 1869 which included about 8 acres of European larch and about an acre each of Scotch, Austrian, and white pine, and Norway and black spruce. Besides this, seeds of soft maple, white ash, white elm, box elder, walnut, butternut, chestnut, and catalpa were planted. On the whole, the larch made the most satisfactory growth, followed by the white pine. The best specimens of larch were a foot in diameter and 60 ft. in height in 1901. The white pine had attained nearly the same diameter and a height of about 35 ft., the other species showing less satisfactory growth. The catalpa did not prove hardy and was several times killed back by the severe cold of winter. The only returns received from this plantation were about \$200 worth of telephone poles cut in January, 1900. As the land was estimated as being worth \$55 per acre, the author does not believe that the planting was a financial success.

Shelter planting, W. M. BOMBERGER (*Proc. Iowa Park and Forestry Assoc.*, 1 (1901), pp. 18-21).—The author describes his experience in planting shelter belts on 2 farms, by which ample protection was secured in from 8 to 9 years. He suggests that in planting such belts the Scotch and Austrian pine among evergreens and the cottonwood of deciduous trees are the best to begin with. After these are established other species may be introduced as occasion demands. Clean cultivation of the rows should be continued for 1 or 2 years after the grove is planted, and on the whole the trees should be set at distances of about 8 by 8 ft. The white pine is said to be one of the best species for such planting, and although making little growth for the first few years, it afterwards made a terminal growth of 18 to 32 in. per season, depending upon the moisture and other conditions. During the first 3 winters a mulch of brush or straw is said to be of decided advantage in protecting the trees.

Forest trees for park purposes, J. T. D. FULMER (*Proc. Iowa Park and Forestry Assoc.*, 1 (1901), pp. 29-33).—The relative value of a number of trees for park purposes in Iowa is indicated. Among the trees described are the ash, box elder, buckeye or horse chestnut, sycamore, elm, various maples, chestnut, poplar, hackberry, and several species of oak.

The decay of timber and methods of preventing it, H. VON SCHRENK (*U. S. Dept. Agr., Bureau of Plant Industry Bul. 14, pp. 96, pls. 17, figs. 27*).—This bulletin gives a report in which the structure of timber is considered and the factors which cause the decay of wood are described at some length. Accounts are given of attempts which have been made to preserve timber from decay. An experiment which has been begun in connection with some railroads in eastern Texas is briefly described. In this experiment railroad ties consisting of different varieties of oak, beech, hemlock, tamarack, and pine have been subjected to a number of different treatments which are claimed to protect the ties against decay. These railroad ties have been treated and laid in the usual manner of railroad construction, and records will be kept of the length of their service. In connection with his investigations, the author visited various countries in Europe, and gives a report on the results of timber impregnation experiments in those countries. An appendix to the report shows the forms of specifications and contracts which are in use at present by various European lines of railway.

SEEDS—WEEDS.

The intramolecular respiration of seeds, E. GODLEWSKI and J. POLZENIUSZ (*Ann. Agron.*, 28 (1902), No. 3, pp. 151-165).—This article gives the results of an extensive series of experiments with seeds and various fungi, in which the intramolecular respiration was studied. The authors claim that their investigations show a marked analogy between intramolecular respiration and alcoholic fermentation, if

not indicating the identity of the two phenomena. Peas, beans, barley, castor beans, etc., were experimented with, and it is claimed that when deprived of oxygen the peas were able to produce a true alcoholic fermentation. The decomposition of the saccharose, which at the end of the experiment seemed to be converted into a form of invert sugar, seems to indicate that the presence of amylase is necessary for the transformation of starch into glucose. The experiments are briefly summarized by the authors, who claim that the intramolecular respiration of seed and of all vegetable organisms whose products of respiration are formed from hydrolysable carbohydrates is identical with alcoholic fermentation. In the absence of air, peas not only ferment the carbohydrate reserves, but accomplish the decomposition of such carbohydrates as glucose and saccharose which have been artificially added. In pure water peas transformed 22 per cent of their original dry matter into alcohol, and in the glucose solution 27 per cent was produced. The fermentation of starch presupposes the formation of amylase, and the decomposition of saccharose depends upon inversion. It is believed that the formation of enzymes in the absence of oxygen depends upon the nitrogenous material present, and they can not be considered as oxidation products of albuminoids. In a solution of saltpeter peas were able to partially reduce the nitrate, but the nitrite formed ultimately destroyed the seed. The intensity of intramolecular respiration is directly dependent upon the temperature, but the total production of alcohol and carbon dioxide is independent of it. Different kinds of seeds vary in their respiratory capacity, those of legumes possessing it in a high degree, cereals less so, and in oil-bearing seeds it is reduced to a minimum. Intramolecular respiration or alcoholic fermentation is the first phase in the normal respiration of plants whenever that depends upon the hydrolysis of carbohydrates. Whenever there are no carbohydrate reserves, respiration is dependent upon the direct action of oxygen, but there is no relation between these two functions. The chemical processes which take place within the plant cell during respiration are not identical with all cells of the same type, but the phenomena vary with the nature of the material entering into the respiration.

Tests of the vitality of seed grain and other seeds for 1901, W. SAUNDERS (*Canada Expt. Farms Rpts. 1901, pp. 58, 59*).—A report is given of a number of samples of seed grain and other seeds which were tested for vitality during the season of 1901. The total number of samples tested was 2,385, of which 900 were wheat, 312 barley, 972 oats, and the remainder mostly field and garden seeds. The maximum and minimum percentages, as well as the average vitality, for the lot are shown. In some instances the averages are quite low, due to the fact that a number of samples of very low germinative ability were tested. A table is also given showing the results of the grain tests for each province.

How long may beet seed be stored? F. LUB. NSKI (*Bt. Zuckerrübenbau, 8 (1901), No. 17, pp. 259-263*).—An account is given of experiments conducted at the experiment station of Nemerze, Podolia, Russia, on the vitality of stored beet seed. Two lots of seed of the harvest of 1892 were selected for the experiment, half of which were stored in a double linen bag, the other hermetically sealed in a jar. Beginning in 1893, samples of seed from each lot were tested bimonthly for 3 years, and thereafter semiannually for 4 years. In every case a gradual diminution in vitality was noted, the seed kept in sacks falling from an average of 133.1 to 50 germinations per 100 seed bolls in 14 days and those hermetically sealed depreciating from 133.7 to 0 germinations in the same time. When tested at bimonthly periods the seed gave higher percentages of germination during the spring and summer months than when tested during the winter.

Report of the Skara Chemical and Seed-Control Station, 1901, S. HAMMAR (*Ber. Verks. Skara Kem. Sta. Frökontrollanst., 1901, pp. 32*).—Chemical analyses to the number of 6,482 were made during the year, and 353 tests of seed and 686

kg. of oats were certified to. Cereals, clover, and grass seed were most commonly submitted for examination for their purity, germination ability, etc.

Weed seed as an indicator of the origin of clover and grass seed, O. BURCHARD (*Landw. Vers. Stat.*, 56 (1902), No. 4, pp. 297-302, pl. I).—In continuation of the opinions expressed in the author's book relating to this subject (E. S. R., 11, p. 1054), a further discussion is given of the value of the weed seed contained in clover and grass seed as an indication of the region in which the seed was grown. The author still maintains that certain common weed seed characterize the clover and grass seed of different countries. Descriptions are given of a number of species of weed seed which are occasionally found in clover and grass seed imported into Germany. The species described are *Apiastrum patens*, found in timothy seed from North America; *Verbena angustifolia*, *Solanum carolinense*, and *Cuphea viscosissima*, in North American red clover seed; *Grindelia squarrosa*, in alfalfa seed from the United States; *Argemone alba*, in South American alfalfa seed; and *Sideritis scordioides* and *Leontodon crispus* in red clover seed from the south of France.

Noxious weeds, T. N. WILLING (*Rpt. Dept. Agr. Northwest Territories*, 1901, pp. 56-64).—A report is given by the chief inspector of noxious weeds of the inspection work conducted during the past season for the enforcement of the law relative to the destruction of noxious weeds. This includes inspection of farms, public lands, etc., as well as elevators and mills. Attention is called to the necessity of the use of clean seed in sowing to prevent the spread of weeds. On the whole the enforcement of the law is in a fairly satisfactory condition.

New method for combating wild radish and mustard, HEINRICH (*Landw. Ann. Meckl. Patriot. Ver.*, 1900, No. 26, pp. 201-203; *abs. in Centbl. Bakt. u. Par.*, 2, Abt., 8 (1902), No. 23, p. 749).—The results of experiments in which 15 to 40 per cent solutions of Chili saltpetre, ammonium sulphate, and potassium chlorid were sprayed over weed-infested fields. The weeds were affected similarly as when sprayed with an iron sulphate solution, while the cereals, clover, peas, vetches, lupines, and beets were not injured. The cost of the application, when the fertilizing value of the solution is considered, is not so great as other means that have been recommended.

DISEASES OF PLANTS.

Plant diseases of 1901, W. PADDOCK (*Colorado Sta. Bul.* 69, pp. 23, pls. 9).—The principal purpose of this bulletin is to stimulate a greater interest in plant diseases and call attention to some of the prevailing ones. Among those mentioned are apple-tree root rot, apple-tree rosette, injury of apples from improper spraying with Bordeaux mixture, blackberry-root disease, asparagus rust, aster wilt, currant cane disease, grape anthracnose, pea-root disease, plum-leaf blight, potato diseases, strawberry-leaf blight, and stinking smut of wheat.

The apple-tree root rot was noted in various localities in the State, and is usually indicated by the yellow foliage of the trees. Certain fungi are constantly associated with the diseased roots, and it is thought probable that they may be ultimately responsible for the destruction of the tree. Investigations showed, however, that much of the injury was due to overirrigation and lack of drainage of the soil.

The apple-tree rosette is reported from a number of orchards which were inspected by the author and numerous specimens secured. No parasitic organism of any kind could be discovered and the conclusion is reached that the nature of the soil was probably the primary cause of the disease. The orchards were planted in a soil which contained an excess of marl, in some places the substance forming a solid substratum. During the early part of the season water is plentiful but later the supply usually becomes exhausted. The soil rapidly dries out and the trees suffer from the lack of moisture, consequently the growth stops and the tissues harden. Later in the

season the supply of water is restored and the orchard irrigated, with the result that in many instances distinct second growth is made which is immature when winter sets in, and the branches are either killed outright or severely injured. Second growth is not always necessary for the appearance of the disease, as was shown by examinations in a number of orchards. The soil is estimated to contain 1,820 lbs. of common salt per acre, taken to a depth of 1 ft. In addition, sodium carbonate is very abundant, and it is probable that these alkalis exert an injurious effect upon the trees. Attention should be paid to the nature of the soil where the orchards are planted, and irrigation water should be judiciously used to prevent the occurrence of the disease. A number of instances are cited in which the Ben Davis apple suffered severe injury due to applications of Bordeaux mixture. It is thought probable that it will be necessary to modify the formula commonly recommended for spraying trees of this variety.

The blackberry-root disease, due to *Rhizoctonia* sp., has proved quite destructive about the station. There appears to be no cure for the disease, and the destruction of all affected plants is recommended as a preventive measure.

The occurrence of the asparagus rust (*Puccinia asparagi*) is mentioned. Asters planted in the college campus are said to have been almost entirely destroyed by attacks of species of *Fusarium*. This fungus seems to have been present in the soil, and it is recommended that the beds be removed or the soil replaced with fresh earth.

The pea-root disease proved one of the most destructive of the diseases under investigation during the season reported upon. The author's attention was first called to it in September, 1900. During the following winter soil from infected fields was secured and greenhouse experiments conducted with it. Plants in the soil were nearly always attacked by fungi on the roots and stems below ground, and although attempts to cultivate the fungus artificially failed, the distinctive characteristics showed that it belonged to the genus *Rhizoctonia*. A potato disease due to *Rhizoctonia* sp. was under investigation at the same time, and inoculation experiments were undertaken with the potato organism. While the experiments did not prove conclusively that the *Rhizoctonia* disease of potatoes was the cause of the trouble with peas, the indications pointed strongly to this conclusion. For the prevention of the potato disease and the stinking smut of wheat treatment with corrosive sublimate or formalin solutions is recommended.

Report of the botanists, G. E. STONE and R. E. SMITH (*Massachusetts Sta. Rpt. 1901, pp. 57-85, figs. 3*).—During the season covered by the report a number of species of fungi affecting shade trees have been observed. Among these are the *Gleosporium nervisequum*, which caused the partial defoliation of the white oak throughout the State, *Gleosporium* sp. on maple and sycamore, *Dothidea ulmi* on elm, and *Cercospora microsora* on the European linden. The dying of cut-leaved birches was quite prominent in the eastern part of the State during the summer. The cause of the trouble was incidentally due to borers, but it is thought that the drought of the previous season was the primary cause of the trouble.

The chrysanthemum rust, which was first noticed in the State in 1896 and has since extended over a large portion of the United States, is considered at some length. The disease was most prevalent in 1897 and 1898, and during the past 3 years has shown a marked tendency to decrease. Various remedies have been tried by different growers, and the practice of inside culture during the summer has proved very beneficial in obtaining plants free from rust. Most growers now consider the chrysanthemum rust of little consequence, and, so far as the authors' observations go, the proper remedies lie in the judicious selection of healthy rust-free stock and inside cultivation.

The practice of desiccation, or drying of greenhouse soils by the aid of the heat of the summer sun, has been followed for some time to observe the effect of such treat-

ment on certain organisms. The drop fungus of lettuce (*Sclerotinia* sp.) is greatly accelerated in its activity by such treatment. The resting spores of many other fungi are doubtless affected in the same way. With lettuce it has been repeatedly observed that such drying of soil results in a stunted growth, producing an abnormally colored and worthless crop. The texture of the plants is poor, the leaves being thick and tough and inclined to crinkle. As showing that this condition is brought about by desiccation alone, it is stated that wherever any drip from the roof fell upon the soil plants grown in such places were always normal, and distinctly sharp lines can be observed in the lettuce crop grown under such conditions. It is suggested that the soil in lettuce houses should not be allowed to become too dry during summer, but if this occurs the soil can be renovated by applying hot water or steam to it, as has been previously shown.

During the past season the growing of muskmelons was attended with considerable loss due to the melon blight caused by *Alternaria* and the anthracnose (*Colletotrichum lagenarium*) as well as the attacks of the downy mildew (*Plasmopara cubensis*). The *Alternaria* during the season was less abundant than previously, but the anthracnose was quite common. The downy mildew has been comparatively unknown up to the present time when it occurred upon muskmelons over widely extended areas. With the exception of the anthracnose, the chief troubles with melons occur about September 1 as the fruit begins to mature. As considerable success has been attained by spraying for the prevention of these diseases, the authors suggest thorough spraying throughout the season, beginning as early as July 1.

The stem rots of chrysanthemums, carnations, and asters are described at some length, the latter disease having already been noted (E. S. R., 13, p. 1060).

The asparagus rust continues to be a serious factor among the large growers of this vegetable. A large number of inquiries have been instituted in which the effects of dew, elevation, and shelter on infection were investigated. In no instance was the shelter produced by forest growth found to exert any beneficial influence; but there seemed to be considerable differences in the amount of the disease apparently attributable to the slope of the ground. It is possible that dew plays a part in asparagus rust infection in those regions where the conditions are favorable for an outbreak from the uredospore form of the fungus. Experiments in spraying were conducted, following the recommendations of the New York State Station (E. S. R., 13, p. 147). This method proved an expensive one and asparagus growers do not favor it. Fully as beneficial results were obtained by an application of Paris green. This method is a cheap one and is considered worthy of further trial.

The sterilization of soil in greenhouses for the prevention of fungus diseases has been under consideration at the station for a number of years. It has been recommended for the extermination of soil fungi such as *Rhizoctonia*, *Pythium debaryanum*, nematode worms, *Botrytis* sp., etc. During the past year the commercial use of this method has been greatly extended. The effect of sterilized soil on the growth of plants has been noted, and for the purpose of determining this factor 2 beds of equal size were selected, one of which was treated with hot water until the soil was soaked and showed an average temperature of 145° F. at a depth of 4 in. The seed was planted in boxes of earth which had been heated to 212° F. with steam. The other bed remained untreated, the only difference in the 2 lots being the hot-water treatment. These beds were planted to lettuce and the weight of the largest as well as the weight of typical plants showed a gain of 33 per cent in favor of the plants grown upon the treated soil. Various methods of sterilizing on a commercial scale are described at considerable length.

Notes on fungus diseases, H. H. LAMSON (*New Hampshire Sta. Bul.* 87, pp. 127-130).—Brief descriptive notes are given, together with suggestions for the pre-

vention of the peach-leaf curl, plum rot, peach rot, downy mildew of the grape, cucumber and muskmelon downy mildew, and apple-tree canker.

Studies in smut diseases of cereals and their prevention, C. VON TUBERTZ (Arb. K. Gesundheitsamte, Biol. Abt., 2 (1901), No. 2, pp. 179-349).—A description is given of the principal smuts affecting cereals, and suggestions given for their prevention.

New species of Uredineæ, J. C. ARTHUR (Bul. Torrey Bot. Club, 28 (1901), No. 12, pp. 661-666).—The author describes a number of new forms of Uredineæ which have been sent him from various localities in the United States, the type specimens of which are retained in its herbarium. The species described are as follows: *Puccinia batesiana*, *P. epicampus*, *P. xylorrhizæ*, *P. vilis*, *P. panicularia*, *Æcidium boltoniæ*, *A. magnatum*, *A. anogræ*, *Peridermium ornamentale*, *Gymnosporangium nelsoni*, *Rastelia nelsoni*, *R. fimbriata*.

A new disease of alfalfa, G. POLLACCI (Separate from Atti Inst. Bot. Univ. Paria, VII, pp. 6, pl. 1; abs. in Ztschr. Pflanzenkrank., 11 (1901), No. 4-5, pp. 285, 286).—A disease of alfalfa is described which is said to be due to an undescribed fungus to which the author gives the name *Pleosphaerulina briosiana*. This fungus forms ash-gray spots with brownish borders on the leaves. The spots increase and run together, finally destroying the leaves. In addition to alfalfa, it is reported as occurring on the related species (*Medicago falcata*).

Clover anthracnose, B. MEHNER (Ztschr. Pflanzenkrank., 11 (1901), No. 4-5, pp. 193-196).—During the summer of 1901 clover anthracnose was noted in a number of localities in Germany as affecting the red clover. The disease in some regions proved very destructive, 25 or 30 per cent and sometimes more of the plants being killed. The fungus which causes the disease was identified as *Glaeosporium trifolii*. Investigations made on the disease seem to indicate that it spreads during the growing season by means of the conidia, and that it survives the winter as mycelium and in pycnidial form in the tissues of the clover plants. This disease is thought to have been introduced from America through clover seed, and is more destructive to plants grown from American than from German seed, the American being a more hairy plant, is more subject to disease.

Potato failures, F. M. ROLFS (Colorado Sta. Bul. 70, pp. 20, pls. 12).—Numerous inquiries had been received from potato growers regarding a failure of the crop, and investigations showed that the trouble was due to attacks of *Rhizoctonia solani* (E. S. R., 13, p. 55), which is an active parasite of the potato plant. The annual loss in the State from this disease is quite large, and it is reported as quite common in the potato fields of New York, Ohio, Iowa, Minnesota, Florida, Oklahoma, Texas, Colorado, California, and Washington. The effect of the fungus on the potato plants is described, one of the common results being the formation of an abnormal number of very small potatoes of no marketable value. The organism is peculiarly a soil fungus, and the disease may be transmitted through the use of infected seed. Inoculation experiments are reported in which the disease was readily produced. Examination of a lot of potatoes during the planting season showed that 91 per cent were more or less covered with sclerotia of the fungus. The disease may be carried not only by potatoes but also by beet roots, dead potato stems, or on the dead stems of many weeds which grow in potato fields. The results of seed treatment with corrosive sublimate and formalin solutions indicate that the diseased potatoes may be readily disinfected by such treatment, but in order to secure good results the treated seed must be planted in soil which is free from disease. When a field has become thoroughly infected with the disease the fungus will doubtless remain in the soil for a number of years. Attention should be paid to the sorting and disinfecting of the seed tubers, and by practicing a long and systematic rotation of crops the soil may be prevented from becoming badly infested with this fungus.

Study of a new bacterial disease of the potato, G. DELACROIX (*Compt. Rend. Acad. Sci. Paris*, 133 (1901), No. 24, pp. 1030-1032).—In a previous publication (E. S. R., 13, p. 1058) the author described a bacterial disease of potato which was then attributed to the organism which had been previously described as *Bacillus solanacearum*. Subsequent studies have led to the conclusion that the disease in question is not to be attributed to this organism but to another, apparently undescribed, to which the name *B. solanincola* is given. The effect upon the host and the action of the organism in various media are described. The author states that tomatoes are also affected by this organism, but that they are less susceptible than potatoes. The organism is believed to be present in the soil, from which it spreads to the plants, and unfavorable meteorological conditions are a contributive cause of the infection. Associated with it is frequently found the fungus *Rhizoctonia solani*, which proves quite destructive, and the mycelia of other fungi have also been isolated. Their presence is attributed, however, to the penetration of the plant by the bacteria.

Asparagus rust, W. T. MACOUN (*Canada Expt. Farms Rpts.* 1901, pp. 110-112).—The asparagus rust (*Puccinia asparagi*), which has been reported from a number of localities in the United States within the past 5 years, has made its appearance in Canada, being reported at the Central Experimental Farm for the first time during this season. The life history of the fungus and suggestions for its treatment are given, the statements being largely compiled from New York State Station Bulletin 188 (E. S. R., 13, p. 147).

Cantaloupe blight in 1901, H. H. GRIFFIN (*Colorado Sta. Bul.* 68, pp. 12-14).—In continuation of the investigations on this disease (E. S. R., 13, p. 362), work was planned in treating the seed with Bordeaux mixture, and in spraying to determine the time at which it is most efficient. The work attempted at the station grounds was destroyed by a hail storm the latter part of July. Sprayings at a number of localities reaffirmed the general efficiency of Bordeaux mixture. Two prominent features were brought out in the investigation, one of which was the necessity of avoiding the use of heating manures previous to planting melons, and the other the need of rotation of cantaloupes with other crops. Comparisons between fields planted the latter part of March and early in May showed that while the season was one of the most favorable for extremely early planting there was no advantage over planting a month later.

Nematodes as enemies of garden plants, A. OSTERWALDER (*Gartenflora*, 50 (1901), No. 13, pp. 337-346, pl. 1, fig. 1).—A description of nematodes, together with suggestions for their eradication are given.

Canker of apple trees, H. HASSELBRING (*Illinois Sta. Bul.* 70, pp. 225-239, pls. 4).—Descriptions are given of some of the fungi which cause diseases known as canker of fruit trees, and of a new canker disease, designated as the Illinois apple-tree canker, which is doing serious damage in the apple orchards of Illinois. This canker is caused by the fungus *Nummularia discreta*, which has long been known, and as a saprophyte has frequently been reported on various hosts in Europe and America, but hitherto has not been reported as a parasitic organism. The disease was first noticed in the apple-growing regions of southern Illinois during the past season. Within an infected orchard the disease is usually scattered, the infected trees occurring here and there. The canker wounds are usually formed on the larger limbs near the trunk of the tree, from which they extend upward on the limb, and frequently down into the trunk. The appearance of the canker varies with age. At first the spots are inconspicuous, so that they are readily overlooked by the casual observer. In the earliest stages the diseased bark has an unhealthy, dirty brown appearance, and is usually depressed a little below the living bark. The spots vary in size, sometimes attaining a diameter of 6 in. They grow most rapidly in the direction of the long axis of the limb. The interior of the spot has a mottled appear-

ance, due to sound areas scattered here and there throughout the dead tissue. The boundary between the dead and sound bark is usually sharply marked, sometimes cracks appearing along the boundary. Often the wound is accompanied by a flow of sap, which is probably a secondary phenomenon not due to the parasite. Late in the summer or autumn the fruiting bodies of the fungus appear near the margin of the diseased spot. These are produced under the bark, which soon splits, forming star-shaped ruptures and exposing the pale grayish-yellow spore cushions, which are $\frac{1}{4}$ to $\frac{1}{2}$ in. in diameter. As the canker spots increase in size they change in appearance, the bark in the older part becoming rough and blackened, as though charred. The entire blackened area is dotted over by these circular stomata, which form the most pronounced distinguishing feature of this disease. The injury which the fungus causes is first local, being restricted to the area of the canker spot; but the rapid advance of the mycelium along the longer axis of the limbs spreads the disease, so that branches may sometimes be diseased for a distance of 2 or 3 ft. before they are finally and completely girdled.

So far as the observations of the author go, the fungus is a wound parasite, and on this account care should be exercised not to injure the bark, and in pruning to cover wounds with paint or some fungicide. Badly diseased limbs should be cut and burned, and when first noticed the removal of the bark with a portion of the underlying tissue, and covering the wound with paint or Bordeaux mixture, is recommended.

Notes on spraying for bitter rot, J. T. STINSON (*Missouri Fruit Sta. Bul. 2, pp. 20, figs. 4*).—Suggestions are given for the spraying of apple trees, and the time of application, formulas for use, and machinery are described. A report is also given on experiments in the prevention of bitter rot of apples. The trees were sprayed with Bordeaux mixture, the foliage and fruit being well covered with the fungicide during July and August. In every case the amount of marketable fruit from the sprayed trees equaled or exceeded that from the unsprayed, but the fruit from the unsprayed trees was the more highly colored. The investigations showed that Bordeaux mixture as used was injurious to some varieties, particularly the Ben Davis.

Brown rot of peaches and plums, C. C. NEWMAN (*South Carolina Sta. Bul. 69, pp. 12, figs. 3*).—It is said that the peach crop has proved an almost total failure in many sections of the State, due to the attacks of the fungus *Monilia fructigena*. The fungus is popularly described, and for its prevention spraying with Bordeaux mixture is recommended. A formula is given for Bordeaux mixture; and the cost of 4 applications for 6-year-old trees is estimated at 6 cts. per tree, or for 10-year-old trees about 12 cts. per tree. The importance is pointed out of destroying the decayed fruits in order that the fungus should not be carried over the winter. A tabular statement is given showing the results of spraying 60 varieties of peaches. All of the early varieties received 3 applications, the later ones 4 and 5, and the very late-ripening 6 sprayings. As a result of the spraying the amount of sound fruit is said to have been increased by from 25 to 75 per cent.

A new disease of orange, T. FERRARIS (*Separate from Malpighia, XIII, pp. 14, pl. 1; abs. in Ztschr. Pflanzenkrank., 11 (1901), No. 4-5, pp. 291, 292*).—An account is given of a rot of the orange fruit which is due to *Oidium citri-aurantii*, n. sp., which is described. Pure cultures of it were grown on agar containing orange juice, and from these cultures sound oranges were inoculated, producing the disease.

Coffee diseases in Brazil, F. NOACK (*Ztschr. Pflanzenkrank., 11 (1901), No. 4-5, pp. 196-203, pl. 1*).—The author describes at considerable length some of the more destructive diseases of coffee which have been observed upon the coffee trees in Brazil. Those described are due to the fungi *Cercospora coffeicola*, *Mycosphaerella coffea*, and *Colletotrichum coffeanum*, the latter two being described as new species. The

different fungi are described in detail and the effect produced upon the host plants is shown. While originally reported from Brazil, these fungi are known from other localities.

On the use of potassium permanganate against oidium, B. CHAUZIT (*Rev. Vit.*, 16 (1901), No. 416, p. 631).—An account is given of the successful use of a 2 per cent solution of potassium permanganate in protecting 2 exceptionally susceptible varieties of table grapes against attacks of oidium. The question of the probable presence of the permanganate in wines made from grapes treated with this solution has been raised, and the author shows that it is hardly probable that any of the fungicide will find its way into the wine.

A new factor in combating mildews, F. W. NEGER (*Ztschr. Pflanzenkrank.*, 11 (1901), No. 4-5, pp. 207-212).—In combating the powdery mildews the author calls attention to the necessity of ascertaining the form in which the fungus passes the winter and mode of distribution of the spores, grouping the different powdery mildews into two classes based upon this factor.

Life history and means for detection of timber rot fungi and similar organisms, G. MARPMANN (*Centrl. Bakt. u. Lar.*, 2. Abt., 7 (1901), No. 22, pp. 775-782).—Notes are given on *Merulius lacrymans*, *Polyporus* spp., *Trametes radiciperda*, *Agaricus melleus*, etc.

A fungus disease of juniper, A. VON JACZEWSKI (*Ztschr. Pflanzenkrank.*, 11 (1901), No. 4-5, pp. 203-207, figs. 7).—A description is given of a disease of junipers caused by *Erosporium juniperinum*. This fungus has been previously described under the name *Coryneum juniperinum*. Subsequent to this description it was given the name *Erosporium defletans*, and as the fungus belongs to the latter genus the author has made the transformation of the specific name to conform with the recent laws of botanical nomenclature. In addition to this fungus, the author reports the occurrence of another (*Hendersonia notha*) as sometimes occurring, as well as a second species (*H. follicola*).

Studies on *Xecidium elatinum*, E. FISCHER (*Ztschr. Pflanzenkrank.*, 11 (1901), No. 6, pp. 321-343, figs. 4).—This fungus, which is said to cause the hexenbesens on silver fir, has been studied by the author and its uredo and teleutospore forms determined. The uredo and teleuto forms are reported as having been found upon various species of *Cerastium* and *Stellaria*. The inoculation experiments are reported on a large number of species of plants representing widely varying orders of plants. Experiments are also reported on the production of hexenbesens from material obtained from species of *Stellaria*, etc.

The poplar rust, J. FLETCHER (*Canada Expt. Farms Rpts.* 1901, pp. 259-261).—The poplar trees of the Northwest Territories (*Populus tremuloides*) are reported as badly affected by the fungus *Melampsora populina*, and as a result of the attacks the trees are frequently defoliated. A similar fungus is reported on the birch foliage. Most of the young seedlings planted in this region are imported from Minnesota and Dakota, and it is noted that those varieties of poplar which have been imported from Russia have so far escaped the attacks of the fungus. If they should continue to show this immunity their importance for tree planting in the West would be greatly increased.

Maple seed blight, J. FLETCHER (*Canada Expt. Farms Rpts.* 1901, p. 259).—During the summer of 1901, at Indian Head and the surrounding district, the seed of the ash-leaved maple (*Negundo aceroides*) were found seriously attacked by a fungus which proved to be a species of *Fusarium*. When trees are affected by this disease the seed show the injury, the edges of the wing becoming bleached and spotted, and the seeds fail to fill. The importance of the ash-leaved maple as a shade tree in the West can scarcely be overestimated, and should this disease persist it would be necessary to grow seedlings from seed obtained from localities which are not infested.

The action of copper on leaves. S. M. BAIN (*Tennessee Sta. Bul.*, Vol. XV, No. 2, pp. 21-108, pls. 8, fig. 1).—This bulletin gives the results of investigations begun in 1895 and continued with some interruption until 1901, a preliminary account of which has already been given (*E. S. R.*, 13, p. 866). The object of the experiments was to ascertain the effect of fungicides on peach foliage, which might be of economic value in the treatment of the diseases of that plant. Comparative studies were made on the effect of fungicides on apple and grape. The poisonous action of copper solutions introduced through the roots, the action on the leaves and conditions affecting the action, the permeability of the cuticle of the leaf and its relation to the action of fungicides, wound healing of the leaves and leaf fall, and the influence of copper on the assimilative function of leaves are all discussed at considerable length.

From the evidence presented there appears to be little doubt that copper is absorbed by the leaves of plants sprayed with Bordeaux mixture. The conclusive and final evidence of the entrance of copper into the tissues of the leaf is a subject for future investigation. One of the first conditions permitting the absorption of any substance by the leaf is that the substance shall be either a liquid or dissolved in a liquid. The injury to peach foliage caused by copper is the same whether supplied in the form of a soluble salt or an insoluble hydrate. There appears to be some substance escaping from the peach leaf which has a solvent action on copper hydroxid, but the nature of this substance is as yet not known. It is shown that while peach leaves are able to dissolve copper hydrate, the presence of lime has a tendency to prevent this solvent action and retards or wholly prevents the injury of copper to the leaves. One of the most important features in this connection is the solubility of copper applied to the leaves. Attention is called to the action of the so-called strong and weak Bordeaux mixtures. If properly made, these differ only in the amount of copper hydrate deposited upon the leaves. An excess of lime in Bordeaux mixture has a tendency to retard the rate of the entrance of copper into the leaf by simply preventing the copper from passing into solution. Another important factor controlling the entrance of copper into the leaf is the presence of water. It is shown by the author's experiments that no injurious effect follows the spraying of peach leaves, providing they are not exposed to rain or dew. Another factor to be considered is the rate of entrance of the copper into the leaf through the permeability of the leaf cuticle.

Summing up his investigations, the author concludes that peach foliage is very susceptible to injury by fungicides because the leaves are especially sensitive to poisons in general and to copper in particular. Peach leaves have the power, which may or may not be possessed by other leaves, of dissolving copper hydroxid. They have a cuticle which is thinner and more permeable than many other leaves, and the glandular surfaces terminating their marginal teeth are especially fitted for the absorption of copper in solution by reason of their thin cuticular covering. Peach leaves are especially sensitive to the various agencies producing leaf fall by the production of a normal abscissal layer. They have the power, in common with other leaves of the same genus, to exfoliate any injured region, and this involves much more than the really injured cells. If this process removes a large portion of the lamina, the whole leaf falls. As a practical suggestion for the prevention of injury the author recommends the spraying of leaves with a thin solution of milk of lime about 2 days in advance of the spraying with Bordeaux mixture. This will offer considerable protection to the leaves against the injurious action of the copper, and the Bordeaux mixture lying above the stratum of calcium carbonate can act upon any fungus spores coming in contact with it. An extensive bibliography on the subject concludes the bulletin.

Some recent work with fungicides by the experiment station. A. D. SELBY (*Proc. Columbus Hort. Soc.*, 16 (1901), pp. 134-136).—A report is given of experiments

conducted by the Ohio station on spraying a vineyard and on treating onions for the prevention of disease. The vineyard received 7 applications of fungicides, the first 4 of Bordeaux mixture and the last 3 of ammoniacal copper carbonate. These were applied at a cost of about \$6.50 per acre. The fruit produced on the unsprayed tract was of an inferior quality and sold at the rate of about \$6 per acre. The sprayed tract gave a gross return of \$122 per acre. When soda-Bordeaux mixture was used to follow the ordinary Bordeaux, an increase of \$18 per acre over the above sum was noted.

Experiments with onion smut treatment consisted of the application of ground lime to the soil just before seeding the onions and the sprinkling of a solution of formalin on the scattered seed. The results obtained show that either of the two methods is a better remedy than any heretofore used for onion smut prevention in infected soils.

The solubility of a mixture of copper and sodium sulphates, MASSOL and MALDES (*Compt. Rend. Acad. Sci. Paris*, 133 (1901), No. 5, pp. 287-289).—The solubility of copper and sodium sulphates when mixed in varying proportions has been determined. It was found that at different temperatures the different compounds vary in their strength of solution. At comparatively low temperatures there is ordinarily little variation in the composition of the solution, but if the temperature be raised to from 23 to 33° C. the composition of the solution will vary in proportion to the relative amount of the 2 salts in the mixture.

ENTOMOLOGY.

Some insects injurious to vegetable crops, F. H. CHITTENDEN (*U. S. Dept. Agr., Division of Entomology Bul. 33, n. ser., pp. 117, figs. 30*).—The author presents descriptive, biological, and economic notes on a large number of insects injurious to various garden crops. Brief mention may be made of the following species which are discussed by the author:

Potato stalk weevil (*Trichobaris trinitata*) (pp. 9-18).—This insect is distributed on the north to Pennsylvania, New Jersey, Illinois, Iowa, and even into Canada; in the South the insect is found as far as Florida and Texas. The beetles were seen in the District of Columbia as early as May 20. The pupal stage is said to vary from 8 to 11 days. All the beetles mature by September and hibernation takes place in the adult stage. The insect is attacked by *Sigalphus curculionis*. The best remedy for this insect consists in pulling up infested vines as soon as they begin to wilt and destroying all vines in the field as soon as the crop is harvested. All solanaceous weeds in the neighborhood of the potato patch should also be burned.

The northern leaf-footed plant bug (*Leptoglossus oppositus*) (pp. 18-25).—The species of this genus live in all of their stages preferably upon the fruit of the plants which they attack. There is but one generation per annum of this species. The fruit plants are usually cucurbits, but hibernated adults may appear on fruit trees in the spring. The insect is attacked by *Trichopoda pennipes*. The best remedies are hand picking, capturing in inverted umbrellas or nets saturated with kerosene, and free use of kerosene emulsion.

The carrot rust fly (*Psila rosæ*) (pp. 26-32).—This pest caused much damage in a celery field in New York during 1901. The insect occurs in England, continental Europe, and has been for some years known to be an injurious species in Canada. The life history of the carrot rust fly has not been carefully worked out. It is attacked by *Alysia apii*. The best methods of control are the use of kerosene emulsion, late sowing, rotation of crops, destruction of insects in stored carrots, and direct treatment of the insect in celery beds.

The carrot beetle (*Ligyrus gibbosus*) (pp. 32-37).—This insect is described and notes are given on its habits and life history. It is distributed from Long Island to Cali-

ifornia, and in the Gulf States. It is perhaps the most injurious species of carrot insect in this country. The knowledge of the life history of the insect is still incomplete. Some larval injury has been noted, but the larvae frequently feed on humus, manure, and decomposing roots. The species is single brooded. One species of bird, chuck-will's-widow, is reported as feeding on the beetles in the adult stage. The best remedy for this insect consists in the use of lantern traps and scattering lime through infested fields.

The beet army worm (Laphygma exigua) (pp. 37-46).—This species is evidently of foreign origin, and has gradually spread from California eastward into the eastern portion of Colorado on the Atlantic side of the Continental Divide. It was first reported as injurious by C. P. Gillette, in Colorado, and has subsequently been noted as quite injurious in that State. Sugar beet is its favorite food plant, but the insect also feeds upon lamb's quarters, pigweed, corn, potato, peas, onions, etc. The caterpillar is sometimes parasitized by *Frontina archippivora*. The best methods of fighting this insect are by means of Paris green and kerosene emulsion. Brief notes are given on garden webworms (pp. 46-49). The species considered are *Loxostege similis*, *L. sticticalis*, and *Hellula undalis*.

The red turnip beetle (Entomoscelis adonidis) (pp. 49-53).—This species is said to be common to North America, Europe, and Asia, and to be generally distributed over these countries. The eggs are usually laid in the autumn and the species hibernates in the egg stage. The red turnip beetle may be destroyed by the remedies which are commonly used against Colorado potato beetle.

The cross-striped cabbage worm (Pieris rimosalis) (pp. 54-59).—This species agrees very closely in its life history with the imported cabbage butterfly. A number of parasitic insects of the genus *Apanteles* have been bred from it. The best remedy is perhaps Paris green applied dry or as a spray. Other remedies may be tried, such as bran mash, kerosene emulsion, pyrethrum, mechanical methods, clean cultivation, trap crops, and spraying with water.

The cabbage looper (Plusia brassicae) (pp. 60-69).—This species usually feeds on Cruciferae, but also attacks asparagus, clover, and various greenhouse plants. It is parasitized by 1 or 2 species of insects, and is preyed upon by black and white spiders. A number of larvae were found apparently suffering from a bacterial disease which was not determined. A fungus disease (*Botrytis rileyi*) sometimes causes the death of the larvae. The artificial remedies may be the same as those recommended for cross-striped cabbage worm. *A new cabbage looper (P. precatonis)* (pp. 69-72), was observed attacking cabbage and other garden plants in the District of Columbia in 1900. The moth is generally distributed east of the Rocky Mountains. The best remedy for this species is probably Paris green.

The celery looper (Plusia simplex) (pp. 73, 74).—This species appears throughout the season in a large number of localities east of the Rocky Mountains. It may be destroyed by the use of Paris green.

Notes on Dipterous leaf miners on cabbage (pp. 75-77).—A brief account is given of the feeding habits and life history of *Scaptomyza flaveola*, *S. adusta*, *S. graminum*, and *Agromyza diminuta*.

Notes are given on a considerable number of insects injurious to cabbage, especially late cabbage, and similar crops (pp. 77-84). The species discussed in this section are *Phyllotreta bipustulata*, *Ceutorhynchus rapae*, *C. quadridens*, wasps as destroyers of cabbage worms, cabbage-root maggot injurious to celery, cabbage-plant louse, diamond-back moth, harlequin cabbage bug, imported cabbage butterfly, and cabbage looper. The desirability of keeping up applications of insecticides late in the fall is urged upon gardeners.

Notes on insects injurious to peas and beans are presented on pages 84-110. The species upon which notes are given include *Phorbia fusciceps*, which attacks the seeds and sprouting plants of various kinds of beans and corn, and which may be checked

by placing sand soaked in kerosene around the seed when planted; *Eurymus proteus*, which is apparently injurious only in Florida and a few other Southern States and may be controlled by spraying with Paris green; *Semasia nigricans*, the injuries of which may be partly controlled by planting very early and late varieties of peas, by clean culture, and early fall plowing. *Ogdoconta cinereola*, which injures the foliage and pods of beans, is distributed generally east of the Rocky Mountains, has no parasitic or predaceous enemies, and may be best controlled by spraying with arsenate of lead; *Uranotes melinus*, *Ceratomyia trifurcata*, *Monoptilota nubellula*, *Diabrotica atripennis*, *Spermophagus pectoralis*, pea weevil, bollworm, fall webworm, *Halticus uhleri*, *Acanthocercus galeator*, *Alydus eurinus*, leaf hopper, *Aphis rumicis*, and wireworms.

Notes are also given on a number of flea-beetles (pp. 110, 117), including the following species: *Systema blanda*, *S. frontalis*, *S. hudsonias*, *Chaetocnema denticulata*, *C. pulicaria*, *Disomycha xanthomelana*, and *Epitrix fuscula*.

Proceedings of the Entomological Society of Washington (*Proc. Ent. Soc. Washington*, 5 (1902), No. 1, pp. 92, pl. 1, figs. 2).—In this number of the proceedings various articles on entomological subjects are contained. A considerable proportion of the articles are given in abstract and are reprinted elsewhere. The papers read at the various meetings of the Society include the following:

Some Insects from the Summit of Pikes Peak, Found on Snow, by A. N. Caudell; Evolutionary Inferences from the Diplopoda, by O. F. Cook; A Review of the Species of Haploa, A New Form of *Clisiocampa* from Colorado, A Lepidopterous Larva on Leaf-hopper, Illustrations of the Early Stages of some Diptera, and The Collection of Lepidoptera in the National Museum, by H. G. Dyar; Hemiptera from the Summit of Pikes Peak, Found on Snow, by O. Heidemann; Some Notes on the Genus *Dendroctonus*, and A New Genus of Scolytids from Florida, A. D. Hopkins; Notes upon the Structure and Classification of Chrysomelid Larvæ, E. D. Sanderson; Notes on the Life History of the Codling Moth, C. B. Simpson; and The Cattle Ticks of North America, C. W. Stiles.

Thirty-second annual report of the Entomological Society of Ontario, 1901 (*Rpt. Ontario Ent. Soc. 1901*, pp. 128, pls. 2, figs. 58).—This report contains the proceedings of the thirty-eighth annual meeting of the Entomological Society of Ontario, held in London, November 13 and 14, 1901, and the proceedings of the third annual meeting of the Northwest Entomological Society, held in Lacombe, Alberta, Northwest Territory, November 9, 1901.

A discussion of the San José scale problem (pp. 3-12) was had, in connection with an address by J. Fletcher on the San José scale in Ohio and Ontario. The 3 remedies which were considered practicable and effective were crude petroleum, whale-oil soap, and hydrocyanic-acid gas.

The importance of entomological studies to the community at large was discussed by T. W. Fyles (pp. 13-21). In this paper the extent of damages from injurious insects is briefly mentioned and notes are given on the economic importance of a general knowledge of the habits of insects.

Brief notes are given on the insects of the year by C. H. Young, J. D. Evans, and J. Johnston (pp. 24-28). This discussion embraces short notes on white cabbage butterfly, birch bucculatrix, cankerworms, Hessian fly, potato beetle, and asparagus beetle. The injurious insects of the season of 1901 are reported upon by W. Lochhead (pp. 43-50). The author gives notes on the habits and life history of codling moth, potato-stalk borer, asparagus beetle, blister beetle, currant aphid, cherry aphid, snowy tree cricket, raspberry cane maggot, rose chafer, and oak pruner. Notes on the season of 1901 are given by J. A. Moffat (pp. 50-53), including a brief account of the turnus and archippus butterflies and *Euphoria inda*. The habits and life history of the painted butterfly (*Pyrameis cardui*) are discussed by J. Fletcher (pp. 54-56).

North American fall webworms, H. H. Lyman (pp. 57-62). The author gives short notes on the habits and life history of a number of species of *Hyphantria*, with tables indicating the months in which they appear in various stages and in which they are most injurious.

The trend of insect diffusion in North America is discussed by F. M. Webster (pp. 63-67). A map is presented showing the general directions of the movements of insects in different parts of the country at the present time. The same author (pp. 67-74) also read papers on the imported willow and poplar curculio and on the common cheese mite, which is reported as living in cultures of *Sporotrichum globuliferum*.

The hibernation of insects, W. Lochhead (pp. 74-78). Lists were compiled by the author of insects which hibernate in larval, pupal, adult, and egg conditions.

A paper was read by J. A. Moffat on the archippus butterfly (pp. 78-82), in which evidence was presented to show that this butterfly does not hibernate in the adult form and that the peculiar collections of this species, which are sometimes observed in autumn on bushes or trees in Northern altitudes, are also seen in the South, where the purpose of this collection is not hibernation.

The following papers were also presented at this meeting: Collecting at Light in 1901, J. D. Evans (p. 82); The Milkweed at Dusk, A. F. Winn (pp. 82-84); A Collecting Trip in Southwestern Ontario, by E. M. Walker (pp. 85-90); Crickets, by T. W. Fyles (pp. 90-94); Nature Study Lessons on Mosquitoes, by W. Lochhead (pp. 94-98); Entomological Record for 1901, by J. Fletcher (pp. 99-108); Commercial Entomology, by C. Stevenson (pp. 113-115); and The Food of the Grass Snake (*Liopeltis vernalis*), by J. B. Williams (p. 115).

At the third annual meeting of the Northwest Entomological Society the president of the Society, in his annual address, presented short notes on a number of injurious insects, including cabbage butterfly, tent caterpillars, crane flies, horse botfly, and Colorado potato beetle.

Biographical notes of Eleanor A. Ormerod and O. Luggar are also presented.

Report of the entomologist, J. FLETCHER (*Canada Expt. Farms Rpts. 1901, pp. 196-252, figs. 18*).—The author gives brief descriptive notes on the conditions found in various parts of Canada during a trip of inspection. The insects which were most injurious to cereals during the year were grain aphid, wheat-stem maggot, Hessian fly, cutworms, and grasshoppers. The ravages of the Hessian fly on winter wheat in Ontario were more serious than they had been for many years; barley also suffered considerably in a number of localities. Notes are given on the extent and seriousness of the attacks of the Hessian fly in different parts of Canada, as reported by various farmers and voluntary observers. The time to sow winter wheat so as to avoid as far as possible the attacks of the Hessian fly can not be fixed for all years, but must be regulated according to the season rather than the almanac. Apparently it is not safe to sow wheat in the counties bordering on Lake Erie before September 15. During the year the most widespread and disastrous outbreak of cutworms which had ever been reported for Manitoba occurred in various parts of this Province. The cutworm chiefly concerned in this injury was *Carnedeus ochrogaster*. Similar injuries were caused to grain in Ottawa by *Hadena devastatrix*. Various kinds of grain were eaten down to the surface of the ground, or in some cases cut off beneath the surface. The poisoned bran remedy is recommended for future outbreaks of this sort. Locusts of various species also caused considerable loss, especially in central Manitoba and British Columbia. The species concerned were chiefly *Melanoplus atlans*, *M. packardii*, *M. bivittatus*, and *Camula pellucida*. One of the most successful remedies in combating these insects was found in the use of a poisoned bait consisting of fresh horse manure, salt, and Paris green. The locusts were easily attracted to this bait, and when it was scattered around the edge of grain fields and thrown into

the fields to a distance of 20 or 30 ft., it was found that the attack of the locusts was very materially checked. The use of horse dung for this purpose in the place of bran has the advantage of cheapness.

Notes are given on a number of insects which were injurious to some extent upon root crops and garden vegetables. The species of insects chiefly concerned in these attacks were cabbage aphid, cabbage worm, variegated cutworm, and other species of cutworm, cabbage-root maggot, asparagus beetle, zebra caterpillar, squash bug, and striped cucumber beetle. Brief notes are given on the habits and life history of the species and the usual remedies are recommended for combating them.

The insects which were most injurious to potatoes were striped blister beetle, cucumber flea-beetle, tomato worm, potato-stalk weevil, and variable cutworm (*Mamestra atlantica*). The striped blister beetle was injurious to potatoes, tomatoes, mangel-wurzels, beets, and other garden crops. It is suggested that it may be easily destroyed by spraying with Paris green, but that this measure should not be adopted except where it is necessary, since the larvæ of the beetle are beneficial in destroying the eggs of grasshoppers. The potato-stalk weevil has not previously occurred in Canada in sufficient numbers to cause any serious damage to potatoes. It is recommended that all infested vines should be destroyed as soon as the potato crop is harvested. Observations on the variable cutworm indicate that this species may possibly be double brooded at Ottawa, since moths were captured as early as May 22 and as late as August 25.

A number of fruit insects are discussed in this report, including codling moth, oyster-shell bark-louse, cankerworm, tent caterpillar, apple-tree borer, rose chafer, wireworm, San José scale, *Colaspis brunnea*, *Lecanium fitchii*, *Cecidoptes pruni*, and *Phloeotribus liminaris*. *L. fitchii* caused a great amount of damage to blackberries near Trenton, Ontario, where about 8 acres of this fruit were found covered with scales from about a foot above ground to the top of the canes. The injury was chiefly done to the old plantations. *C. pruni* is reported as causing galls of small size on the young twigs, usually on old trees. They were found very abundantly during the year at one orchard in Queenstown. The San José scale is still a very important fruit tree pest; it occurs in no other province of Canada except Ontario. Notes are given on the rapidity of increase and the nature of damage done by this species. It is stated that the Federal San José Scale Act has been rigidly enforced, with good results. The three remedies which are recommended for the San José scale as especially effective in Canada are whale-oil soap, crude petroleum, and hydrocyanic-acid gas. Crude petroleum proved very effective on peach trees; in a 15 per cent mechanical mixture with water, and no injury was done to the trees. G. E. Fisher carried out some successful experiments in fumigating small fruits and young trees in an inverted barrel. Brief notes are given on two species of insects injurious to forest trees, viz, birch skeletonizer (*Bucculatrix canadensisella*) and *Semioophora youngii*. The latter species was observed attacking American larch and black spruce, and was described by J. B. Smith as a new species. The moths appear at the end of August and the early part of September.

Entomological notes, J. A. ORTIZ (*Bol. Ofic. Agr. Ganadera*, 2 (1902), Jan., pp. 408-415, figs. 5).—Brief notes on pea weevil, *Eumolpus viti*, fruit-tree bark beetle, Colorado potato beetle, and *Lytta otomaria*.

Injurious insects, J. C. CHAPPAIS (*Nat. Canad.*, 29 (1902), No. 5, pp. 65-70).—Brief notes are given on the habits and life history of the grain weevil, rice weevil, and raspberry sawfly. The usual remedies are recommended for combating these insects.

Some insects which are injurious in springtime, H. FAES (*Chron. Agr. Canton Vaud*, 15 (1902), No. 7, pp. 189-195, figs. 2).—Brief notes are given on the habits and life history of *Anthonomus pomorum*, *Hyponomeuta malinella*, and other injurious fruit insects of less importance.

Notes on entomology, A. LEHMANN (*Dept. Agr. Mysore State Bul. 1, 1902, pp. 8*).—Brief general notes on the habits and life history of injurious insects. Directions are given for collecting specimens and sending them to the department.

Modern methods of studying and dealing with horticultural insect pests, J. B. SMITH (*Proc. New Jersey State Hort. Soc., 27 (1902), pp. 65-75, pls. 2*).—The author gives a brief popular account of the progress of economic entomology with reference to horticultural insects, and of various means which have been adopted for controlling injurious insects by artificial and natural agencies.

Insects and insecticides, C. P. GILLETTE (*Colorado Sta. Bul. 71, pp. 40, figs. 27*).—This bulletin contains a general account of the more important injurious insects in Colorado and of the remedies which have been found most effective in combating them. Notes are given on the insects injurious to the apple, pear, plum, cherry, peach, grape, currant, and strawberry.

The more important insects injurious to wheat in Missouri, J. M. STEDMAN (*Missouri State Bd. Agr. Rpt. 1902, pp. 55-141, figs. 42*).—Notes are given on the distribution, habits, life history, and injuries caused by chinch bug, Hessian fly, wheat-bulb worm, wheat-straw worm, army worm, fall army worm, wheat-head army worm, *Feltia subgolia*, *Peridroma saucia*, *Agriotes mancus*, crane fly, wheat plant louse, Angoumois grain moth, and grain weevil. The article constitutes a sort of compendium of popular information concerning the most important insects in Missouri which are injurious to wheat.

Orchard enemies in the Pacific Northwest, C. V. PIPER (*U. S. Dept. Agr., Farmers' Bul. 153, pp. 39, fig. 1*).—The Northwestern Pacific region is divided, from a horticultural standpoint, into coast region, inland valleys, and inland uplands. Brief notes are given on the conditions which affect orchards in the coast region, and on the more common insect and fungus enemies of apple, pear, cherry, plum, and prune. In the inland valleys the chief enemies to horticulturists are said to be San José scale, codling moth, plant lice, peach-twig borer, peach mildew, and pear blight. In the inland uplands the chief enemies are codling moth, San José scale, pear blight, and apple scale. Notes are given on the value and method of preparation of lime, sulphur, and salt wash; kerosene emulsion; Paris green; London purple; arsenic and lime; arsenic, soda, and lime; whale-oil soap and quassia; Bordeaux mixture; and ammoniacal solution of copper carbonate. A special discussion is given to San José scale, codling moth, peach-twig borer, western pulvinaria, woolly aphid, peach-leaf blister-mite, black spot apple canker, apple scab, pear scab, brown rot, pear blight, and crown gall.

Principal insects liable to be distributed on nursery stock, N. BANKS (*U. S. Dept. Agr., Division of Entomology Bul. 34, n. ser., pp. 46, figs. 43*).—This bulletin is in response to a resolution passed by the official horticultural inspectors for the United States requesting this Department to prepare and publish a bulletin treating of insects injurious to nursery stock. The species which are discussed in the bulletin include peach lecanium, oyster-shell bark-louse, scurvy bark louse, San José scale, Putnam's scale, cherry scale, walnut scale, greedy scale, grape scale, peach scale, rose scale, woolly apple aphid, black peach aphid, apple plant lice, plum plant louse, cherry aphid, pear-tree psylla, buffalo tree-hopper, apple-tree tent caterpillar, fall webworm, brown-tail moth, leaf crumpler, white-marked tussock moth, gypsy moth, cankerworms, peach-tree borer, peach-twig borer, bagworm, round-headed apple-tree borer, flat-headed apple-tree borer, sinuate pear borer, fruit-tree bark beetle, apple-twig borer, pear-leaf blister mite, codling moth, apple maggot, cherry fruit fly, plum curculio, quince curculio, pear midge, and other less important species.

Treatment for San José scale in orchard and nursery, J. B. SMITH (*Pennsylvania Dept. Agr. Bul. 90, pp. 33, pls. 2, figs. 5*).—A general discussion is presented of the problems connected with the injurious action of this insect, including its history in California, introduction and spread in the Eastern United States, life history, food

plants, injurious effects, natural methods of dissemination, natural enemies, summer treatments, winter treatments, lime-salt-and-sulphur wash, whale-oil soap, kerosene, crude petroleum, insecticide machinery, and fumigation with hydrocyanic-acid gas.

Experiments with lime mixtures for the eradication of the oyster-shell bark-louse, W. T. MACOUN (*Canada Expt. Farms Rpts. 1901, pp. 109, 110*).—Experiments were made in spraying with lime mixed with water at the rate of 1 or 2 lbs. to the gallon of water. It was found as the result of experiments during several years that lime slaked in water and sprayed upon apple trees has the effect of loosening the scales. For this purpose it should preferably be applied to the trees soon after the leaves fall in autumn, so that the rain and wind may have their full effect in removing the loosened scales. The lime apparently does not destroy the eggs under the scales, nor is it injurious to either peach or apple trees.

Treatment for the oyster-shell bark-louse, W. S. BLAIR (*Canada Expt. Farms Rpts. 1901, pp. 379, 380*).—Spraying with lime slaked in water at the rate of 1 or 2 lbs. to the gallon of water was found a cheap and effective remedy for this insect. The use of kerosene emulsion for destroying the young lice soon after they hatch was found to be fairly effective, but no trees were entirely freed from the pest. Tobacco water as a remedy for the oyster-shell bark-louse was tried on 5 trees and was found to be of little value. Not more than 10 per cent of the insects were killed by this treatment.

Arsenical sprays for the codling moth (*Jour. Agr. and Ind., South Australia, 5 (1902), No. 9, pp. 745, 746*).—Brief notes on the successful use of various arsenical insecticides, especially arsenite of soda, in destroying the codling moth.

Chemistry of insecticides and fungicides, F. T. SHUTT (*Canada Expt. Farms Rpts. 1901, pp. 191-193*).—Analyses of various brands of lye and gas lime are reported, together with notes on insecticide mixtures which were proposed by correspondents. The different brands of lye were found to vary in the amount of chlorid of soda which they contained, and nearly all of them contained some impurities, such as sulphates and oxids of iron and aluminum. These impurities, however, are not considered as interfering with the efficiency of the lye. In the use of gas lime it was recommended that care be exercised not to apply this substance when it is too fresh, since it may then be injurious to vegetation. It is recommended to fruit raisers that no attempt be made to use mixtures of lime wash and soft soap, since a curdy lime soap is precipitated which is perhaps not so effective as soap alone. Whale-oil soap is considered rather more effective than soft soap, partly on account of its deterrent properties. While no experiments have been made to determine whether sal soda can be used with Paris green in the place of lime, the author believes that there is no reason why this substance can not be used to replace lime, but does not think it would be any more effective than lime.

A new emulsion for spraying, J. D. ORMSBY (*Jour. Jamaica Agr. Soc., 6 (1902), No. 1, p. 11*).—The author had unsatisfactory results from the use of kerosene emulsion and prepared an insecticide containing 1 lb. hard soap, 1 qt. castor oil, $\frac{1}{4}$ lb. carbonate of soda, 1 gal. water. The soap and acid were boiled in water and mixed with the castor oil while heated; the mixture was then diluted with 10 to 20 per cent of water for spraying.

Carbolic emulsion, J. D. ORMSBY (*Jour. Jamaica Agr. Soc., 6 (1902), No. 4, p. 145*).—For combating scale insects the author had good results from using an insecticide prepared as follows: 10 qt. boiling water, 1 qt. carbolic acid, 1 qt. soft soap. The mixture is stirred until an emulsion is formed and is applied by means of a brush.

The use of an acetylene gas lamp for the destruction of insects, R. ROGER (*Rev. Hort., 74 (1902), No. 8, pp. 188-191, figs. 3*).—The author gives a brief account of the practical experiments which have been made in the use of a lantern trap lighted by acetylene gas for catching various species of insects. It is stated that this

device may be successfully used in the destruction of insects in vineyards, gardens, storehouses, and other locations wherever the lamp can be operated.

How insects affect health in rural districts, L. O. HOWARD (*U. S. Dept. Agr., Farmers' Bul. 155, pp. 20, figs. 16*).—The author discusses in a popular manner the agency of mosquitoes in carrying malaria and yellow fever and the relation between flies and typhoid fever and other diseases which may be carried under certain circumstances by flies and other insects, such as bedbugs, fleas, ticks, etc.

The house fly, C. P. LOUNSBURY (*Agr. Jour. Cape Good Hope, 20 (1902), No. 3, pp. 185-194, figs. 2*).—The author describes in detail the life history, habits, breeding season, and breeding places of the common house fly, and presents notes on the agency of this insect in carrying infectious diseases. The author recommends the usual approved remedies in combating this insect.

The humblebee, A. GALE (*Agr. Gaz. New South Wales, 13 (1902), No. 1, pp. 22-24*).—A brief description of the habits and life history of this insect. Attempts thus far made to introduce the species into New South Wales have been unsuccessful.

The apiary, J. FIXTER (*Canada Expt. Farms Rpts. 1901, pp. 252-259, fig. 1*).—The average returns from the apiary of the Central Experimental Farm were 79½ lbs. extracted honey per colony. Experiments with different kinds of hives for the production of comb and extracted honey showed that the greatest amount of honey was produced in the Langstroth hive and the smallest amount in a hive 15 by 20 by 15 in. in size. Experiments were also made in feeding sugar for winter stores. The natural stores were removed from 4 colonies on September 17, 1900, and a constant surplus of sirup was kept accessible to the bees, by means of a Miller feeder. The sirup was supplied at about blood heat. No sign of uneasiness or dysentery was observed in the bees during the whole winter. The average weight of the colonies when put into winter quarters was 52½ lbs., and when removed, 40¾ lbs. Experiments with foundations of different sizes in the sections indicated that full sheets of foundation are best. The bees began to work on them first and filled them out better. Only a few of the sections which had only ½ or ¾ sheets of foundation were well filled, while no work was done on sections where no starters were used. Similar results were obtained in experiments with brood foundations of different sizes.

An experiment was made for the purpose of determining whether bees injured whole fruit. On September 7, when there was no surplus honey to be obtained from outside plants, ripe peaches, pears, plums, and grapes were exposed inside the hives, on branches of trees in the apiary inclosure, and on shelves in a workshop to which the bees had access. The fruit was exposed in three conditions with the skin intact, with the skin intact and dipped in honey, and with the skin punctured in several places with the blade of a knife. It was found that wherever the fruit was exposed the bees began work at once upon the fruit that was dipped in honey and upon the punctured fruit; they worked steadily upon the dipped fruit until all the honey was removed, and sucked the juices from the punctured fruit until it began to decay. In no case was any injury done to the whole fruit, whether dipped in honey or not, and this remained true even after the experiment had been continued for 3 weeks, at the end of which time many of the bees began to die of starvation.

Brief notes are also given on the bee moth, packing of bees for shipping in hot weather, moving bees from one part of the apiary to another, and feeding honey, sugar, and water, so as to secure the completion of unfinished sections.

Bees, S. A. BEDFORD (*Canada Expt. Farms Rpts. 1901, pp. 428, 429*).—The author reports that 2 out of 6 colonies of bees wintered in the cellar died of diarrhea. The disease was due to the frames becoming damp and moldy. The hives were apparently placed too near the cellar wall. Ordinarily it is stated there is little trouble in wintering bees in the cellar in this province.

Treatment of foul brood with essence of rosemary, E. E. BOCHATEY (*Rev. Internat. Apicult., 24 (1902), No. 1, p. 12*).—This remedy is highly recommended in

the treatment of foul brood, on account of its moderate price, and especially on account of the simplicity of the treatment. It is only necessary to place from 15 to 20 drops of the essence of rosemary in one corner of the hive and allow the substance to volatilize.

FOODS—NUTRITION.

An experimental inquiry regarding the nutritive value of alcohol. W. O. ATWATER and F. G. BENEDICT (*Mem. Nat. Acad. Sci.*, 8 (1902), VI (*U. S. Senate*, 57. *Cong.*, 1. sess., *Doc.* 233), pp. 231-337).—Twenty experiments are reported, in some of which alcohol was substituted for an isodynamic quantity of fats and carbohydrates. The experiments were made with the aid of the respiration calorimeter with three subjects, one of whom had used alcohol with great moderation since his youth, while the other two had always been abstainers. The amount of alcohol used per day was about 2½ oz., or as much as would be supplied in a bottle of claret, 6 oz. of whisky, or 5 oz. of brandy. The principal conclusions drawn follow: The quantities of alcohol eliminated by the lungs, skin, and kidneys, averaged 1.3 gm. per day. In other words, over 98 per cent of the injected alcohol was oxidized in the body. The average coefficients of digestibility and the fuel values of protein, fat and carbohydrates of ordinary diet as compared with diet containing alcohol are shown in the following table:

Comparison of digestibility and fuel values of nutrients of food in ordinary diet with those of alcohol.

	Heat of combustion per gram.	Digestibility of material.	Availability of energy.	Fuel values.			
				Referred to digestible material.		Referred to total material.	
				Per gram.	Per pound.	Per gram.	Per pound.
	<i>Calories.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Calories.</i>	<i>Calories.</i>	<i>Calories.</i>	<i>Calories.</i>
Protein	5.65	92	70	4.4	2,000	4.0	1,820
Fats	9.40	95	95	9.4	4,260	8.9	4,040
Carbohydrates	4.10	97	97	4.1	1,860	4.0	1,820
Alcohol	7.07	98	98	7.1	3,210	6.9	3,140

"The isodynamic values of alcohol, carbohydrates, and fats are thus in the ratios of 6.9 : 4 : 8.9, and 1 gm. of alcohol would be isodynamic with 1.73 gm. carbohydrates or 0.78 gm. of fats of ordinary food materials. The proportions of food and of the several kinds of nutrients digested and made available for use in the body were practically the same in the experiments with and those without alcohol in the diet. . . . The potential energy of the alcohol was transformed into kinetic energy in the body as completely as that of the ordinary nutrients. The income and outgo of energy were equal in the experiments without alcohol; the same was true in the experiments with alcohol. In all the experiments the body obeyed the law of conservation of energy.

"With the exception of the energy of the external muscular work in the work experiments, all of the energy of the food, including that of the alcohol, left the body as heat, and must therefore have been transformed into heat within the body. Part of this total energy must have been used for the internal mechanical (muscular) work; the energy thus used was therefore transformed into heat before leaving the body.

"The radiation of heat from the body was very slightly greater with the alcohol diet than with the ordinary diet, but the difference was extremely small—enough to

make only about 1 per cent of the whole energy metabolized, and not over 6 per cent of the energy of the alcohol.

"The efficiency of alcohol in the protection of body fat from consumption was very evident. The losses of fat were no larger and the gains no smaller with the alcohol diet than with the corresponding diet without alcohol. In this respect there was no indication of any considerable difference between the alcohol and the nearly isodynamic amounts of fats and carbohydrates which it replaced. This was the case in all the experiments.

"The efficiency of the alcohol in protecting body protein was evident, but it was not fully equal in this respect to the isodynamic amounts of the ordinary nutrients. The results, however, were not the same with the different subjects. . . . On the whole these experiments accord with the belief that with some persons, especially with those who are not accustomed to the use of alcohol, it may fail to protect protein; but this action is temporary, and the more permanent influence is to protect protein.

"That a part of the potential energy of the alcohol was transformed into the kinetic energy of muscular work these experiments do not prove, though they make it highly probable. They imply that, so far as the utilization of the total energy of the diet was concerned, there was a slight advantage in economy in favor of the ordinary as compared with the alcohol diet, especially when the subjects were at hard muscular work, but the difference was inside the limits of experimental error and too small to be of practical consequence. On the average it was less than 1 per cent of the total energy, and hardly reached 5 per cent of the energy of the alcohol. From this it follows that the energy of the alcohol was utilized nearly if not quite as well as that of the fats, sugar, and starch which it replaced.

"We repeat that there is a very essential difference between the transformation of the potential energy of alcohol into the kinetic energy of heat, or of either internal or external muscular work, and the usefulness or harmfulness of alcohol as a part of ordinary diet. Regarding this latter question the experiments bring no more evidence than they do regarding the influence of alcohol upon the nervous system or its general effect upon health and welfare."

Some new nutrient preparations, S. WEISSBEIN (*Deut. Med. Wchnschr.*, 28 (1902), No. 2; *abs. in British Med. Jour.*, 1902, No. 2145, *Epit.*, p. 23).—Analytical methods suited to the examination of plasmon and similar preparations are described and results obtained are reported.

Some new foods prepared from plant protein, M. WINTGEN (*Ztschr. Untersuch. Nahr. u. Genussmtl.*, 5 (1902), No. 7, pp. 289-301).—The composition and digestibility of roborat, aleuronat, and energin, all of which are foods prepared from the protein of cereals, was studied and a bacteriological examination of the products made.

Milk flour in Sweden, V. E. NELSON (*U. S. Consular Rpts.*, 69 (1902), No. 260, pp. 118, 119).—According to the author, flours are prepared in Sweden from whole and from skim milk. These materials, it is said, are readily soluble in water and may be used in a variety of ways as food.

Milk flour in Sweden, R. S. S. BERGH (*U. S. Consular Rpts.*, 68 (1902), No. 257, p. 238).—A brief note on powder or flour made from skim milk.

Edible fungi, A. ZEGA (*Chem. Ztg.*, 26 (1902), p. 10; *abs. in Chem. Centbl.*, 1902, I, No. 6, p. 362).—The composition of *Agaricus esculentus*, *A. arvensis*, *Lactarius pipereatus*, and *Coprinus comatus*, is reported.

On the composition of the nuts of *Gingko biloba*, U. SUZUKI (*Bul. Col. Agr. Imp. Univ. Tokyo*, 4 (1902), pp. 357, 358).—The author reports an analysis of the nuts of *Gingko biloba* which are used in the Orient as food.

On the occurrence of cane sugar in the seeds of *Gingko biloba* and *Camellia theifera*, U. SUZUKI (*Bul. Col. Agr. Imp. Univ. Tokyo*, 4 (1902), pp. 349, 350).—The occurrence of cane sugar in these seeds is noted.

Wheat and maize starches of commerce, D. SAARE (*Ztschr. Spiritusind.*, 24 (1901), pp. 502, 512, 513; *abs. in Jour. Soc. Chem. Ind.*, 21 (1902), No. 2, p. 129).—The composition and characteristics of wheat starch and maize starch are discussed.

The baking quality of wheat and ways of estimating it, A. MAURIZIO (*Landw. Jahrb.*, 31 (1902), No. 1, pp. 179–234, pls. 3, fig. 1).—Different methods of estimating the baking quality of wheat flour were tested. In connection with this work the author determined the amount of carbon dioxide produced by the fermentation of dough and during baking. Some of the principal conclusions follow: In mixing dough as much water should be used as the flour will take up. The maximum volume of bread which can be obtained from 100 gm. of flour is 560 to 580 cc. Medium grade flour will yield 400 to 480 cc., and flour of poor baking quality 250 to 350 cc. The baking quality of medium flour can not be determined by laboratory experiments or practical experiments alone, though pure flour may be readily recognized. The specific gravity of bread furnishes a very valuable indication of the baking quality of flour and grain. Products of the best quality have a specific gravity of 0.23 to 0.28; medium quality of 0.35, and low grade of 0.46 and over.

Milling and baking experiments with domestic and foreign wheat, M. FISCHER (*Fühling's Landw. Ztg.*, 51 (1902), Nos. 1, pp. 17–28; 2, pp. 43–58; 3, pp. 87–102).—From milling and baking tests, the author believes German grain to be superior to that from other countries.

Losses in cooking meat, H. S. GRINDLEY (*British Food Jour.*, 4 (1902), No. 37, pp. 2, 3).—A summary of a publication noted elsewhere (*E. S. R.*, 13, p. 772).

The manufacture of preserves, P. DEGENER (*Ztschr. Ver. Deut. Zuckerind.*, 1902, No. 554, II, pp. 193–203).—The manufacture of jellies and preserves is described and discussed.

The making of jelly from the fruit of *Pyrus baccata*, W. SAUNDERS (*Canada Expt. Farms Rpts.* 1901, p. 82).—A method is described of making jelly from the fruit of this crab in such a way that unpleasant astringency is avoided.

Should milk be boiled? W. B. RANSOM (*British Med. Jour.*, 1902, No. 2147, *Epit.*, pp. 440–443).—A review of the literature led the author to the conclusion that there is no good evidence to show that milk heated to boiling for from 10 to 15 minutes suffers any diminution in food value. The data cited are discussed with special reference to diseases of infants.

Variations in body temperature with special regard to the effect produced on man by a reversal of the ordinary method of living, F. G. BENEDICT and J. F. SNELL (*Arch. Physiol. [Pflüger]*, 90 (1902), No. 1–2, pp. 33–72, *dgms.* 27).—Using the thermometer of special construction previously described (*E. S. R.*, 13, p. 878), the authors made a series of investigations which are reported in detail to determine the normal body temperature, the temperature at different parts of the body, and to study the effect of muscular work and fasting. They also studied the effect of reversing the ordinary method of living—that is, of working during the night and sleeping during the day, upon body temperature. Among the conclusions drawn were the following: Muscular work increases body temperature rapidly, the temperature remains high as long as the work continues. Work of the same intensity produces the same increase in temperature. When work ceases, the temperature soon begins to decrease, and this effect is noticed for a considerable time. During fasting the average temperature is not markedly different from normal temperature if no work is performed. When the subjects fasted and performed severe muscular work, the average temperature was lowered about 1° C. Under the experimental conditions no change in the temperature curve was observed when work was performed at night and subjects rested during the day.

Vegetarian diet and the production of work, BAELZ (*Berlin, Klin. Wchnschr.*, 1901, No. 26, p. 689; *abs. in Hyg. Rundschau*, 12 (1902), No. 4, pp. 200, 201).—The author reports a study of the diet of two Japanese jinrikisha runners. According to

this investigation the diet consisted almost entirely of rice, potatoes, barley, chest-nuts, and lily bulbs, and furnished less protein than the commonly accepted dietary standard calls for. Japanese diet in general is discussed.

Diet in the several periods of life, E. PALIER (*Diet. and Hyg. Gaz.*, 18 (1902), No. 5, pp. 257-263).—A general discussion of the subject.

The dietary of the Scottish peasant, W. G. LITTLE (*Caledonian Med. Jour.*, 5 (1902), Nos. 1, pp. 22-26; 2, pp. 95-101).—A general discussion of the subject.

The utilization of sugars (hexoses) by the body, CHARRIN and BROCARD (*Compt. Rend. Acad. Sci. Paris*, 134 (1902), Nos. 1, pp. 48-50; 3, pp. 188-190).—The authors believe that experiments which were made with pregnant women show that levulose, galactose, and glucose rank in the order mentioned, when judged by their utilization in the body economy. Tests also showed that the human body induces cleavage in maltose more easy than in lactose and cane sugar, although the intensity of cleavage and the utilization of the food is believed to depend upon the diet the body is accustomed to. Other conclusions of a special nature were also drawn.

The digestion of carbohydrates in the stomach by ptyalin, HENSAY (*München. Med. Wchnschr.*, 1901, No. 30, p. 1208; *abs. in Hyg. Rundschau*, 12 (1902), No. 4, pp. 199, 200).—Examination of the stomach contents showed that larger quantities of starch were digested by ptyalin than might be expected. The possibility of the continuation of ptyalin digestion in the stomach is discussed.

Concerning the influence of fats and carbohydrates upon the protein metabolism in man, T. W. TALLQVIST (*Arch. Hyg.*, 41 (1902), No. 3, pp. 177-189).—From experiments with man in which the income and outgo of nitrogen was determined the conclusion was drawn that the variations in fat and carbohydrates in the diet influence the amount of nitrogen required, and that carbohydrates protect protein more than fat.

Concerning a special rôle of carbohydrates in the assimilation of insoluble salts by the body, L. VAUDIN (*Ann. Inst. Pasteur*, 16 (1902), No. 1, pp. 85-93; *abs. in Chem. Centbl.*, 1902, I, No. 9, p. 535).—According to the author's experiments the carbohydrates formed by the hydrolysis of starch by saliva aid in the solution of earthy phosphates.

The effect of boric acid on the metabolism of man, M. RUBNER (*Hyg. Rundschau*, 12 (1902), No. 4, pp. 161-170).—Metabolism experiments in which the respiratory products were taken into account lead the author to the conclusion that boric acid increased the production of carbon dioxide and water vapor and increased the cleavage of fat or carbohydrates in the body.

On the effects of forced feeding in cases of pulmonary tuberculosis and in normal individuals, N. D. BARDSWELL, F. W. GOODBODY, and J. E. CHAPMAN (*British Med. Jour.*, 1902, No. 2147, pp. 449-451).—From experiments with healthy individuals of normal weight and in nitrogen equilibrium, the following conclusions were drawn: Forced feeding, i. e., consuming an excessively large diet, caused a marked increase in the amount of nitrogen excreted in the urine, with a proportionate increase in the amount of urea. No diminution in the absorption of nitrogen was observed, but the absorption of fat was diminished. There was a large and rapid gain in weight, which was in every case associated with marked impairment of general health. There was a corresponding loss of weight when ordinary diet was resumed.

The amount of combined pentoses in the body, G. GRUND (*Ztschr. Physiol. Chem.*, 35 (1902), No. 2, pp. 111-133).—The author studied the methods of estimating pentoses and determined the amount in different organs and tissues of a steer and calf. The largest amount, on an average 0.447 per cent, was found in the steer pancreas (fresh material). The average amount in the other materials examined ranged from 0.021 in the steer muscular tissue to 0.099 in the calf thymus. The results obtained are discussed at some length.

Further investigations on the silica content of animal and human tissues, H. SCHULZ (*Arch. Physiol. [Pflüger]*, 89 (1902), No. 1-2, pp. 112-118).—Continuing previous work (E. S. R., 13, p. 168), analytical data are reported and discussed.

ANIMAL PRODUCTION.

Spontaneous combustion of alfalfa, H. M. COTTRELL (*Kansas Sta. Bul.* 109, pp. 217-222).—A number of instances of spontaneous combustion of alfalfa hay are recorded and discussed. In every case this phenomenon was observed with hay of the first cutting, which is ordinarily of rank growth. The spontaneous combustion is apparently due to the imperfect curing of such hay before stacking. According to the author, "some alfalfa growers, in stacking the first cutting of alfalfa, put alfalfa and dry straw or prairie hay in alternate layers. This is a satisfactory way if the dry material is available. Others use 10 to 15 pounds of salt or air-slaked lime for each ton of hay, sprinkling the salt or lime so as to cover as much of each load as possible. Experiments made at this station indicate that considerably less gains are made by cattle when salt is mixed with the feed. A trial of lime on alfalfa, made at this station, showed little effect. From all the experience we have gained to date [it seems probable] that the best way to prevent spontaneous combustion of alfalfa is to thoroughly cure before stacking. It is not often that all the conditions necessary to produce spontaneous combustion are present, and ordinarily there is no danger, where reasonable care is taken, except with the first cutting, and with this cutting only when the growth is rank."

On the changes in the composition of roots during storage, F. T. SHUTT (*Canada Expt. Farms Rpts.* 1901, pp. 163-166).—The dry matter, total nitrogen, and the albuminoid and nonalbuminoid nitrogen were determined in mangel-wurzels, carrots, turnips, and sugar beets in the fall, winter, and the spring. According to the author—

"The percentage of albuminoid nitrogen . . . appears to remain fairly constant in the dry matter throughout the period of storage, though in the case of two of the roots, Giant Yellow Globe mangel, and Improved Short White carrot, there had been a notable decrease, due probably, in part at least, to the breaking down of the albuminoids. Since . . . the percentage of total nitrogen (calculated on the dry matter) in the majority of the examples increased somewhat during storage, it necessarily follows that the percentage of nonalbuminoid nitrogen has slightly increased."

The author infers "(1) that nitrates, resulting more particularly from high manuring with soluble nitrogenous fertilizers, and which are more or less injurious to the animal, tend to disappear on storage of the roots; (2) that there is a tendency to fermentative changes during storage that lead chiefly to the destruction of the sugar, the most important nutrient of roots. This deterioration may no doubt in a large measure be controlled by low temperature and good ventilation; under such conditions we imagine the loss does not assume in our winter climate any grave proportions. It would no doubt be found to increase markedly after March. Further, (3) that the nonalbuminoid nitrogenous compounds increase, as a rule, with storage, and especially so during the spring months."

Fodders and feeding stuffs, F. T. SHUTT (*Canada Expt. Farms Rpts.* 1901, pp. 160-162).—Determinations are reported of the dry matter and sugar in beets, carrots, and mangel wurzels, special attention being paid in the case of the latter to the sugar content in the portion of the root above and below ground. The larger amount was found in the latter portion. "A consideration of the fact that sugar is the chief constituent of value in roots might lead us to infer, in the light of this experiment, that a system of culture which tends to keep the roots fairly well earthed up is one that will result in the most nutritious crop. Further, those

varieties which naturally tend to grow beneath the soil, providing they furnish an adequate yield per acre, will be the most profitable to grow."

Compilation of analyses of fodder articles made at Amherst, Mass., 1868-1901, E. B. HOLLAND and P. H. SMITH, jr. (*Massachusetts Sta. Rpt. 1901*, pp. 171-192).—The results of proximate and fertilizer analyses of feeding stuffs are quoted, and in many cases the digestibility is also included.

Corn by-products—gluten meal, gluten feed, etc., F. T. SHURT (*Canada Expt. Farms Rpts. 1901*, pp. 185-190).—Analyses of feeding stuffs including gluten meal, cattle feed, rice feed, calf meal, and potato starch are reported.

Cattle-feed inspection, J. B. LINDSEY (*Massachusetts Sta. Rpt. 1901*, pp. 152-156).—Results of the inspection of cattle feeds during the year are briefly stated and the text of the feed stuff law is given.

Coefficients of digestibility of American feed stuffs, J. B. LINDSEY and N. J. HUNTING (*Massachusetts Sta. Rpt. 1901*, pp. 195-216).—A compilation including the results of experiments with ruminants, swine, horses, and poultry.

Distillery refuse, DIETRICH (*Landw. Vers. Stat.*, 56 (1902), No. 4, pp. 321-366).—A summary of the information available regarding the manufacture and composition and feeding value of fresh and dry distillery refuse of different sorts.

[Panicum grass] better than sorghum, D. C. SHOREY (*Honolulu Bul.*, 1902, Feb. 7).—The composition of local grown panicum grass was determined and its food value discussed.

The exact calculation of balanced rations, J. T. WILLARD (*Industrialist*, 28 (1902), No. 21, pp. 319-330).—A method of calculating rations on the principles of alligation is described.

Cleavage of fat by micro-organisms, K. SCHREIBER (*Arch. Hyg.*, 41 (1902), No. 4, pp. 328-347).—From experiments which are reported in detail, the following conclusions were drawn: Pure fat is not a nutrient medium for micro-organisms. A number of bacteria which occur in soil and elsewhere in nature induce cleavage in fat, provided nutrient material and oxygen are present. Their action is especially energetic if the acid formed is neutralized with calcium carbonate. The cleavage is most rapid when the fat is finely divided as in an emulsion. External conditions, such as temperature, lack of oxygen and light, which hinder the growth of the bacteria under consideration, doubtless hinder in like measure their action upon fat. At any rate, the extent of cleavage brought about by different species is affected in many ways. A number of molds also induce cleavage in fat. Their action is not diminished by the acidity of the fat on which they grow. The adipolytic power of the micro-organisms mentioned is intimately connected with their life processes and is dependent upon the presence of oxygen. In the case of anaerobic bacteria, there is probably a slight cleavage of fat which is, however, not sufficient to be regarded as destructive.

Calcium soaps as a proof that the resorption of fat takes place in aqueous solutions, E. PFLÜGER (*Arch. Physiol. [Pflüger]*, 89 (1902), No. 5-6, pp. 211-226).—Continuing earlier work (E. S. R., 13, p. 775), the author discusses critically the experiments of a number of investigators, the final conclusion being that all digestion is a process of hydrolysis, and that all resorption is a diffusion of substances in aqueous solutions.

Concerning pepsin, C. A. PEKELHARING (*Ztschr. Physiol. Chem.*, 35 (1902), No. 1, pp. 8-30).—A chemical study of pepsin from pigs' and from dogs' stomachs. The author obtained the latter in a very pure form of practically constant chemical composition.

The movements of the intestines studied by means of the Röntgen rays, W. B. CANNON (*Amer. Jour. Physiol.*, 6 (1902), No. 5, pp. 251-277, figs. 10).—When bismuth subnitrate is mixed with food, the movements of the intestinal contents can be observed with a fluorescent screen. Experiments with a cat are reported. The

author found that "signs of emotion, such as fear, distress, or rage, are accompanied by a total cessation of the movements of both large and small intestines. The movements continue in the cat both during sleep and at night." Other conclusions regarding the movements of the food in the intestines, etc., are given.

Digestion in the small intestine, F. KUTSCHER and J. SEEMANN (*Ztschr. Physiol. Chem.*, 34 (1902), No. 5-6, pp. 528-543).—From experiments reported in detail, the conclusion was drawn that under normal conditions trypsin induces in the small intestine a cleavage of protein to such an extent that crystallizable products are formed. Of these the authors have identified only leucin, tyrosin, lysin, and arginin. Such cleavage products may be so changed in the intestinal wall that they are unrecognizable. Noticeable amounts of albumoses and peptones were not found in the intestinal contents.

The metabolism of phosphorus, calcium, and magnesium by herbivora, F. TANGL (*Arch. Physiol. [Pflüger]*, 39 (1902), No. 5-6, pp. 227-239).—A number of experiments with horses on the metabolism of phosphorus, calcium, and magnesium are reported. According to the author, these show that a certain parallelism exists between the metabolism of nitrogen and phosphorus. The amount of phosphorus, calcium, and magnesium required per kilogram body weight is discussed, as well as related topics.

Concerning the metabolism of horses, T. PFEIFFER (*Landw. Vers. Stat.*, 56 (1902), No. 4, pp. 283-288).—A controversial article.

Remarks on Pfeiffer's criticisms, N. ZUNTZ and O. HAGEMANN (*Landw. Vers. Stat.*, 56 (1902), No. 4, pp. 289-292).—A reply to the above.

Steer feeding experiments, J. H. GRISDALE (*Canada Expt. Farms Rpts. 1901*, pp. 277-290).—Continuing earlier work (E. S. R., 13, p. 270), several feeding tests with steers are reported. The comparative gains made by calves, yearlings, 2-year-olds and 3-year-olds was studied with 4 lots, lot 1 containing 5 animals, and the other lots 9 each. The calves in lot 1 were fed for 196 days, the other animals for 203 days. The calves gained on an average 2.09 lbs. per day, the cost per pound of gain being 3.24 cts. The yearlings, 2-year-olds, and 3-year-olds gained respectively 1.55, 1.58, and 1.76 lbs., the corresponding cost of a pound of gain being 5.77, 5.71, and 6.37 cts.

The comparative gains made by dehorned steers and those not dehorned were tested with 2 lots of 9 each. The former were loose—the latter tied in stalls. The average daily gain under similar conditions of feeding was 1.78 and 1.7 lbs., respectively; the cost of a pound of gain 6.55 and 6.60 cts. The gain made by large and small lots of dehorned cattle, all loose, was tested with 3 lots containing respectively 9, 6, and 3 steers. The average daily gains were 1.78, 1.79, and 1.7 lbs., the cost of a pound of gain being 6.55, 6.25, and 6.76 cts.

The test previously reported (E. S. R., 13, p. 270) on the comparative merits of a limited and a full fattening ration was continued under practically the same conditions, and a second test with 2 lots of 5 calves each undertaken. The average daily gain in the new test (covering 28 weeks) on a full fattening ration was 1.92 lbs., and the cost of a pound of gain 2.6 cts. On a limited growing ration the corresponding values were 1.68 lbs., and 2.49 cts. The average daily gain in the test covering a year on the limited ration was 1.14 lbs., the cost of a pound of gain 3.42 cts., the daily gain on a full ration 1.9 lbs., the cost of a pound of gain 8.53 cts.

Steer feeding; dehorning, R. ROBERTSON, S. A. BEDFORD, and A. MACKAY (*Canada Expt. Farms Rpts. 1901*, pp. 360-365, 422-427, 507-510, pl. 1).—At the Experimental Farm of the Maritime Provinces the comparative merits of feeding loose and tied in stalls was tested with dehorned and not dehorned steers. One lot of steers fed loose in a box stall was led to water, the others were not. Three of the lots contained 8 animals and one of the lots 4. The dehorned steers fed loose gained 231 lbs. and those tied 286 lbs. each, on an average. The steers not dehorned fed

tied made an average gain of 278 lbs. each, and the dehorned steers fed loose and turned out to water 282 lbs. Considering the test as a whole, which covered 135 days, the average daily gain per steer was 2.19 lbs.; the cost of a pound of gain, 7.42 cts.

Limited and full rations were tested with 2 lots of 6 calves each. The ration at first consisted of whole milk and skim milk. Grain and other feeds were added gradually, and finally the milk was omitted. In 196 days of the test the average daily gain on a full fattening ration was 1.64 lbs.; the cost of a pound of gain, 4.64 cts. The corresponding values on a limited growing ration were 1.22 lbs. and 4.4 cts.

At the Manitoba Experimental Farm the total gain in 20 weeks of 4 steers not dehorned and tied in stalls was 852 lbs.; of 4 dehorned steers tied in stalls 640 lbs.; and of 4 dehorned steers loose 852 lbs., the rations in every case being similar. The greatest profit, \$42.49, was obtained with the horned steers; the least, \$32.81, with the dehorned steers tied in stalls. The station also tested the comparative merits of speltz and mixed grain (oats, wheat screenings, and barley, 1:1:1) with 2 lots of 2 steers each. All the grains were chopped, the speltz with the chaff. In addition to grain, both lots were fed straw, corn fodder, and silage. The total gain in 16 weeks on speltz was 308 lbs., on mixed grains 228 lbs.; the profit on the 2 lots, \$24.54 and \$20.82. Two steers pastured on brome grass 16 weeks each gained 245 lbs. Brief notes are given regarding the station bulls.

At the Indian Head Experimental Farm 5 horned steers tied gained 790 lbs. in 16 weeks; 5 dehorned steers tied gained 600 lbs. The same number of steers dehorned and fed in box stalls gained 1,090 lbs., the feed in every case being similar. The total profit per head in the 3 lots was \$9.99, \$9.11, and \$12.74.

The cost of beef, H. M. COTTRELL (*Industrialist*, 28 (1902), No. 30, pp. 450-453).—On the basis of a feeding experiment made at the Kansas Agricultural College, the author discusses the cost of fattening steers of different breeds.

Preliminary report on Argentina as a market for pure-bred cattle from the United States, D. E. SALMON (*U. S. Dept. Agr., Bureau of Animal Industry Circ. 37*, pp. 4).—Statements are made concerning the sort of cattle in demand in Argentina, the quarantine regulations of that country, and related topics.

Mexico as a market for pure-bred beef cattle from the United States, D. E. SALMON (*U. S. Dept. Agr., Bureau of Animal Industry Bul. 41*, pp. 28, map 1).—The advantages of Mexico as a market for pure-bred cattle from the United States are treated of. Suggestions are given for introducing such cattle into Mexico, the Mexican Government regulations are pointed out, and the kind of cattle which are most satisfactory for export are described. The author also discusses the selling price of such cattle and quotes a number of letters from the United States consuls in Mexico on the general subject.

Some experiments with beet pulp as a stock food, C. D. SMITH (*Michigan Sta. Bul. 193*, pp. 1-16, 20-27).—Two tests on the feeding value of beet pulp are reported. In the first, which was made by L. M. Geismar, a lot of 30 steers was fed a ration of grain, hay, stover, and beet pulp, while a second lot of 20 steers was fed the same ration of grain and coarse fodder, but no pulp. All the steers were fed for maintenance rather than for fattening. In the 3 months of the test the lot fed beet pulp made an average daily gain of 1.42 lbs., consuming per head per day 55 lbs. of beet pulp, 8.5 lbs. of mixed hay, 4 lbs. of shredded corn stover, and 2.4 lbs. of ground corn and beet seed. The lot receiving no pulp made an average daily gain per head of 0.684 lb., consuming 11.5 lbs. of mixed hay, 8 lbs. of shredded corn stover, and 2.4 lbs. of the same grain mixture as lot 1. The author calculates that in this test a ton of beet pulp took the place of 421.5 lbs. of corn stover, 274 lbs. of mixed hay, and 68.8 lbs. of grain.

The second test, which was carried on by W. C. Bourns, was made with 2 lots of 10 steers each. Both lots were fed what was considered a fattening ration, consist-

ing of mint hay, wheat bran or oats, and corn meal, lot 2 receiving beet pulp in addition. The steers in lot 1 made an average daily gain of 1.84 lbs., and those in lot 2 an average daily gain of 2.52 lbs. It was calculated that in this test a ton of pulp was equivalent to 244 lbs. of mint hay, 32.6 lbs. of wheat bran, 296 lbs. of corn meal, and 27.2 lbs. of oats. These tests were favorable to the use of beet pulp, but the author calls attention to the fact that more experiments are needed before definite conclusions can be drawn.

A number of letters from farmers are quoted, as well as results of tests at other experiment stations.

"The consensus of opinion among farmers who have fed pulp is that for milch cows it is a good feed, although the pulp from frozen beets should be used with caution. Growing and fattening cattle do well on it, and owners declare that it saves one-third of the coarse fodder. Both fattening lambs and breeding ewes like pulp, and for them it proved a valuable factor in the ration."

Sheep, J. H. GRISDALE (*Canada Expt. Farms Rpts. 1901, pp. 290, 291*).—Brief notes on the station flock and on the feeding value of rape.

Sheep, R. ROBERTSON (*Canada Expt. Farms Rpts. 1901, p. 367*).—A brief statement concerning the flock at the Maritime Provinces Experimental Farm.

Swine, J. H. GRISDALE (*Canada Expt. Farms Rpts. 1901, pp. 291-295*).—Besides statistics and a discussion of the causes of soft pork, a feeding test with 4 lots of 4 pigs each was briefly reported. In addition to meal (equal parts of corn and of oats, barley, and peas) and skim milk, lot 1 was fed turnips, lot 2 mangel-wurzels, lot 3 sugar beets grown for forage, and lot 4 sugar beets grown for sugar. At the beginning of the trial the pigs ranged in weight from 57 lbs. in lot 4 to 101 lbs. in lot 1. Lots 1, 2, and 3 were fed 106 days, and lot 4 was fed 138 days. The average daily gain per pig in the 4 lots was 0.85, 0.90, 1.18, and 0.95 lbs., respectively, the corresponding cost per pound of gain being 3.69, 4.0, 3.22, and 3.6 cts.

Pigs, R. ROBERTSON, S. A. BEDFORD, and A. MACKAY (*Canada Expt. Farms Rpts. 1901, pp. 366, 367, 427, 510*).—The gain made by different breeds of pigs on corn meal and crushed oats, pea meal and crushed oats, shorts, and buckwheat, fed in every case with skim milk, was studied at the Maritime Provinces Experimental Farm. Deductions were not drawn from the test, which is very briefly reported. Notes are given regarding the pigs at the Manitoba and Indian Head farms.

Further experiments on different methods of preserving pork (*Ber. K. Vet. Landbohøjskoles Lab. Landökön. Forsög [Copenhagen], 1902, pp. 57, pls. 2*).—Experimental data are reported and discussed.

Report of the poultry manager, A. G. GILBERT (*Canada Expt. Farms Rpts. 1901, pp. 313-334, pl. 1, fig. 1*).—The author records the usual data regarding the poultry kept at the Ottawa Station, the egg production, growth made by chickens, the observations and investigations on hatching eggs, the feeding and care of chickens, and similar topics. Based on experience at the station, the statement is made that a mash, when fed in too great quantities to 1 and 2 year old hens, is apt to create an overfat condition, which, in the case of the heavy breeds, is likely to be fatal. If fed in too great quantity as a morning ration, mash is likely to make the hens disinclined for exercise. It is decidedly a valuable aid to molting hens, and is a convenient form of utilizing much of the farm and farmhouse waste. Where hens have had a comparatively free run, its beneficial effect in egg production has been noticeable. In a more or less liquid form a mash is an invaluable means of quickly fattening old or young stock.

Two feeding tests with chickens fed in crates and those having limited and unlimited runs are briefly reported. The author recommends that the chickens should be placed in crates either before or after they begin to molt, when $4\frac{1}{2}$ or 5 months old, preferably at the earlier period. In both tests the greater gains were made by the chickens fed in crates. In a study of breeds, Buff Orpingtons, Rhode Island Reds, and Salmon Faverolles were compared, the results being briefly reported.

Continuing early work (E. S. R., 13, p. 277) on the different methods of preserving eggs, the following conclusions are drawn:

"The common salt solutions without lime, both 1 per cent and 2 per cent, caused the eggs to have a more marked and disagreeable odor, especially on cooking. All the eggs in the 2 per cent fluid were unusable. Vaseline-covered eggs were not quite as well preserved as those simply in lime water. The paraffin-covered eggs were decidedly inferior to those simply preserved by lime water. The eggs dipped in a solution of permanganate of potash were decidedly bad, showing that the claims for this much-vaunted chemical are without foundation. In summing up the conclusions, we feel justified in repeating the statement that saturated lime water is a most effective preservative. We can further say that it is a cheap, easily prepared, and pleasant fluid to handle. The addition of a small amount of salt (not exceeding 1 per cent) appears to be an advantage, but a larger amount—even 2 per cent—of salt is decidedly detrimental to the quality of the preserved eggs."

Report of cooperative experiments with egg preservatives, W. R. GRATHAM (*Ontario Agr. and Expt. Union Rpt. 1901, pp. 31-33*).—Comparative tests of the merits of different egg preservatives led to the following conclusions:

"Where eggs were put up in ordinary salt, the evaporation was equal to 33 per cent of the contents of the egg. Where the eggs were greased this was reduced to 25 per cent. There is no evaporation of the egg with the water-glass or lime solution. Three per cent of the eggs put up in salt were bad, but where the eggs were greased there were none bad. In the experiments with water-glass, one to five, the eggs scored 44 out of a possible 50. Where the water-glass was one to seven, the eggs scored 43.2 out of 50. With the lime and salt solution the eggs scored 40, and in the lime water they scored 41. The eggs put up in salt scored 37, and the greased egg put up in salt scored 38."

Poultry, R. ROBERTSON, S. A. BEDFORD, and A. MACKAY (*Canada Expt. Farms Rpts. 1901, pp. 367, 368; 427, 428, 510*).—Brief statements are made concerning the poultry kept at the Maritime Provinces, Manitoba, and Indian Head Experimental Farms. At the Manitoba Farm the average cost of a pound of gain in a test covering about a month was 3.66 cts. with Light Brahmas and 4 cts. with Plymouth Rocks. Four Light Brahmas fed oats and skim milk for 20 days gained 8 lbs. and 5 ozs., at a cost of 3.7 cts. per pound. The same number of Light Brahmas fed mixed grains gained 7 lbs. and 7 ozs., at a cost of 3.9 cts. per pound.

The digestibility of maize by chickens, S. PARASCHITSCHUK (*Jour. Landw., 50 (1902), No. 1, pp. 15-32*).—Four experiments on the digestibility of maize by chickens are reported. The urine and feces were collected separately, this being rendered possible by a surgical operation, which is described. It was found on an average that the coefficient of digestibility of maize was as follows: Organic matter, 89.21; protein, 92.5; fat, 83.43; crude fiber, 62.40; nitrogen free extract, 91.76; mineral matter, 43.35. In one of the tests, which covered 3 days, the average amount of nitrogen consumed per day was 1.22 gms.; the amount excreted in the urine 0.830 gms., and in the feces 0.120.

The intestinal bacteria of chickens, M. RUBNER (*Centbl. Bakt. u. Par., 1. Abt., 30 (1901), No. 6, p. 239; Hyg. Rundschau, 12 (1902), No. 9, p. 448*).—A bacteriological study of the intestines and dejecta of young chickens. The dejecta of newly hatched chickens were sterile. Bacteria appeared after 2 days.

The value of intestinal bacteria in nutrition, II, M. SCHOTTELIUS (*Arch. Hyg., 42 (1902), No. 1-2, pp. 48-70*).—Continuing earlier work (E. S. R., 10, p. 885), the author reports experiments which lead to the conclusion that intestinal bacteria are necessary. Chickens hatched under sterile conditions and fed sterile food lived from 10 to 30 days only, yet they ate regularly and produced an abundance of feces. Similar chickens grew rapidly after they were fed cultures of *Bacillus coli gallinarum*, the bacillus which is apparently the first one to make its appearance in the intestinal tract of normal chickens.

Robinson method of breeding squabs, E. C. RICE (*Boston: Plymouth Rock Squab Co., 1902, pp. 79, pl. 1, figs. 41, dgm. 7*).—Detailed directions are given for raising squabs for market. The volume embodies the results of a number of years of practical experience.

DAIRY FARMING—DAIRYING.

Feeding experiments with dairy cows, C. D. SMITH (*Michigan Sta. Bul. 193, pp. 16-19*).—The feeding value of sugar-beet pulp was tested with 2 lots of 4 cows each. The experiment covered 2 periods of 6 weeks each, the first week in each period being considered as preliminary. Pulp was fed to lot 1 during the first period and to lot 2 during the second period, a hay and grain ration being fed to both lots throughout the experiment. Both lots increased in weight when eating pulp, and lost in weight on dry feed alone. When pulp was fed the 2 lots ate 9,463 lbs. of pulp, 3,381 lbs. of hay, 2,259 lbs. of bran, and 1,124 lbs. of corn meal, and when no pulp was fed 3,649 lbs. of hay, 2,431 lbs. of bran, and 1,217 lbs. of corn meal. The amount of pulp eaten was therefore offset by 268 lbs. of hay, 172 lbs. of bran, and 93 lbs. of corn meal. When fed pulp the 2 lots gave 7,258.6 lbs. of milk and 259.67 lbs. of butter fat, as compared with 6,843.6 lbs. of milk and 258.27 lbs. of fat when no pulp was fed, showing practically no increase in the yield of fat due to feeding pulp, but a total increase of 415 lbs. in the yield of milk.

Feeding trials with dairy cows, D. A. GILCHRIST and A. C. HALL (*Reading Col., Agr. Dept. Rpt. 1901, pp. 42-46*).—Three rations made up of different combinations and quantities of mangels, brewers' grains, oats, wheat, beans, and cotton-seed cake in addition to 6 lbs. of straw and 20 lbs. of hay were compared with 3 lots of 4 cows each. The test proper lasted 6 weeks. The ration composed of 28 lbs. of mangels, 2 lbs. of oats, 1 lb. of wheat, and 5 lbs. of cotton-seed cake gave the best results.

Experiments with dairy cattle, J. H. GRIDDALE (*Canada Expt. Farms Rpts. 1901, pp. 269-277*).—Tabulated data are given for 3 experiments conducted to ascertain the influence of milking cows at equal and unequal intervals. The results confirm the conclusions stated in the previous report that where the intervals between milkings are unequal the richer milk is produced after the shorter interval and that where the intervals are equal there is no appreciable difference in the quantity or the quality of the milk.

An experiment with 2 lots of 3 cows each is reported in which a ration consisting of barley, oats, and oil meal fed dry was compared with a ration consisting of bran and gluten feed fed wet. The rations were fed for 2 periods of 14 days each, and were reversed at the end of the first period. On the ration fed wet the 6 cows gave a total daily yield of 114 lbs. of milk, containing 3.83 per cent of fat, and on the ration fed dry a daily yield of 116½ lbs. of milk testing 3.99 per cent of fat, showing an increased daily yield of butter fat of 6 per cent in favor of dry feed.

Dairying in the South, S. M. TRACY (*U. S. Dept. Agr., Farmers' Bul. 151, pp. 48, figs. 4*).—The natural advantages of the South for dairying are pointed out and suggestions are given concerning the construction of dairy buildings, the formation and management of a dairy herd, watering and feeding cows, handling milk, butter making, etc.

Dairy herd records, J. H. GRIDDALE, R. ROBERTSON, and S. A. BEDFORD (*Canada Expt. Farms Rpts. 1901, pp. 266-269, 357-359, 422*).—Records for one year are given of 19 cows at the Central Experimental Farm, of 22 cows at the Experimental Farm for the Maritime Provinces, and of 21 cows at the Experimental Farm for Manitoba.

The milk of spayed cows, H. LERMAT (*L'Ing. Agr. Gembloux, 12 (1902), No. 11, pp. 516-523*).—Analyses of the milk of spayed cows showed no more uniformity in composition than ordinary milk. In general there was a notable increase in the content of fat and sugar and to some extent in the content of casein. The author considers that such milk is especially suited for infants.

Composition of the milk of sheep, TRILLAT and FORESTIER (*Jour. Agr. Prat.*, n. ser., 4 (1902), No. 28, pp. 38, 39).—The authors analyzed 171 samples of milk obtained during February, March, and April in 6 localities. Some of the results are summarized. Ten samples obtained in the region of Roquefort showed the following average composition: Solids 18.9, fat 6.98, sugar 5.53, casein 5.54, ash 0.96, lime 0.25, and acid 2.66 per cent.

Comparative skimming qualities of Holstein, Ayrshire, and Jersey milk, J. MAHON (*Queensland Agr. Jour.*, 10 (1902), No. 6, pp. 446, 447).—In 2 tests the 3 kinds of milk were separated under similar conditions. The percentage of fat in the skim milk was lowest in the case of Jersey milk and highest in the case of Holstein milk, though the difference was not marked.

Influence of food on the quality of milk, W. E. G. ATKINSON (*Jour. Southeast. Agr. Col. Wye*, 1902, No. 2, pp. 115-120).—Data are given for an experiment in which 6 cows were fed a ration composed of cabbages, oat straw, bean meal, and barley meal during a preliminary period, after which 2 of the cows received in addition corn meal and 2 linseed meal. Variations observed in the percentages of fat were not consistent with changes in the rations fed and are considered as due to other causes, such as the weather.

Effect of feed on the composition of milk and on the consistency or body of butter, J. B. LINDSEY ET AL. (*Massachusetts Sta. Rpt.* 1901, pp. 162-168).—A summarized account is given of an experiment similar to work previously reported (E. S. R., 13, p. 385). Two lots of 5 cows each were fed for periods of 3, 5, 6, and 4 weeks, respectively. Lot 1 received during the 4 periods a daily ration consisting of 3 lbs. of wheat bran, 5 lbs. of ground oats, $\frac{1}{2}$ lb. of cotton-seed meal, and $\frac{1}{2}$ lb. of gluten meal, in addition to hay and rowen. Lot 2 received the above ration during the first period, and the same ration a portion of which was replaced, respectively, by cotton-seed meal containing a minimum amount of oil, cotton-seed meal with the addition of cotton-seed oil, and Cleveland flax meal during the second, third, and fourth periods. The author gives the more important results as follows:

"(1) Cotton-seed meal with a minimum percentage of oil did not alter the percentage composition of the milk.

"(2) The addition of one-half to three-fourths of a pound of cotton-seed oil to the cotton-seed meal appeared to increase the fat percentage in the milk about four-tenths of one per cent, and this increase was maintained during the 6 weeks of the feeding period.

"(3) The substitution of Cleveland flax meal for the cotton-seed meal and oil resulted in a decrease of the fat in the milk to about the percentage found in the first period, while the nitrogen percentage was increased. This change in composition was probably due to the removal of the cotton-seed oil from the ration, and not to the influence of the flax meal.

"(4) Cotton-seed meal with minimum oil caused no marked variation in the chemical composition of the butter fat.

"(5) The addition of cotton-seed oil to the cotton-seed meal ration produced a noticeable increase in the melting point and iodine number of butter fat.

"(6) Cotton-seed meal with a minimum oil produced a firm butter.

"(7) The addition of cotton-seed oil, while it increased the melting point of the butter fat, produced a softer, more yielding butter than that produced by either the cotton-seed meal or the standard ration.

"(8) An excess of cotton-seed oil in the ration is likely to affect the health of the animal."

The production of milk and butter—variations in the composition of butter, L. MALPEAUX and J. DELATTRE (*Ann. Agron.*, 28 (1902), No. 4, pp. 209-223).—Causes of variation in the composition of butter are discussed and experiments relating especially to the influence of food are reported. Determinations were made of the volatile and fixed fatty acids, saponification number, and the critical temperature

of solubility in alcohol, of butter made from the milk of cows fed sugar-beet pulp, beets, brewery residue, malt sprouts, bran, and different oil cakes and forage crops. Pulp, brewery residue, and black medic in comparison with beets lowered the content of volatile fatty acids. During two seasons the percentage of volatile fatty acids was lower when cows were pastured than when fed green forage in the stable, the difference being considered largely due to food. Horse beans increased the volatile fatty acids, and colza, copra, linseed and cotton-seed cakes reduced the percentage in the order named. The establishment of a fixed limit for the proportion of volatile fatty acids in butter is discussed. Of 71 determinations made by the authors only 1 showed a percentage less than 5, while the average was 6.14. It is pointed out, on the other hand, that the percentage of volatile fatty acids in Dutch butter often falls below 5.

Effects of variations in the ripening and churning of cream upon the butter produced, D. A. GILCHRIST (*Reading Col., Agr. Dept. Rpt. 1901, pp. 47-50*).—Butter churned into small grains and into lumps contained, respectively, 11.4 and 12.5 per cent of water. The loss of fat in buttermilk from sweet cream was much greater than in buttermilk from ripened cream. Immersing butter in water at 70° F. for 15 minutes and churning slightly increased the weight 3 per cent. Salting butter in brine did not increase the water content over dry salting.

Killing tubercle bacillus in milk by exposure to temperatures under 100° C., E. LEVY and H. BRUNS (*Hyg. Rundschau, 11 (1901), No. 14, pp. 669-675*).—Experiments were carried out during which milk containing tubercle bacilli was subjected for different lengths of time to various temperatures under 100° C. The tubercle bacilli were obtained from pathological tissue of bovine origin. From these experiments it is concluded that when milk is exposed in a water bath to a temperature of from 65 to 70° C. for a period of from 15 to 25 minutes, all bacteria contained in the milk are destroyed. This method of sterilization is not recommended for practical use in individual families, but it is believed to be practical for dairymen. It is urged that care should be taken to have the milk and vessels in which it is contained heated to a proper temperature before beginning the treatment in order to be sure that a sufficient temperature is maintained during the whole period.

A micrococcus the thermal death limit of which is 76° C., H. L. RUSSELL and E. G. HASTINGS (*Centbl. Bakt. u. Par., 2. Abt., 8 (1902), No. 11, pp. 339-342, pl. 1*).—A description is given of the micrococcus used in pasteurization experiments at the Wisconsin Station (*E. S. R., 13, p. 986*).

Compilation of analyses of dairy products made at Amherst, Mass., 1868-1901, E. B. HOLLAND and P. H. SMITH, JR. (*Massachusetts Sta. Rpt. 1901, p. 193*).—Average analyses of 3,281 samples of milk, 3 of human milk, 2 of colostrum, 358 of skim milk, 31 of buttermilk, 203 of cream, 131 of butter, and 8 of cheese.

Canadian butter as exported, F. T. SHUTT (*Canada Expt. Farms Rpts. 1901, pp. 190, 191*).—An analysis of one sample of butter reported as adulterated with oleo-margarine by the customs analyst at Havana showed a fat content of 83.15 per cent, Reichert number of 27.45, saponification equivalent of 219.3, and a specific gravity of 0.912.

Butter and margarin, L. GRANDEAU (*Jour. Agr. Prat., n. ser., 3 (1902), No. 25, pp. 789-791*).—Statistics on the production and consumption of margarin in different countries.

Annual report of the experiment station for cheese making at Lodi, 1901 (*Ann. R. Staz. Sper. Caseif. Lodi, 1901, pp. 148*).—In addition to a report of the director on the work of the station during the year and a statement concerning the amount of the different kinds of cheese produced, this includes articles on the following subjects: An experiment in feeding calves with skim milk; use of separator skim milk; conferences on butter and separators at the Lodi exposition; researches and observations on the industrial use of casein; use of casein in the clarification of wine; experi-

ments on the feeding value of oil cakes for dairy animals; new lacto-densimeter for the determination of solids in milk; development of the cheese industry in Sardinia.

Annual reports of the dairymen's associations of the Province of Ontario, 1901 (*Ontario Dairymen's Assocs. Rpts. 1901, pp. 176*).—Among the subjects discussed and reported in the proceedings are the following: Developing a Dairy Herd, by J. E. Gould; Dairy Chemistry, by R. Harcourt; Creamery Leaks, by J. W. Hart; Creamery and Cheese Factory Buildings, by J. A. Ruddick; The Canadian Dairy Industry, by S. Fisher; Practical Cheese Making, by G. G. Publow; Bacterial Infection of Cheese, by W. T. Connell; Permanent Pasture and Hay Mixtures, by J. Fletcher; Conditions Affecting the Curing of Cheese, by L. L. Van Slyke; Developing a Dairy Herd, by H. H. Dean; Silos and Silage, by H. H. Dean; Cheese Making, by G. G. Publow; Cold Storage for Hot Weather Cheese, by H. H. Dean; Bitter Milk and Cheese, by F. C. Harrison; Summer Creameries, by A. Smith; Continuous Pasteurization of Milk for Butter Making, by F. C. Harrison; Loss of Casein and Fat by Washing Curds, by R. Harcourt; The Marketing of Cheese and Butter, by A. Pattullo; Judging Cheese, by A. F. MacLaren; Transportation, by A. F. MacLaren; and Judging Butter, by I. W. Steinhoff.

Dairy legislation, J. B. LINDSEY (*Massachusetts Sta. Rpt. 1901, pp. 156-160*).—An act to provide for the protection of dairymen is given and the work of the station in compliance with this law is reported. Of 5,041 pieces of glassware tested, 291 were found to be incorrect.

Officials, associations, and educational institutions connected with the dairy interests of the United States for the year 1902 (*U. S. Dept. Agr., Bureau of Animal Industry Circ. 36, pp. 8*).

VETERINARY SCIENCE AND PRACTICE.

Annual report of the board of cattle commissioners, A. PETERS, L. F. HERRICK, and C. A. DENNEN (*Massachusetts State Bd. Cattle Com. Rpt. 1901, pp. 97, figs. 3*).—The authors present a historical account of the establishment of the work of the Board of Cattle Commissioners of the Commonwealth of Massachusetts. During the past year the principal item of expense in conducting operations was incurred in combating tuberculosis. The operations of the cattle commissioners against tuberculosis were as usual along 3 lines: The maintenance of quarantine regulations, inspecting animals and herds, and testing herds with tuberculin at the request of owners. Detailed notes are given on the number of animals imported into the State and shipped out of the State at different points, and a tabular statement is given of the number of herds and animals inspected and the number of animals found infected with various diseases. During 1901 little work was done in the direction of testing whole herds. Only 5 herds were tested, comprising 75 animals. Of these 23 were killed. The State still pays an indemnity for animals condemned for tuberculosis, and the expense is therefore considerable.

During the year glanders has continued to prevail in many different parts of the State. A larger number (745) of cases were reported than ever before. The disease is controlled with comparative ease in small towns and outlying country districts, but in large cities, especially in Boston, much difficulty has been experienced in preventing the spread of glanders. It has been found that many horses suffering from a chronic form of the disease are owned by express companies and other organizations which possess large numbers of horses, and healthy animals are thus continually exposed to infection. Of the 745 animals which were killed on account of being affected with glanders 4 were mules and the rest were horses.

During the year little trouble from blackleg was reported to the commission. A peculiar disease previously reported by the commission as closely resembling black-

leg proved on further investigation to be identical with blackleg; the disease merely existed under peculiar conditions, with unusual symptoms.

A number of cases of actinomycosis were reported during the year; 4 cases were observed in the udder. No cases of Texas fever were noticed. A few isolated cases of rabies were reported from different localities. During the year 23 reports of outbreaks of hog diseases were received, and of these cases 12 proved to be hog cholera.

Annual report for 1900 of the principal of the Royal Veterinary College, J. McFADYEAN (*Jour. Roy. Agr. Soc. England*, 62 (1901), pp. 215-238).—During the year 1900, 577 outbreaks of anthrax were reported. As a rule only 2 or 3 cases of the disease occurred in each outbreak. Attention is called to the necessity of destroying the carcasses of animals dead of anthrax in order to prevent its further spread among susceptible animals. During the season a considerable increase in the number of cases of glanders was reported, there being 1,865 affected horses. While mallein is freely used for the detection of incipient cases of this disease, it is stated that in many instances the mallein test is not applied until cases of the disease are observed which may be recognized from the clinical symptoms.

After 5 years' complete freedom from foot-and-mouth disease it reappeared in 1899 and spread to a serious extent, in spite of the efforts of the board of agriculture to stamp it out. A brief historical statement is given of the outbreaks of this disease in England since 1839. During the year 1900, 21 outbreaks were reported, in which 266 animals were attacked. The symptoms and course of the disease in cattle, sheep, and pigs are discussed. There are a number of diseases of sheep which resemble foot-and-mouth disease to some extent and are occasionally mistaken for it. Among these mention should be made of foot rot, malignant aphtha, and a disease which is not well known, and commonly called "ori." This disease attacks lambs up to a year of age, and rarely appears in adult sheep. In the course of the disease lesions appear on the face and on the leg from the hoof as far up as the knee.

During the season 1,940 outbreaks of hog cholera were reported. It was observed in this connection that the extent of each outbreak was less than in previous years.

It appears that rabies was entirely eradicated from Great Britain in 1900, and no cases have subsequently been discovered.

An account is given of the extent of disease from stomach worms in cattle and sheep. Experiments with thymol in the treatment of this disease were unsatisfactory. The maximum quantity of thymol for each animal was $2\frac{1}{2}$ ozs. in 5 equal doses covering a period of 25 days, and it is believed that these were the largest doses which could be safely administered. It is suggested that the presence of stomach worms is a frequent cause of chronic diarrhea, and has sometimes been mistaken for generalized tuberculosis.

The sheep botfly is not of such common occurrence in England as to cause serious trouble. Occasional complaints are made of the attacks of this insect. Recommendations are made concerning methods for preventing trouble from this source.

While fowl cholera has been considered of rare occurrence in England, a few outbreaks of the disease were reported and investigated. The symptoms of the disease are described and preventive measures recommended.

Report of the chief inspector of stock, C. J. VALENTINE (*Rpt. Min. Agr. South Australia, 1900-1901*, pp. 23-26).—Brief notes are given on the prevalence of ticks, lice, fluke worms, foot rot, and ophthalmia among sheep. A number of cases of poisoning are reported from eating various plants, such as *Lotus australis* and *Euphorbia drummondii*. Among the cattle of the colony 42 cases of pleuro-pneumonia were observed and 510 cases of tuberculosis were reported. Brief notes are also given on actinomycosis and cancer in cattle. Notes are presented on the sanitary condition of horses and camels in the colony.

Report of the chief inspector of stock, P. R. GORDON (*Queensland Dept. Agr. Rpt. 1900-1901*, pp. 81-87).—Brief statistical notes on the extent of various diseases in Queensland during this season, on the numbers and distribution of horses, on brands, and marsupials. It is reported that during the season pleuro-pneumonia prevailed in a number of localities, but not in a very virulent form. Some loss from ticks is reported and a number of clips were tested with reference to their efficiency in destroying the ticks.

Report of the veterinary service of the minister of internal affairs for the year 1898 (*Otchet Vet. Uprav. Min. Vnutr. Dyel, St. Petersburg, 1901*, pp. 597).—A general statistical account of the number of domesticated animals in various parts of Russia, together with notes on the extent of various diseases among different kinds of animals. A brief account is given of the extent and virulence of 34 infectious or epizootic diseases. Tables are given showing the results of tuberculin and mallein tests and of experiments in preventive inoculation against anthrax.

The relationship between human and bovine tuberculosis, J. McFADYEAN (*Jour. Roy. Agr. Soc. England*, 62 (1901), pp. 50-57).—The author confines his discussion to the question of the identity of human and bovine tuberculosis. Attention is called to reports from children's hospitals in England, from which it appears that as high as 28 per cent of the cases of tuberculosis in children originated in the intestines. Other arguments are presented to support the belief in the identity of the disease in man and animals and in the possibility of its transmission from man to animals or from animals to man.

Transmission of tuberculosis through meat and milk, J. J. REPP (*Reprint from Amer. Med.*, 2 (1901), Nos. 17, 18, pp. 22).—The author presents a brief review of the question concerning the identity of human and bovine tuberculosis. From the evidence obtainable from previous experiments of various authors it is argued that tuberculosis may be transmitted from cattle to man, either in the meat or milk of tuberculous animals. Special attention is given to the consideration of the arguments which are opposed to the conclusions of Koch regarding this matter.

Certificate of health, H. LERMAT (*Jour. Agricole [Paris]*, 12 (1901), No. 141, pp. 203-212).—Statistical notes are given on the prevalence of tuberculosis of man and its relationship to the same disease among cattle. Copies of regulations for the inspection of milk and dairies in Nice are given. While it is recognized that the milk of cows which react to tuberculin does not necessarily contain the tubercle bacillus, it is highly desirable that all precautions be taken in order to prevent the transmission of the bacilli in the milk and meat of tuberculous cattle.

The infectiousness of milk of tuberculous cows. Bacteriological diagnosis and practical value of tuberculin in the extermination of bovine tuberculosis, LYDIA RABINOWITSCH (*Ztschr. Hyg. u. Infektionskrankh.*, 37 (1901), No. 3, pp. 439-448).—A critical review of the literature on this subject is given as a basis for a discussion of the practical value of tuberculin and bacteriological study of milk in the extermination of tuberculosis. The author believes that without the use of tuberculin it would be impossible to exterminate tuberculosis in cattle. By thoroughly applying the tuberculin test, all animals which are infected become known and may be separated from the rest of the herd. A study of the milk may then be made among the reacting animals to determine at what time the milk becomes infectious. For this purpose it is necessary to inoculate guinea pigs with the milk of suspected animals.

Further investigations concerning tubercle bacilli in the milk of cows which have simply reacted to tuberculin but do not show clinical symptoms of tuberculosis, R. OSTERTAG (*Ztschr. Fleisch u. Milchhyg.*, 12 (1901), Nos. 1, pp. 1-5; 3, pp. 72-76; 12 (1902), No. 4, pp. 109-113).—The author undertook an extensive investigation of the question concerning the presence of tubercle bacilli in the milk

of cows in which tuberculosis could not be recognized by clinical symptoms, although the animals reacted to the disease. The experiments involved the selection of 10 cows all of which reacted to tuberculin, inoculation and feeding experiments with the milk of these cows, and subsequent post-mortem examination of all of the cows. Microscopic examination and inoculation experiments with the milk in guinea pigs failed to show a single instance in which tubercle bacilli were present. A number of inoculation experiments were made on guinea pigs, but none of the animals developed any symptoms of the disease or showed evidence of being infected when a microscopic examination was made post-mortem. Feeding experiments with the milk of these cows were undertaken upon guinea pigs, pigs, and calves. The general result of the feeding experiments substantiated that which was previously obtained by the author in similar experiments. It was shown that the milk of cows which simply reacted to tuberculin does not contain tubercle bacilli. This was proved by microscopic examination and by inoculation and feeding experiments with guinea pigs. Further proof was obtained by feeding calves and pigs. In these experiments it was found that calves and pigs could be fed for weeks or even months upon the milk of such cows without becoming infected. The author recognizes that for the prevention of further spread of tuberculosis the most important measure is the extermination of mammary tuberculosis and cases which may be recognized by external symptoms.

Influence of antituberculous serum on the virulence of the tubercle bacillus, F. ARLOING (*Compt. Rend. Soc. Biol. Paris*, 53 (1901), No. 26, pp. 781-783).—Two series of experiments were conducted on guinea pigs and rabbits. Guinea pigs which were inoculated hypodermically with 2 drops of an emulsion of tubercle bacilli, grown on potato, were killed and examined for the purpose of determining the extent of infection. Other guinea pigs were inoculated at the same time with 2 drops of emulsion of tubercle bacilli in an antituberculous serum. The development of the disease was more rapid and more extensive in animals which received the antituberculous serum than in those which were inoculated simply with tubercle bacillus. Similar experiments were made on rabbits with similar results. It is concluded that antituberculous serum increases the virulence of the tubercle bacillus and favors the generalization of infection.

The favoring action of antituberculous serum toward infection by the tubercle bacillus in homogenous liquid cultures, F. ARLOING (*Compt. Rend. Soc. Biol. Paris*, 53 (1901), No. 34, pp. 950, 951).—Continuing the above work, experiments were made with tubercle bacillus grown on various other media. Rabbits were inoculated with a mixture of cultures of tubercle bacillus and an antituberculous serum in the peritoneum. Similar inoculations were made in the pleura of rabbits. All the rabbits which were inoculated with mixtures of pure cultures and antituberculous serum showed the development of a generalized infection of tuberculosis. Some of them died and others were killed and examined after death for the purpose of determining the extent of the disease. As a result of post-mortem examinations it was found that the antituberculous serum favored peritoneal infection from pure cultures of tubercle bacillus. It is concluded that this serum increases the virulence of the tubercle bacillus, whether inoculated intraperitoneally or hypodermically.

The value and significance of the Arloing-Courmont serum reaction, especially in reference to the early recognition of tuberculosis, M. BECK and LYDIA RABINOWITSCH (*Ztschr. Hyg. u. Infektionskrankh.*, 37 (1901), No. 2, pp. 205-224).—Since 1898 a number of articles have been published by Arloing and Courmont in which experiments were reported indicating that cultures of the tubercle bacillus could be brought to agglutination by means of the blood serum of tuberculous animals. The authors undertook an investigation of this subject and the results of their studies are reported in detail in tabular form. The experimental animals included 78 cattle, of which 19 were nontuberculous. Among the 19 healthy cattle the serum reaction was negative in only 1 case; in 2 cases it appeared to develop in

a proportion of 1:5; positive in 4 cases in the same proportion; in 4 cases in a proportion of 1:10; in 3 cases in a proportion of 1:20; in 4 cases in a proportion of 1:30; and in 1 case in a proportion of 1:40. The serum reaction in the tuberculous cattle was equally irregular and unsatisfactory, being negative in some cases and positive in others, without any apparent explanation for the irregular results. From these investigations the authors conclude that the method of serum reaction is of little value in diagnosing tuberculosis among cattle; that a positive reaction does not necessarily indicate the presence of tuberculosis; and a negative reaction does not necessarily mean that the animal is free from the disease.

Actinomycosis, W. SILBERSCHMIDT (*Ztschr. Hyg. u. Infektionskrankh.*, 37 (1901), No. 3, pp. 345-380, pls. 2).—A study was made of the pathogenic organisms concerned in a number of cases of actinomycosis in man and cattle. Inoculation experiments were made with purulent material obtained from human and bovine cases of actinomycosis and bacteriological studies were made of the organism obtained from pure cultures from these substances. In the inoculation experiments with actinomycotic material of human origin, rabbits and guinea pigs proved to be almost but not quite resistant. Similar results were obtained from inoculating these animals with material of bovine origin. In all, 8 forms of micro-organisms were obtained from the cases of actinomycosis which were studied. None of these forms corresponded in their morphological characters with the organism described by Boström as the only cause of actinomycosis in man and animals. The author concludes that the assumption that actinomycosis is a specific disease caused by a single parasitic fungus is incorrect. Typical symptoms of the disease may be produced by a number of different micro-organisms. The direct microscopic investigation of the actinomycotic tumors does not suffice for making a certain diagnosis of the disease. In order to identify the micro-organisms it is necessary to make pure cultures. Nearly all of the micro-organisms which were found in cases of actinomycosis in man and animals are considered by the author as belonging to the group Actinomyces.

Germination of anthrax spores, R. WEIL (*Arch. Hyg.*, 39 (1901), No. 3, pp. 205-229).—The general problem of the biology of the anthrax bacillus was investigated with special reference to spore germination. It was found that when material containing anthrax spores was subjected to favorable conditions for germination, the majority of the spores germinated within a fairly constant period, depending upon the temperature. It was impossible, however, to find a time at which no spores were present in the material, and it is therefore considered impossible to free such material from spores by the method of fractional sterilization. New spore formation took place before the old spores had all germinated. When large masses of spores were brought to the point of germination at an optimum temperature, it was found that only a small number of them germinated, multiplied, and produced new spores. It was impossible to determine the cause of this failure of the majority of spores to reproduce themselves. The germination of a greater number of anthrax spores which were able to develop normally took place as a rule after 8, 16, and 70 hours, at temperatures of 37, 24, and 18° C. respectively. In a few cases germination of spores took place at 0° C. The formation of new spores occurred after 21, 23, 48, and 96 hours, at temperatures of 37, 29, 24, and 18° C. respectively. The germination of anthrax spores was strongly influenced by weak solutions of various chemical reagents. A brief exposure to 1 per cent chloroform, 1.5 per cent aqueous solution of carbolic acid, or 1 per cent solution of formalin, destroyed the germinating power of all spores.

Demonstration of anthrax bacilli, C. FRAENKEL (*Hyg. Rundschau*, 11 (1901), No. 13, pp. 633-635).—A report is given on the method adopted by the author for identifying the bacillus of anthrax in 5 suspected cases, of which 3 were in man, 1 in a cow, and 1 in a horse. A microscopic examination of pathological tissue in stained and unstained conditions failed to give a certain diagnosis. Cul-

tures of the material were then made on gelatin and agar media and inoculation experiments were tried on guinea pigs and mice. In the material of bovine origin a demonstration of anthrax bacillus was secured, both through cultures and through inoculation experiments. In the material of human origin the demonstration was successful only in the inoculation experiments in the mouse. In the other cases, where material came from man and from the horse, inoculation experiments gave negative results, while anthrax colonies developed upon the culture media. The author concludes from his experiments that it is desirable to use both the culture and inoculation methods for demonstrating the anthrax bacillus, and that in some cases the inoculation method is the more sensitive test, while in others the culture method is the better.

The relation of the germicidal power of rabbit serum to anthrax infection, M. WILDE (*Ztschr. Hyg. u. Infektionskrankh.*, 37 (1901), No. 3, pp. 476-496).—As the result of experiments on this subject the author concludes that anthrax bacilli first appear in the blood during the crisis of the disease. At this time, while anthrax bacilli can be readily demonstrated in large numbers in the blood, the germicidal power of the blood is either entirely lost or rapidly disappearing. Besides alexins, there exists in the blood of most rabbits another body, which is antagonistic only to the anthrax bacillus and which is not destroyed by heating for one-half hour at a temperature of 57° C., but requires for its destruction an exposure to that temperature for a period of 24 hours.

Epizootic or contagious abortion, J. MCFADYEAN (*Jour. Roy. Agr. Soc. England*, 62 (1901), pp. 96-112).—A general discussion is given to the various conditions which may bring about abortion, but especial attention is given to the contagious form. The means of dissemination of the disease are briefly mentioned and an account is given of some experiments conducted in England on this subject. The disease is of most frequent occurrence in cows, but may become more or less serious in mares and ewes. Strict measures are necessary in order to prevent the spread of the disease when once it has become introduced in herds of cattle, horses, or sheep. The use of disinfectants in such cases is recommended.

Treatment of contagious mammitis in cows, E. ZSCHOKKE (*Jour. Agric. [Paris]*, 12 (1901), No. 141, pp. 212-214).—After an extended investigation of the symptoms and pathological anatomy of this disease the author calls attention to the great variation in symptoms and consequent difficulty in reaching a reliable diagnosis in a large number of cases. The experience of the author in artificial treatment of the disease was not very satisfactory, and it is urged that where only one quarter of the udder is affected, this part should not be milked after the disease has developed far enough to be recognized. By milking the affected quarter great danger is presented of transmitting the infection to other parts of the udder. In a large proportion of cases recovery takes place, whether artificial treatment is applied or not, but in cases of spontaneous recovery, as well as in those which are treated, the part of the udder which is affected is likely to become nonfunctional. In a large proportion of cases, therefore, all that can be done is to prevent the spread of the disease to other parts of the udder.

Mortality among calves in Munster, E. NOCARD (*Dept. Agr. and Tech. Instr. Ireland, Bul. 1, 1901, pp. 115*).—This bulletin contains a report by Professor Nocard in French, with a translation into English, upon the subject of "white scour" and "lung disease" among calves in Ireland. The bulletin also contains observations made by A. E. Mettam and T. Wade on the same subject. During these researches it was shown that "white scour" and "lung disease" in calves are different symptoms of one and the same disease. The disease is caused by a specific micro-organism belonging to the genus *Pasteurella* and identical with that which causes farcinous lymphangitis in horses and caseous broncho-pneumonia in sheep. The micro-organism gains an entrance to calves at the time of birth through the umbilicus, and the

proper treatment of the disease should be of a prophylactic nature and should be largely confined to sterilization of the umbilical cord and to disinfection of stables in which the disease has occurred. The symptoms of "white scour" usually appear within a day or two after birth while those of "lung disease" occur considerably later. It had already been observed by stockmen, however, that this particular form of lung disease occurred only in localities where "white scour" was prevalent. The experiments of the authors showed conclusively that the two diseases are identical.

Malaria of cattle in Germany, E. JACKSCHATH (*Centbl. Bakt. u. Par., 1. Abt., 29 (1901), No. 14, pp. 585-589, fig. 1*).—A report is given on the results of observations upon 200 cases of this disease in cattle. It is noted that the disease closely resembles Texas fever, but is apparently somewhat different. Cattle which are native to permanently infected localities become immune to the disease, while cattle which are imported from other localities are subject to acute or chronic attacks of malaria. The symptoms of the disease are similar to those of Texas fever and include a high fever, followed by a period of stupor, and accompanied with a destruction of red blood corpuscles. Death seems to be due to a general anæmia and obstructions to the circulation of the blood in the small blood vessels caused by dissolution of organic material. The author believes that the disease is carried from animal to animal by a common species of cattle tick, *Ixodes reticulatus*.

Description and treatment of scabies in cattle, R. W. HICKMAN (*U. S. Dept. Agr., Bureau of Animal Industry Bul. 40, pp. 23, figs. 15*).—Scabies of cattle is widely distributed on the ranges of the West and Northwest. The disease is known as range itch, cattle itch, and cattle mange or scabies, the latter being most correct. Two forms of the disease occur, one being caused by *Psoroptes communis* var. *bovis*. This form is more frequent on the sides of the neck and shoulders, at the base of the horns, and root of the tail. It may spread to the back and sides and cover nearly all parts of the body. When generally distributed over the skin it may in some cases prove fatal. The mites were found to remain alive and active for 8 to 11 days when kept in a glass bottle at the temperature of living rooms. Exposure to dry sunlight, however, killed the majority of the mites within a few hours. The disease does not usually attack cattle in good condition, especially not after they reach 3 years of age. The animals which are most affected are calves, yearlings, 2-year-olds, and those that are in poor condition.

The other form of scabies is due to *Chorioptes symbiotes* var. *bovis*. This form remains localized in the depressions of the back and at the base of the tail. It is not readily contagious, and yields promptly to treatment. The first-named species is distinguished by its relatively larger size. Notes are given on the life history of this species. The second-named species lives especially on the surface of the skin of the extremities, under epidermic scabs. Sarcoptic mange is more serious than either of the forms already mentioned, but is not common in cattle. This form of mange is transmissible from one species of animal to another. The period of incubation of cattle mange varies according to conditions, from 15 days to from 4 to 6 weeks.

It is important that corrals, sheds, and buildings in which infected animals have been should be thoroughly disinfected. Extensive dipping experiments have been made in North Dakota, and some of the details of these experiments, with drawings of the dipping vats used, were furnished by R. H. Treacy. The dipping material which was used was that known as South African official lime and sulphur dip, and contained 21 lbs. flowers of sulphur, 16½ lbs. unslaked lime, and 100 gal. water. A second dipping should be administered a few weeks after the first in order to destroy the mites which may have survived the first treatment. Several thousand cattle which had been dipped were carefully inspected without finding any evidence of scabies on them. The dipping liquid should be kept at a temperature of 102° to 110° F., and cattle should be kept in the liquid for 2 minutes. The size and cost of dipping vats will depend upon the number of animals which are to be dipped. A suit-

able dipping plant for a few farmers may be build for \$150, while a swimming tank costs \$350 or more. A detailed description with illustrations is given of a large and a small dipping vat for this purpose.

Scabies in cattle, R. W. HICKMAN (*U. S. Dept. Agr., Farmers' Bul. 152*, pp. 24, figs. 15).—A popular edition of the preceding bulletin.

Foot-and-mouth disease, with an account of the outbreak in Suffolk during 1901, E. J. CHENEY (*Agr. Students' Gaz., n. ser., 10 (1901), No. 5*, pp. 135-140).—A brief general account of this disease is presented, with special reference to an outbreak in Suffolk. The first case in this outbreak was reported on January 26, in a herd of cows, and 40 of the animals had to be slaughtered. Further outbreaks occurred at intervals for the next 3 months. All cases of this disease were within a radius of 5 miles. The origin of the infection in the first case was not determined.

Treatment for foot rot, J. CORRON (*Agr. Gaz. New South Wales, 12 (1901), No. 2*, p. 1394).—As a remedy for foot rot in sheep the author recommends a mixture containing $\frac{1}{2}$ lb. copper sulphate, $\frac{1}{2}$ lb. common salt, and 1 qt. of water. The mixture is to be boiled for about 10 minutes in order to dissolve the copper sulphate.

Bots in sheep, J. D. STEWART (*Agr. Gaz. New South Wales, 12 (1901), No. 12*, pp. 1542, 1543, pl. 1).—The sheep bot fly is of comparatively rare occurrence in New South Wales. The symptoms of the disease are given from cases observed by the author and the insect which causes the trouble is described in all its stages. The usual remedies for the disease are recommended.

Immunization against swine plague and hog cholera by means of immune proteidin, H. GREITHER (*Inaug. Diss. Univ. Bern, 1901, pp. 16*).—The author attempted to apply in the treatment of swine plague and hog cholera the method proposed by Emmerich and Löw, according to which immune enzymes are applied in checking the development of contagious diseases. It was found that a bacteriolytic enzyme was formed in fluid cultures of swine-plague bacteria and in experiments with this disease inoculation with this enzyme had the effect of checking the disease. Similar experiments with hog cholera were not so encouraging. It was found during these experiments that hog-cholera bacteria in bouillon cultures containing nitrates formed large quantities of nitric acid within a short period. It is suggested that this effect might also be produced in the intestines of hogs suffering from hog cholera, and it is therefore recommended that no food containing nitrates be given during the prevalence of this disease.

Pulmonary antiseptics in infectious pneumonia of horses, PRUNEAU (*Rec. Med. Vet., Paris, 8. ser., 8 (1901), No. 5*, pp. 145-155).—The author discusses the action and effectiveness of various antiseptics which are suitable to be applied in the way of intratracheal injections. The following formula was used in experimental treatment of the disease: Eucalyptol 5 gm., guaiacol 5, menthol 5, essence of thyme 10, essence of wintergreen 10, essence of cinnamon 10, essence of turpentine 30, iodoform 10, pure sterilized olive oil 150. The chemical action of this mixture brings about a disinfection of the respiratory passages, drying of the mucous surfaces, cessation of cough, and a more rapid absorption of medicinal substances by the pulmonary mucous surfaces. The mixture was injected into the trachea by the ordinary method in doses of 20 cc. Experiments on 9 horses indicated that this mixture checks the development of the pathogenic micro-organisms to such an extent that the chances of a rapid and complete recovery are much increased.

Emergency report on surra, D. E. SALMON, C. W. STILES, and A. HASSALL (*U. S. Dept. Agr., Bureau of Animal Industry Bul. 42*, pp. 152, pls. 33, figs. 79).—This report was prepared by the authors in response to a request from the War Department for information concerning surra. The disease recently began to attract attention in the Philippines, where it affects horses, mules, and caribao. The present report is compiled from the literature of the subject, especially from the works of A. Lingard, G. Evans, et al. The report includes a discussion of all the principal problems connected

with surra, including etiology, means of infection, pathology, course of the disease, treatment and preventive measures. Notes are also given on the tsetse-fly disease, mal de caderas, and the trypanosoma disease in rats and bandicoots. A bibliography of the literature on this subject occupies pages 131-148.

Cytological modification of the parasitized animal cell, P. DORMOY (*Bul. Soc. Sci. Nancy*, 3. ser., 2 (1901), No. 2, pp. 68-72).—Different conditions have been found by different authors in work on the problem of the effect of parasitism in animal cells. In some cases the presence of the parasite causes great changes, hypertrophy, and degeneration; in others, the parasite appears to remain in the cell without causing any recognizable disturbance. The differences in the conclusions deduced from this study by different authors probably depend on differences in conditions under which the studies were made. In the author's investigations special attention was given to the study of *Karyophagus salamandrae*. It was found that parasitized cells were not modified, that the cytoplasm did not differ from that of unparasitized cells, and that no hypertrophy took place in the nucleus. In some cases it is believed that as soon as cells become parasitized they begin the secretion of a digestive enzyme, and that the parasitic organism antagonizes this substance to a greater or less extent by the secretion of a substance which has a tendency to neutralize the enzymes.

Notes on parasites, M. G. TARRAKOVSKI (*Arch. Vet. Nauk, St. Petersburg*, 31 (1901), No. 11, pp. 1043-1049).—The author discusses the occurrence of surra in gray rats. *Trypanosoma lewisi* was found in the blood *Mus decumanus* and *M. sylvestris*. Notes are given on the occurrence of *Trichosoma tenuissimum* and *Filaria clara* in pigeons. Species of lung worm were found causing serious disease among rabbits (*Lepus cuniculus* and *L. timidus*). The species of lung worm chiefly concerned in causing infestation among rabbits is *Strongylus commutatus*.

The method of adhesion of certain parasitic nematodes to the intestinal walls of mammals, A. RIZZO (*Atti R. Accad. Lincei. Rend. Cl. Sci. Fis. Mat. e Nat.*, 5. ser., 10 (1901), I, No. 8, pp. 309-317, figs. 3).—The author studied the mode of attachment of a number of species of nematode worms to the intestines of mammals, and also the effect produced by the presence of these parasites in the alimentary tract. The species upon which most work was done were *Sclerostomum tetracanthum* and *Trichocephalus affinis*. A description is given of the organs by means of which the worms secure their hold upon the wall of the intestines, and anatomical details are presented concerning the pathological effects of the irritation set up by the presence of the worm.

The button disease of chickens (*Jour. Agr. Trop.*, 1 (1901), No. 6, pp. 172-174; reprint from *Bul. Union Agr., Calcutta*, 1901, Oct. 20).—In the tropical countries a disease of young chickens characterized by the appearance of button-like tubercles at the angle of the mouth is comparatively frequent. This disease is due to a parasitic fungus and is considered a kind of aspergillosis. The parasitic fungus is normally present in the soil and on various grains, especially rice. In preventing the disease it is recommended that all rice should be disinfected before being fed to young chickens. As a treatment for the button disease it is recommended that the tubercle be removed and that the raw surface thus exposed be painted with tincture of iodine. In all cases in which this treatment was applied in the early stages of the disease complete recovery was brought about.

Vaccination and serum therapy in roup, C. GUÉRIN (*Ann. Inst. Pasteur*, 15 (1901), No. 12, pp. 941-952).—An organism was isolated from chronic cases of roup in chickens and was found to be of slight and variable virulence. Taken from the first culture it would kill pigeons or chickens, but would produce no disturbance when inoculated in large doses from the second culture. In order to increase the virulence of the organism for experimental purposes, it was repeatedly inoculated into the lower eyelid of pigeons, and after several generations the virulence was found to be much increased. After passing twelve times through pigeons in this

manner it was of sufficient virulence, in doses of $\frac{1}{4}$ cc., to kill pigeons in 18 hours when inoculated in the conjunctiva of the eyelid. Still further operations of this sort rendered the organism of sufficient virulence to kill rabbits, chickens, and other small experimental animals. Notes are given on the pathological changes produced by inoculations of the organisms. During these experiments the same symptoms were produced as those observed in cases of natural infection. It was found possible to vaccinate chickens against roup by means of 2 injections. The first injection was made with a virulent culture 24 hours old in bouillon after heating to a temperature of 55° C. for 1 hour. The organism is killed by this process. The second injection should follow 12 hours after the first, and should be made with a virulent culture of the same age, exposed for 1 hour to a temperature of 50° C. Both injections are made in doses of $\frac{1}{2}$ cc. Within from 12 to 15 hours after the second inoculation the animal possesses complete resisting power to fatal doses of the virulent organism.

From horses which were previously immunized a serum was obtained of remarkable antitoxic power. Two inoculations of the serum are necessary at intervals of 24 hours.

The relation of the agglutinins to the protective bodies, A. CASTELLANI (*Ztschr. Hyg. u. Infektionskrankh.*, 37 (1901), No. 3, pp. 381-392).—For studying the relationship between these two substances the author made experiments on rabbits, using the bacillus of dysentery. It is concluded that the agglutinating substance and protective bodies react in the same manner toward chemical and physical influences. There is no parallelism between the development of the agglutinating and immunizing power in the living body. In immunized animals during the first few days the serum is always richer in agglutinins than the spleen, while the spleen contains more of the protective bodies. The author believes that the view that a close relationship exists between the protective and agglutinating substances must be abandoned.

Comparative experiments on the reliability of different methods of disinfecting by means of formaldehyde, A. REISCHAUER (*Hyg. Rundschau*, 11 (1901), No. 13, pp. 636-655).—The author conducted extensive experiments with various forms of apparatus which have been recommended for producing formaldehyde gas for disinfecting purposes. From these experiments it is concluded that there is a large variety of apparatus by which formaldehyde gas may be generated in sufficient quantity and distributed uniformly in an active condition throughout the space to be disinfected. The generation of the gas is not very expensive. It is apparent, however, that the general application of this method of disinfection has two disadvantages, in that formaldehyde gas is not capable of destroying bacteria in the spore form, and does not penetrate clothing, carpets, and other similar material to an extent which renders certain the destruction of bacteria in such situations. A bibliography of 156 titles is appended to the article.

The grass pea (*Lathyrus sativus*), F. T. SHUTT (*Canada Expt. Farms Rpts.* 1901, pp. 183-185).—A request was made of the chemist to investigate statements which have obtained some currency to the effect that the grass pea possesses poisonous qualities. In times of famine, when the natives of India live largely upon the seed of this pea, a disease develops, apparently as a result of this diet, which is known as lathyrismus. Careful analyses were made by the author of considerable quantities of the seed of this pea, but all results were negative, no alkaloid or other poisonous principle being found. A feeding experiment was then conducted with a rooster and hen which were fed almost exclusively on grass peas for a period of 72 days. The fowls ate on an average from 2½ to 2¾ oz. per day. No poisonous effects were produced by this diet, and all data collected by the chemist indicate that the grass pea raised in Canada is not poisonous.

Index-catalogue of medical and veterinary zoology, C. W. STILES and A. HASSALL (*U. S. Dept. Agr., Bureau of Animal Industry Bul.* 39, pt. 1, pp. 46).—In this part of the bulletin a beginning is made of the publication of the card index in the

zoological division of the Bureau. It is arranged alphabetically according to authors and includes all authors' names beginning with A. The subjects covered by the catalogue are along the lines of medical and veterinary zoology. The hope is expressed that subsequently a subject catalogue of this material may be published.

AGRICULTURAL ENGINEERING.

The engineering of agriculture, O. V. P. STOUT (*Agriculture [Nebraska]*, 1902, June, pp. 5-10).—This article discusses briefly the need and opportunities for investigation along the following lines: Irrigation and drainage; road making; water supply and sewerage engineering; landscape gardening; the use of steam, electric, water, and wind power; construction of farm buildings, bridges, etc.; heating, ventilation, and refrigeration; prevention of erosion; the mechanical principles of draft; and machine construction.

Irrigation at the station farm, 1898-1901, A. J. McCLATCHIE (*Arizona Sta. Bul.* 41, pp. 48, figs. 4).—This bulletin discusses the available water supply, soil of the station farm, season of growth, rainfall during the years covered by the experiments, temperature and relative humidity, evaporation, method of measuring water, the importance of using water economically, the amounts of water applied during different years, and the methods used in irrigating alfalfa, beets, cabbages, corn, cow-peas, grain, grapes, melons, onions, orchards, peas, potatoes, pumpkins and squashes, sorghum, strawberries, tomatoes, and small garden vegetables. The water supply of this region (the Salt River) is irregular, being smallest in summer when most needed, thus emphasizing the need of storage reservoirs to equalize the flow. "Without storage reservoirs, the most rational procedure is to store in the soil during the periods of heavy river flow, as much water as practicable, and to irrigate all crops in the most economical manner during periods of scarcity."

The average rainfall is about 7 in., but was below the average for the period covered by the experiments here reported. "With the exception of a few of the rains of winter, local rains are seldom of direct benefit to crops, and in many cases are a decided injury. . . . The mean annual temperature at the farm has been 68 to 69° F., during the past 4 years, and the mean relative humidity 33 to 37. The total evaporation from a water surface for the one year during which a record has been kept was 65.6 in., evaporation being most rapid during July, and slowest during December and January. . . . The total amount [of water] used upon the station farm during 1901 was approximately 6 acre-feet per acre, more than necessary being applied during winter, and the available supply during summer being inadequate. Of the crops of which a record was kept during 1900, barley received the smallest amount of water, and onions the greatest. Of the crops grown during 1901, potatoes received the smallest amount of water, and strawberries the greatest. . . . Orchards and vineyards need irrigation throughout the summer, when young; but when established, most of the water needed by them may be applied during winter."

Irrigation in the East (*Forestry and Irrig.*, 8 (1902), No. 7, pp. 298-300).—A brief summary of statistics from the Twelfth Census showing the extent of irrigation in Maine, Massachusetts, Connecticut, Rhode Island, New Jersey, New York, and Pennsylvania.

Irrigation and rice growing in Louisiana (*Forestry and Irrig.*, 8 (1902), No. 9, pp. 366-370, figs. 2).—A brief account of the recent rapid growth of the rice industry in Louisiana, due mainly to the introduction of improved methods of irrigation.

The distribution of water. Powers and duties of irrigation officials in Colorado, H. N. HAYNES (*Colorado Sta. Bul.* 67, pp. 31).—This bulletin consists of two lectures delivered before the short course for irrigation officials at the Colorado Agricultural College in the spring of 1901, which give a summary of useful information on this subject.

Diagrams of mean velocity of uniform motion of water in open channels; based on the formula of Ganguillet and Kutter, I. P. CHURCH (*New York: John Wiley & Sons; London: Chapman and Hall, Ltd., 1902, pp. 25*).

Dynamometer tests with farm implements, C. W. BURKETT and F. S. JOHNSTON (*New Hampshire Sta. Bul. 87, pp. 122-124*).—Tests of draft of old and modern types of walking plows, disk and spring-tooth harrows, corn binders, and farm vehicles (wagons, carts, and sleds) under different conditions are briefly reported.

The cool side of a house in Arizona, S. M. WOODWARD (*Arizona Sta. Bul. 42, pp. 49-57, fig. 1, chart 1*).—This bulletin shows how the heating effect of the sun may be minimized by attention to size and shape of the building, materials used, method of construction, external protection, etc. According to the calculations given the dimensions of a house which shall receive the minimum amount of heat should bear about the following relations to each other: Breadth (north and south) 2.36, length (east and west) 8.82, height 8.45.

Ventilation of farm stables and dwellings, J. B. REYNOLDS (*Ontario Agr. Col. and Expt. Farm Bul. 119, pp. 24, figs. 16*).—This bulletin includes a general discussion of the subject and details of methods actually in use. (See also E. S. R., 13, p. 1104).

Granaries arranged for mechanical handling of the grain, M. RINGELMANN (*Jour. Agr. Prat., n. ser., 4 (1902), Nos. 33, pp. 213-218, figs. 5; 34, pp. 250-252, figs. 4*).

The modern silo, C. S. PLUMB (*Indiana Sta. Bul. 91, pp. 83-106, figs. 5*).—This bulletin explains the advantage of the round silo and gives details of construction of several kinds of round silos, including the Wisconsin round silo, the stave or tank silo, brick or stone silos, and cement or grout silos.

MISCELLANEOUS.

Fourteenth Annual Report of Massachusetts Station, 1901 (*Massachusetts Sta. Rpt. 1901, pp. 219*).—This contains a brief summary of station work during the year, a financial statement for the fiscal year ended June 30, 1901, and reports of the agriculturists, botanists, entomologists, meteorologist, and chemists, outlining in detail the work of their respective departments, and containing articles noted elsewhere.

Thirteenth Annual Report of New Hampshire Station, 1901 (*New Hampshire Sta. Bul. 87, pp. 111-135*).—This includes a financial statement for the fiscal year ended June 30, 1901, and reports of the vice-director and heads of departments, reviewing the different lines of station work during the year ended October 31, 1901. Parts of the report are noted elsewhere. The report of the chemist contains analyses of 4 samples of drinking water and 7 samples of meadow muck.

Twelfth Annual Report of New Mexico Station, 1901 (*New Mexico Sta. Rpt. 1901, pp. 21-42*).—This includes a brief report of the work of the station during the year, a list of station bulletins, reports of the heads of departments, and a financial statement for the fiscal year ended June 30, 1901.

Crop Reporter (*U. S. Dept. Agr., Division of Statistics Crop Reporter, Vol. 4, Nos. 1-3, pp. 8 each*).—These numbers contain statistical data on the condition of crops in the different States and Territories on May 1, June 1, and July 1, 1902; statements concerning the condition of crops in the principal foreign countries; and miscellaneous articles of a statistical nature, among which are the following: Growth of the sugar industry in Hungary, flax fiber in Michigan, changes in market for horses, transportation of milk and cream to New York City, cane sugar production in Cuba.

Agricultural experiment stations and kindred institutions in Europe, C. A. ZAVITZ (*Ontario Agr. and Expt. Union Rpt. 1901, pp. 55-58*).—Notes are given on agricultural education and investigation in France, Switzerland, Germany, Austro-Hungary, Holland, Belgium, and Great Britain, which were visited by the author in 1901.

NOTES.

ALABAMA TUSKEGEE STATION.—During the past summer the station set out 300 mulberry trees with a view to making experiments in silk culture in the future.

CALIFORNIA UNIVERSITY AND STATION.—J. Burt Davy, assistant in botany, has resigned to accept the position of assistant curator in the Bureau of Plant Industry of this Department. Gen. W. H. L. Barnes, a member of the governing board of the university and station, died in San Francisco July 21, 1902.

DELAWARE COLLEGE AND STATION.—E. Dwight Sanderson, entomologist, has resigned to accept the position of State entomologist in Texas.

FLORIDA COLLEGE AND STATION.—C. M. Conner, of the South Carolina College and Station, has been elected professor of agriculture in the college and agriculturist of the station, and has entered upon his new duties.

GEORGIA COLLEGE AND STATION.—H. N. Starnes, formerly horticulturist of the station, and for the last three years professor of agriculture in the college, has returned to the station to fill the vacancy caused by the resignation of S. H. Fulton, who has come to this Department.

ILLINOIS COLLEGE AND STATION.—E. B. Forbes has been appointed assistant in animal husbandry.

PURDUE UNIVERSITY AND STATION.—H. A. Huston, chemist of the station, has been appointed director to succeed C. S. Plumb. A. N. Hume, assistant agriculturist, has resigned to accept a position in the Winona Agricultural and Technical Institute, Winona Lake, Indiana.

IOWA COLLEGE AND STATION.—P. G. Holden, B. S. A., formerly of the Illinois College and Station, has recently been elected professor of agronomy and vice dean of the division of agriculture. J. J. Edgerton, instructor in agricultural physics, has resigned to accept a position on the *Prairie Farmer*, published in Chicago. W. H. Stevenson has been elected assistant in soils. Mr. Stevenson is a graduate of Illinois College and has been doing advanced work in the University of Illinois. W. H. Olin, M. S. A., has been made assistant in agronomy.

KANSAS COLLEGE AND STATION.—At a recent meeting of the board of regents the work in agriculture was divided into three chairs—agriculture, animal husbandry, and dairying. A. M. Ten Eyck, of the North Dakota College and Station, was elected professor of agriculture; D. H. Otis, of the chair of dairy husbandry, was made professor of animal husbandry; and E. H. Webster, assistant in dairying, was made professor of dairying. C. L. Barnes, of the Washington Agricultural College, recently appointed assistant in the veterinary department, was made assistant professor. Theo. H. Scheffer was appointed assistant in zoology, W. F. Coover assistant in chemistry, and Roscoe H. Shaw assistant chemist of the station.

KENTUCKY COLLEGE AND STATION.—L. O. Beatty, assistant chemist of the station, has resigned to accept a fellowship in Columbia University; and T. L. Richmond, assistant entomologist and botanist, has resigned to accept a position with the department of agriculture of the Philippines. The station has begun the erection of a large dairy barn. It will be in the Swiss style of architecture and consist of a main portion and two wings. One wing will contain 30 stalls for milch cows and the other will

accommodate an equal number of young cattle. The college has begun the erection of a girls' dormitory to cost \$60,000.

MAINE STATION.—The station council has recently been enlarged by the appointment of a member from the State Dairymen's Association, Rutilus Alden, of Winthrop, Me.

MARYLAND COLLEGE AND STATION.—C. F. Austin, of the Alabama Experiment Station, has been appointed associate horticulturist to succeed E. P. Sandsten, who has resigned to go to Wisconsin.

MASSACHUSETTS STATION.—Thorne M. Carpenter, recently appointed assistant in the department of foods and feeding, has resigned to accept a position at the Pennsylvania Station.

MISSOURI STATION.—E. L. Shaw, B. S. (Ohio State University), has been appointed assistant in agriculture to the station, vice T. I. Mairs.

MONTANA COLLEGE AND STATION.—For some months past tests for salicylic acid in various fresh fruits have been carried on in the chemical laboratory by F. W. Trap-hagen and Edmund Burke, with the result of showing the almost constant presence of this acid in extremely small quantity. It has been found in the following fruits, among others: Strawberries, raspberries—both red and black, blackberries, currants, plums, black cherries, apricots, peaches, Concord grapes, apples, crab apples, and oranges; and also in tomatoes, cauliflower, and string beans. In a few instances quantitative determinations have been made. The amount found in currants, for example, was 0.57 mg. per kilo of fruit, in cherries 0.40, in plums 0.28, in crab apples 0.24, and in grapes 0.32 mg. These values are not regarded as absolute, but represent the amounts which have been extracted. This work is thought to have an important bearing particularly on the investigations of food chemists. F. B. Linfield, of the Utah College and Station, has been elected professor of agriculture in the college and agriculturist of the station, to succeed Robert S. Shaw. Professor Linfield will enter upon his new duties November 1. A frame dairy building, 24 by 44 ft. and two stories high, is nearly completed. The lower floor will be used for butter and cheese making, the dairy having a capacity of about 1,000 gal. of milk a day, and the upper floor will be used for class rooms. The equipment is on the ground and will be installed as soon as the building is completed. The cost of the building is about \$2,500, the amount appropriated by the last legislature.

NEBRASKA UNIVERSITY AND STATION.—Henry B. Slade, assistant chemist of the station, has recently been elected chemist of the Idaho Station. Samuel Avery has been appointed professor of agricultural chemistry and chemist of the station. The university has added a course in forestry, to be opened this year. It is four years in length, and the conditions for admission are the same as to other courses of the university.

NEVADA UNIVERSITY AND STATION.—Gordon H. True, of Arizona University and Station, has been elected to the chair of animal husbandry in this university and station.

NEW MEXICO STATION.—Popular interest in the experimental work of irrigating from wells is increasing and is reported greater than in any former work which the station has undertaken. The work of the station so far as it has been carried shows that in the Mesilla Valley at least the amount of underground water available is much greater than was previously considered possible. This water is of good quality for irrigation and is reached at a depth of 20 ft. and lower. A well 48 ft. deep and supplied with a 6-in. pipe has yielded a steady flow of a little more than 800 gal. a minute, which was maintained for a continuous run of 30 hours with no apparent diminution in the available supply. Using wood at a cost of \$2.25 a cord, it was found that the cost of irrigating land with an amount of water sufficient to cover it 3 in. deep amounted to about 58½ cts. an acre. A series of tests

with various pumps under varying conditions and with a variety of fuel is in progress.

NEW YORK STATE STATION.—V. A. Clark, formerly connected with the Office of Experiment Stations and more recently engaged in commercial work in the West, has been appointed first assistant horticulturist of the station, in place of N. O. Booth, who has resigned to become horticulturist in the Washington College and Station. H. O. Woodworth has been appointed assistant entomologist of the station to succeed P. J. Parrott, who went to the Ohio Station some months since.

NORTH CAROLINA COLLEGE AND STATION.—W. R. Morehouse, a graduate of the Lowell (Mass.) Textile School, has been elected instructor in chemistry and dyeing in the college; J. S. Kendall, a graduate of the New Hampshire College, has been appointed instructor in dairying in the college and assistant in dairying in the station; and T. J. McLelland, a graduate of the Ohio State University, instructor in soil physics and agronomy in the college. F. L. Stevens, professor of biology in the college, has been made biologist to the station. H. P. Richardson has resigned his position as poultryman to the station.

OHIO COLLEGE AND STATION.—J. Fremont Hickman, agriculturist to the station, died October 22 of typhoid fever. He had been in poor health for several months from overwork, and during the early part of summer was obliged to give up his work for a time, but returned somewhat improved. Professor Hickman was a native of Ohio, where he was born July 3, 1856. He graduated from Pennsylvania State College in 1880, and from 1881 to 1883 was superintendent of one of the experimental farms which the college operated at that time. For several years he followed farming and sheep raising at his home in East Liverpool, Ohio, and in 1888 became connected with the Ohio Station, then located at Columbus. He took a prominent part in laying out the farm and extensive plat system when the station moved to Wooster, and had since been in immediate charge of this work, together with the keeping of the records. He was a conscientious, systematic, and thorough worker in the lines which he undertook, and gave unusually close personal attention to all important details. His death will be a severe loss to the station. Alfred Vivian, assistant chemist of the Wisconsin University and Station, has been elected associate professor of agricultural chemistry in the College of Agriculture of the Ohio State University. A. F. Burgess, chief inspector of nurseries, and Ida L. Feiel, assistant botanist, are no longer connected with the station.

OKLAHOMA COLLEGE AND STATION.—L. A. Meerhouse, a graduate of the Ontario Agricultural College, has been appointed assistant in soils and crops in the college and station. The college announces a short course in agriculture, horticulture, and mechanic arts, designated as "a business course for farmers," which will extend from January 6 to February 27, 1903. Special efforts are being made to advertise the school in order to reach the progressive farmers and farmers' sons of the Territory. The course offered is quite comprehensive in character, and the total expense of attendance is estimated at less than \$30.

PENNSYLVANIA COLLEGE AND STATION.—Harry Hayward, assistant professor of dairy husbandry and dairy expert of the station, has resigned to become associate professor of animal industry and dairying in the New Hampshire Agricultural College. The instruction in practical dairying has been temporarily assigned to T. I. Mairs. M. S. McDowell, assistant chemist of the station, has resigned to accept a position with the Newport Fertilizer Company. N. W. Buckhout, assistant chemist, has also severed his connection with the station. Dr. H. P. Armsby has been relieved from duty as dean of the School of Agriculture in order to enable him to give more exclusive attention to the work of research and investigation, especially that branch which the station is now carrying on in cooperation with this Department through the operations of the respiration calorimeter. Wm. A. Buckhout has been provisionally appointed acting dean.

PORTO RICO STATION.—The station has removed from Rio Piedras to Mayaguez, where it has taken possession of the land recently purchased for its use through an appropriation of \$15,000 made by the last legislative assembly of the island. The farm contains 230 acres, and cost \$19,000, the \$4,000 additional to the appropriation being given by the municipality of Mayaguez. The old sugarhouse on the place has been repaired and painted, and will serve the present needs of the station for office, laboratory, and working quarters. The 11-room frame house has also been put in condition and serves as living quarters. In addition to these buildings there is a brickyard with several kilns and drying sheds; also a number of small huts in which peons live. The place presents a considerable variation in character of soil, topography, and exposure. It is well located with reference to the city of Mayaguez, and although in a neglected condition it presents very good possibilities and is well suited to the needs of the station. Paul A. English has been appointed assistant agriculturist, in place of James Mackinlay. J. W. Van Leenhoff, a coffee planter from Java, has been appointed coffee expert.

SOUTH CAROLINA COLLEGE AND STATION.—P. H. Mell, formerly professor of botany in the Alabama College and director of the station, was elected president of the Clemson College and director of the South Carolina Station early in September. H. Benton, formerly director of the Alabama Canebrake Station, has been installed as assistant professor of agriculture and assistant agriculturist to succeed C. M. Conner, who has gone to Florida.

TEXAS COLLEGE AND STATION.—At a meeting of the board of directors held early in September the following vacancies in the college and station were filled: W. D. Gibbs, formerly professor of agriculture in the New Hampshire College and director and agriculturist of the New Hampshire Station, was appointed dean of agriculture in the Texas College and director of the station. He entered upon his new duties September 8. F. S. Johnston, formerly associate professor of agriculture in the School of Agriculture of the Purdue University, was appointed professor of agriculture in the college. E. C. Green, chief inspector of orchards in Illinois, was appointed assistant horticulturist of the station and instructor in horticulture in the college. O. C. Hargis, a graduate of the Texas University, was appointed assistant chemist. The new chemical-veterinary building, costing \$31,000, is nearing completion. This will provide adequate accommodations for these two departments, which heretofore have been cramped and unsuitable.

UTAH STATION.—William N. Hutt, B. S. A., of the Department of Agriculture of Ontario, has been elected horticulturist of the station. Professor Hutt has been employed as lecturer at farmers' institutes in Ontario for the last four years, and in 1901 was appointed special lecturer in nature study to the schools and horticultural societies of Ontario. Before taking up the present position he was secretary of the horticultural societies at the Department of Agriculture of Ontario.

WASHINGTON COLLEGE AND STATION.—Geo. Severance, instructor in agriculture in the Michigan Agricultural College, has been elected instructor in agriculture in this college and assistant agriculturist of the station.

WEST VIRGINIA UNIVERSITY AND STATION.—S. W. Fletcher, recently of the Washington College and Station, has been elected horticulturist to fill the vacancy made by the retirement of K. C. Davis; and W. M. Morgan, a graduate of Cornell with the degree of B. S. C. A., has been made assistant horticulturist of the station.

CONVENTION OF AMERICAN VETERINARY MEDICAL ASSOCIATION.—The thirty-ninth annual meeting of this association was held in the assembly room of the West Hotel in Minneapolis, September 2-5, 1902. The attendance was unusually large, and the discussion of the papers which were read and the resolutions which were adopted was enthusiastic. The meeting was counted one of the most successful in the history of the association. The president, J. F. Winchester, delivered an address on the history of the association, in the course of which special emphasis was laid on the necessity of longer and more thorough veterinary courses in colleges. The com-

mittee on intelligence and education recommended greater uniformity in veterinary curricula and supervision of instruction in all colleges. In accordance with these views a resolution was passed instructing the committee on intelligence and education to examine into the organization of veterinary colleges and State examining boards. The committee on diseases gave in its report a résumé of present knowledge concerning anthrax. It was stated that protective vaccination has been found very effective. Live animals are considered more likely to spread infection than carcasses. The committee on army legislation reported failure in securing the desired legislation for army veterinary service, and it was suggested that for the present little hope could be extended for introducing any change in the organization of the veterinary corps of the Army. The State secretaries of the association reported a very satisfactory condition of the State veterinary associations and of veterinary work in the various States.

J. J. Repp read a paper on Ulcerative Anovulvitis of Cattle. The disease may occur in a mild or a severe form, resulting sometimes in death. In males the anus only is affected. The disease spreads rapidly, so as to include the whole herd. The period of incubation appears to be about one week. The ulcers are not deep, the lymphatic glands are somewhat swollen, and the symptoms as a whole render the disease easily differentiated from exanthema. The mortality in the experience of Dr. Repp was about 2 per cent. Treatment may be of a curative or preventive nature. Affected animals may be treated by disinfection and antiseptic washes. Heifers affected with the disease are rendered unfit for breeding purposes.

S. D. Brimhall read a paper on Hemorrhagic Septicæmia in Cattle. The disease is due to *Bacillus borisepicus*. Details were given on the isolation and culture of the organism. The disease may resemble anthrax, blackleg, or poisoning, but can be differentiated by microscopic examination. It is usually of sudden termination, and little opportunity is given for treatment. Carcasses should be burned. About 80 outbreaks were reported from Minnesota, and the disease is known in South Dakota and Wisconsin. The chief symptoms were swelling in various parts of the body and bloody discharges from the intestines, with temperature varying from 98 to 106° F. The author believed that so-called cornstalk disease was in a large percentage of cases to be included under hemorrhagic septicæmia.

C. Schmitt discussed Barrenness in Bovines, reviewing the various causes of sterility, and suggesting remedies which have proved successful in his practice; and W. C. Rayen considered Texas Fever and its Relation to the Live Stock Interests of Tennessee. The topography of Tennessee in relation to the distribution of Texas fever was described in detail. The author spoke of annoying defects in the stock laws of the State. As a means of combating Texas fever the destruction of ticks was recommended, as well as other quarantine measures.

F. A. Rich discussed the subject of Equisetum Poison, which will be noted later from his report in Vermont Station Bulletin 95; and N. S. Mayo presented a paper on Poisonous Stock Foods. Poisonous plants were divided into two classes, those causing immediate effects and those whose effects are manifested only after some time. Brief notes were given on various ptomaines and alkaloids as well as chemical substances, such as nitrate of potash, silica, etc., which may be taken up from the soil. A number of serious cases of poisoning were mentioned which were attributed to *Rumex altissimus*, blue vervain, flaxseed chaff, common yarrow, and cockleburrs. The tall dock is thought to have caused the death of 42 cattle, 3 calves died apparently from eating blue vervain, 6 colts from eating yarrow, and a number of hogs from eating cockleburrs. Thirty-seven hogs were also reported to have died from eating too much rye.

Malaria in the Horse was the subject of a paper by F. Torrance. The disease exists in Manitoba, Minnesota, and North Dakota. It is characterized by a progressive anemia, and animals may die in from 2 weeks to 3 or 4 months. The mucous membranes are pallid and the legs and undersurface of the body become swollen.

It was not discovered how the disease is spread. Inoculation experiments were with negative results. The disease is most prevalent in summer and fall. Native horses are equally susceptible with imported breeds, and one attack does not confer immunity. Prognosis is unfavorable, and the mortality is 50 per cent or greater. The red blood corpuscles are reduced to 2,000,000 per cubic centimeter of blood. No hematozoa were found in the blood. A micro-organism was discovered which may prove to be the cause of the disease. Quinine, arsenic, vegetable tonics, and other remedies have proved unsatisfactory. Intestinal antiseptics gave promising results.

C. C. Lyford described the Differential Diagnosis between Farcy, Furunculus, and Bursattee. Bursattee was said to affect chiefly the epithelia and mucous membranes and to be essentially a warm-weather disease. Moisture favors the development of the sores. Farcy may be superficial or deep, and affects the lymphatic glands. It is further differentiated from bursattee by the exudation of pus from the sores.

J. C. Norton discussed the results of strict sanitary regulations in Arizona, giving special attention to the control of Texas fever, hog cholera, and other infectious diseases, and mentioning peculiar difficulties in enforcing the laws in that Territory. L. Pearson discussed the organization of State veterinary work, calling attention to the great importance of animal industry and to the numerous mistakes which have been made in veterinary legislation. It was argued that the best results were obtained when the work was largely under the direction of veterinarians. Special stress was laid on the value of well-equipped laboratories for the use of State sanitary boards.

A resolution was adopted requiring the State veterinary associations to make their conditions for membership the same as the national association; and another recommending that the clinics at the meetings of the association be enlarged and made to include exhibitions of pathological specimens, etc.

The fourth day of the meeting was spent at the veterinary building of the University of Minnesota in attendance upon clinics illustrating operative and other treatment for various diseases.

The officers elected for the ensuing year were as follows: President, S. Stewart; vice-presidents, J. G. Rutherford, W. H. Dalrymple, E. M. Ranck, M. E. Knowles, and M. H. Reynolds; secretary, J. J. Repp; and treasurer, W. H. Lowe.

The members of the Association of Experiment Station Veterinarians held an informal meeting and after a brief discussion decided to allow that organization to lapse. The meetings of the organization have been held in connection with those of the national association, and since the papers read at both meetings are of similar nature, it was thought best to combine all of this work rather than to attempt to maintain two distinct organizations.

AMERICAN PARK AND OUTDOOR ART ASSOCIATION.—The sixth annual meeting of this association was held in Boston, August 5-7. Addresses on a wide range of subjects connected with landscape architecture and civic improvement were presented and a relatively large space on the program was devoted to the subject of Gardening for Children. Mr. Dick J. Crosby, of this Office, introduced the subject in an address Tuesday evening on The School Garden Movement. On Thursday afternoon the entire session was devoted to the discussion of various phases of this movement as outlined in the following list of topics and speakers: The School Garden as a Phase of Industrial Work, W. A. Baldwin, Principal State Normal School, Hyannis, Mass.; Boston Sand Gardens, Ellen M. Tower, Lexington, Mass.; School Gardens at the Hartford School of Horticulture, H. D. Hemenway, Director, Hartford, Conn.; The National Cash Register Boys' Gardens, George A. Townsend, jr., Dayton, Ohio; Some Neglected Millions, George Henry Knight, New York City; How we Reach Eighteen Thousand School Children in New York, J. W. Spencer, Supervisor Bureau of Nature Study, Cornell University, Ithaca, N. Y.; Nature Study for Children, George T. Powell, Director School of Practical Agriculture and Horticulture, Briarcliff Manor, N. Y.

The widespread interest in this phase of education, as indicated in the large attendance at this session, led to the appointment of the following committee on school grounds charged with the preparation of a report and program for the meeting in Buffalo next year: Dick J. Crosby, Washington, D. C., chairman; Mrs. Mary Morton Kehew, Boston, Mass.; H. D. Hemenway, Hartford, Conn.; J. W. Spencer, Ithaca, N. Y. The officers of the association for the current year are: President—Clinton Rogers Woodruff, Philadelphia, Pa.; vice-presidents—John C. Olmsted, Brookline, Mass.; Mrs. Herman J. Hall, Chicago, Ill.; Chas. W. Garfield, Grand Rapids, Mich.; Warren H. Manning, Brookline, Mass.; Dick J. Crosby, Washington, D. C.; W. Ormiston Roy, Montreal, Canada; secretary—Chas. Mulford Robinson, Rochester, N. Y.; treasurer—Ossian C. Simonds, Chicago, Ill.

PERSONAL MENTION.—Major John Wesley Powell, director of the U. S. Bureau of Ethnology of the Smithsonian Institution, and formerly director of the U. S. Geological Survey, died at Haven, Me., September 23, 1902. Major Powell was born at Mount Morris, N. Y., March 24, 1834. He rendered distinguished service in the civil war, in which he was severely wounded, losing an arm. After the war he was made professor of geology, first at Wesleyan University, Bloomington, Ill., and afterwards at Northern University, Illinois. In 1868 he explored the Colorado canyon, traversing its whole length in boats. As a result of this and subsequent explorations the U. S. Geographical and Geological Survey of the Rocky Mountain Region was established in 1870, which in 1879 was combined with the Hayden, King, and Wheeler surveys to form the present U. S. Geological Survey. Major Powell was director of this from 1880 to 1894, when he resigned. While director he evolved a plan for the irrigation of the arid lands of the United States, which resulted in the organization of an Irrigation Survey under authority of Congress in 1888, and the subsequent investigations of the U. S. Geological Survey on the water supply and the extent to which the arid lands can be reclaimed by irrigation.

In the course of the inaugural address of Prof. James Dewar, president of the British Association, at the Belfast meeting, the speaker referred to the services to agricultural science of the late Sir Joseph Henry Gilbert in the following terms: "He strove with conspicuous success to place the oldest of industries on a scientific basis, and to submit the complex conditions of agriculture to a systematic analysis. He studied the physiology of plant life in the open air, not with the object of penetrating the secrets of structure, but with the more directly utilitarian aim of establishing the conditions of successful and profitable cultivation. By a long series of experiments, alike well conceived and laboriously carried out, he determined the effects of variation in soil, and its chemical treatment—in short, in all the unknown factors with which the farmer previously had to deal according to empirical and local rules, roughly deduced from undigested experience by uncritical and rudimentary processes of inference. Gilbert had the faith, the insight, and the courage to devote his life to an investigation so difficult, so unpromising, and so unlikely to bring the rich rewards attainable by equal diligence in other directions, as to offer no attraction to the majority of men. The tabulated results of the Rothamsted experiments remain as a benefaction to mankind and a monument of indomitable and disinterested perseverance."

We note from *Nature* the death of Dr. H. von Wild at Zürich, September 5, in his sixty-ninth year. He was director of the Central Meteorological Station at Bern, Switzerland, from 1863 to 1865; director of the Russian Meteorological Service from 1868 to 1895, and president of the International Meteorological Committee from 1882 to 1892. He was the author of numerous works on meteorology and terrestrial magnetism, and was the editor of the Russian *Repertorium der Meteorologie*. His greatest work was *Temperatur-Verhältnisse des russischen Reiches*, a volume of 349 pages and 271 plates.

Dr. Frank Pierrepont Graves, formerly president of the University of Wyoming, has resigned the presidency of the University of Washington.

MISCELLANEOUS.—A preliminary announcement of the Dunn County (Wisconsin) School of Agriculture and Domestic Economy has been received. This school opened at Menomonie October 20. A commodious brick building has been provided for the school, with equipment for cooking, sewing, and general instruction along all lines of the course, and a tract of land near by will be used for practical demonstrations. The course of study for boys includes work in the quality and composition of soils, plant life, vegetable gardening, crops, animal husbandry, dairying, poultry, economic insects, farm accounts, blacksmithing and other metal work, carpentry, and rural building. The course of study for girls includes work in sewing, cooking, home economy and management, drawing and designing, domestic hygiene, chemistry of foods, dairying, poultry, farm accounts, vegetable and flower gardening, and other plant studies. Both courses include reviews in common branches and studies in physical geography, civil government, physiology, library readings, English, and elementary science. Only two years will be required to complete the full course for either boys or girls, and shorter courses may be pursued. The principal of the new school, who is also agriculturist, is Dr. K. C. Davis, formerly horticulturist of the West Virginia Station.

A recent number of the *Journal of Horticulture* (54 (1902), No. 2782, p. 77) gives a brief account of the establishment of the Middlesex County Council School of Horticulture, a school of practical and scientific horticulture at Pymmes Park, Edmonton. The main object of the school is to give a thorough horticultural training to those who are anxious to take up gardening as a profession. Scientific training will go hand in hand with practical lectures and demonstrations. The garden work is to be under the direction of John Weathers, author of the recent work entitled *A Practical Guide to Garden Plants* (E. S. R., 13, p. 52).

An agricultural botanical institute was opened at Munich October 1, 1902. Its object is the promotion of agronomy especially and the conduct of experiments in the culture and manuring of plants and in plant breeding; studies of the bacteriology of soils, manures, etc.; the suppression of plant diseases; seed examination, and the botanical, microscopic, and bacteriological examination of feeding stuffs. Dr. Lorenz Hiltner, formerly in charge of the bacteriological section in the Imperial Health Office at Berlin, has been made director of the institute. He will have three assistants, and an experimental field will be placed at his disposal. The institute is a State institution, and will receive an annual appropriation of 24,500 marks (about \$6,000).

The reorganization of the Halle Experiment Station, necessitated by the death of Dr. Maercker, has been completed. According to a note in *Die landwirtschaftlichen Versuchs-Stationen*, the original station has been divided into three parts—the agricultural-chemical experiment station, the control station, and the botanical station. The first, which is under the directorship of Prof. W. Schneidewind, has been so divided into three divisions—the agricultural-chemical division, with the director in charge, and Dr. H. C. Müller vice-director; the botanical division, in charge of Dr. W. Krüger; and the experimental farm at Lauchstädt, in charge of Mr. Grebler. The control station is in charge of Dr. Brühning, director, with Dr. Naumann vice-director. Dr. Steffek is director of the botanical station.

At the recent annual congress of the Royal Institute of Public Health, held at Exeter, England, Eaton Jones presented a paper before the Veterinary Section, on the Veterinary Supervision of Domesticated Animals, in which he called attention to the deplorable condition of town and county stables, cow sheds, and piggeries. Resolutions were adopted advocating the abolition of private slaughterhouses, the appointment of veterinary inspectors of all animals intended for food, the inspection of dairies and cow stables, and the making of suitable provision for the disposal of carcasses unfit for food.

EXPERIMENT STATION RECORD.

VOL. XIV.

NOVEMBER, 1902.

No. 3.

The second International Conference on Plant Breeding and Hybridization, which was recently held in New York City, exceeded in attendance and interest the previous meeting, held in London in 1899, and served to show the large interest in the subject in this country. An extensive programme of papers was presented, but only a portion of them were read. These discussed the principles of plant breeding and their application, as well as giving the results of years of work and observation in the production and propagation of improved varieties of plants.

In the theoretical discussion of the papers there was an almost universal acceptance of Mendel's law regarding the appearance of dominant and recessive characters in the later generation of hybrids. This law, although announced in 1865, has only recently been given wide publicity through its publication in various journals (*E. S. R.*, 13, p. 744). It was the consensus of opinion that it is the best available working hypothesis for the plant and animal breeder, and that it seems to stand the test of experience to a remarkable degree. The methods of Mendel were commented upon, and in a number of papers his conclusions were reaffirmed relative to the necessity of large numbers of individuals in breeding experiments and the continuation of the investigations through many generations, in order that the results may be of permanent value. The futility of indiscriminate crossings and the necessity of working with pure strains or races was shown by abundant examples. A hybrid produced from a mixed ancestry is very liable to be inferior to either or both of its parents, unless by a long system of cultivation the characteristics of the parents have become definitely fixed.

In all kinds of breeding experiments it is necessary to adopt an ideal and adhere closely to it, rejecting for the time all secondary variations that may appear. If these seem very promising, they can be cultivated independently of the main investigation, but nothing should divert the breeder from continuing to follow to its conclusion the line of experimentation, which should be well formulated at the start.

Once a hybrid is established, then selection and cultivation enter into the problem of fixing it. The selection requires keen discriminating powers, and is in many ways more important than the act which produced the hybrid.

Another thought brought out quite prominently was the necessity for breeding to meet definite requirements. Changed seasonal, soil, and climatic conditions will often render worthless what are otherwise promising varieties. It is believed to be impossible to originate a variety of plant that is of universal value, and the transfer of valuable sorts to regions of markedly different character was said to be usually followed by disappointing results.

A high compliment was paid to the plant-breeding work that has been carried on in this country. One of the foreign guests declared that greater advance is being made along this line in the United States than in any other country, the great range of soil, climate, and necessities making such work possible.

The value of such a meeting in arousing an interest in the subject of plant breeding can hardly be estimated. The description of methods, criticism of results, and the application of principles were given and taken in a spirit of scientific earnestness, and the enthusiasm aroused will be continued and exhibited in the wide extension of the work.

The systematic work which is being done in plant breeding, including the study of principles governing it, is worthy of imitation in animal breeding. The field is quite as attractive, as far as possibilities of useful results are concerned. The breeding or selection of plants resistant to disease suggests that something might be done with animals in producing strains more vigorous or resistant to some of our troublesome diseases. In this connection some recent experiments reported from Algeria in attempts to combat Texas fever are interesting.^a In the search for some animal of the bovine kind which was immune to Texas fever, it was found that both the buffalo and zebu were naturally resistant to this disease. The buffalo could not be crossed with the domestic cattle, and appeared to be for other reasons less desirable than the zebu as a substitute for cattle. It was found that the zebu crossed readily with different races of cattle, and that all hybrids thus obtained were perfectly immune to Texas fever. The female hybrids between the zebu and domestic cattle were found to be very fertile, while the males were well adapted to the production of beef or to performing work of various kinds. The hybrids attained a weight of about 360 kg. (792 lbs.) at an age of 3 years and the dressed weight averaged about 62 per cent of the live weight. The large hump composed of muscle and fat tissue and situated over

^aJour. Agr. Prat., n. ser., 4 (1902), No. 29, pp. 75-80.

the shoulders of the zebu largely disappears in the hybrid. The bones are unusually small and of a delicate nature. The meat is said to be of good quality. The milk of the zebu or of the hybrid is claimed to be richer than that of the ordinary Arabian cow. The zebu gives from 6 to 8 quarts per day, while hybrids yield from 15 to 16 quarts. Three different races of zebras have been introduced into Algeria, one from Madagascar, one from Cochin China, and a third from India. The third, or Brahmin race, is the only one which proved to be of economic importance and is the one from which the present zebras and hybrids of Algeria have descended.

These results with the zebu are borne out by the experience in Jamaica. Texas fever is very prevalent in that country, but it has long been known that cattle which contain a strain of zebu blood are immune to the disease. This zebu blood was introduced years ago for another purpose. It is now proposed to import a number of zebu bulls from India for the specific purpose of securing immunity to the fever. These are to be used in connection with the improvement of the common cattle in Jamaica, which are said to be degenerating to some extent.

INTERNATIONAL CONFERENCE ON PLANT BREEDING AND HYBRIDIZATION.

WALTER H. EVANS, Ph. D.

Office of Experiment Stations.

An international conference on plant breeding and hybridization was held in New York City, September 30 to October 2, 1902, under the auspices of the Horticultural Society of New York, with James Wood as president and Leonard Barron secretary. About 80 delegates were present, representing different parts of the United States, Canada, England, West Indies, etc. A programme of more than 50 papers was presented, a number being sent from Germany, Austria, France, Holland, and England. All of the papers are to be published in full in the proceedings of the New York Horticultural Society, which it is hoped will appear early in the coming year. A brief account is here given of a number of papers which were presented at the conference.

Prof. W. Bateson, of Cambridge University, England, considered the Practical Aspects of the New Discoveries in Heredity. He briefly reviewed Mendel's law of heredity, and pointed out some of the great advances which have been made since the enunciation of that law. In general it was stated that while great differences may exist in plants and animals, hybrids in their first generation represent the characters of one parent and not of both. The author believed that the time would soon come when the fundamental principles of plant and animal breeding would be known, so that the breeder would be able to control his work instead of depending upon chance results. For the practical man it is impossible to always determine the characters which exist in the parent plants. As an example, it is cited that green peas may be due to the union of 2 green varieties, of yellow and green varieties, or of 2 yellows, all of which tends to complicate the special hereditary characteristics. The frequent occurrence of bearded wheats in plats of beardless varieties was mentioned, and their presence was attributed to the probable fact that the beardless variety had been developed from a bearded form, the plants still containing some of the germ cells of the bearded ancestors. The predominance of the recessive germs resulted in the appearance of bearded forms, and the presence and influence of recessive germs can be eliminated only gradually. Species, according to the author, are not to be considered necessarily fixed or of long duration. Crosses or, as the author called them, heterozygote

forms do not usually reproduce their kinds, but often result in reversion to ancestral types. A number of examples were cited of reversions which have taken place in the sweet pea, giant lavender primulas, Andalusian fowls, etc., which show that in a number of instances the forms are not readily fixed, being the result of complex crosses that are for the most part infertile.

A paper by C. C. Hurst, entitled *Notes on Mendel's Methods of Plant Breeding*, was read by the secretary. Mendel was apparently the first to recognize the necessity of considering each single character on its own merits. In selecting constant characters, he avoided confusion by crossing only constant and fixed races of plants, each of which had been the product of repeated self-fertilization. If plants are chosen for crossing, the ancestry of which is unknown, the resulting offspring will either be incomparable or incomprehensible. The writer cited his experiments with orchids in which by choosing constant characters he had almost entirely succeeded in eliminating the possibility of reversion. It is stated that some of the apparent exceptions to Mendel's results are probably to be attributed to the crossing of species which were not constant in character. The consideration of differential characters was briefly discussed, and it was stated that Mendel in his experiments always chose his characters in pairs, so that they would be distinctly differential and capable of definite recognition in the offspring. The more clearly defined the differences between the parental characters, the more marked will be the single characters in the resulting offspring. The fourth point in Mendel's method is said to be distinctly new, and that is the crossing together only of dominant and recessive characters. If one of the characters of the differential pair is always distinctly dominant over the other, the latter is known as the recessive character. Knowledge of this fact serves to give uniformity to the first generation and avoids the difficulty of continuing through subsequent generations breeding in which the results secured will not be uniform. The necessity of using large numbers of individuals was pointed out. In this there was great advance over Mendel's predecessors. After having secured hybrids they should be carried through many generations. Mendel in all cases carried his experiments to the third and fourth, and in some cases to the fifth and sixth generations. Summing up the methods of Mendel, the author states that hybridists who desire to follow the footsteps of Mendel and help elucidate the problems of inheritance will find it essential in their work to select parents possessing characters which are at once single and constant, differential and dominant, and they must also take care to raise large numbers of individuals through many generations.

A paper by Hugo de Vries, director of the Botanical Gardens, Amsterdam, Holland, discussed *Artificial Atavism*. Atavism was defined as the occasional restoration of an old type in a compound cross.

Crossing is said to not only combine characters, but to separate them. Among flowers as ordinarily listed in catalogues, there is usually the ordinary wild color as well as a white form, with various intermediates. If a cross be made between the white form and some of the intermediates, the resultant hybrids will fall into types, some of which return to the original color. The color variations and reversions produced by various crossings were shown by illustrations of well-known varieties. It is said to be possible to split up and produce new colors by crossing the original or wild color with any of the white forms. The results obtained usually follow the principles laid down in Mendel's law. A number of instances were cited in which it is shown possible to produce atavism artificially.

In commenting upon this paper, Professor Bateson stated that he believed synthesis in plant breeding, although sometimes apparent, is not truly possible. A compound character consisting of 3 or more components, he believes, can not be recomposed from its original forms.

Some Suggestions for Plant Breeding were made in a paper by Max Leichtlin, of Baden-Baden, Austria, which was read. In crossing plants the author states that the selection of a suitable time for crossing is of first importance. A warm, cloudy day offers the best conditions for about 60 per cent of plants. For some a dry atmosphere is best as it more nearly represents the conditions of their original habitat. Fertilization should not be attempted before the stigmas are in proper condition. This can be easily recognized after some practice. The pollen should be neither too fresh nor overripe. After applying the pollen to the stigma in many cases it will be found advantageous to cover the flower with a hand glass or some similar means for a day or two to give a higher temperature than that of the surrounding air. The pollen of many plants, if in good condition, can be kept in small glass vessels, well corked, for several days without losing its fecundating power. Whether fertilization is possible or not can be easily ascertained by a microscopical examination of the forms of pollen grains. If their forms are fairly constant the pollen will do for fertilization, but if markedly different its use for this purpose is impossible. The prepotency of sex was shown by the statement that in 8 cases out of 10 the female parent has the greatest influence on the progeny. The staminate parent usually controls the color of the offspring, and in most cases the hybrid plants have larger flowers than those possessed by either parent.

In the discussion following this paper a number of interesting facts were brought out relative to the vitality of pollen. The president of the society stated that the pollen of tomatoes would retain its vitality for fully 6 months, as shown by the common practice of gathering pollen during the late summer and fall months from plants grown out of doors, for use in fertilizing tomatoes grown under glass during the

winter. According to another statement, grape pollen retains its vitality for fully 2 months, and the date palm for a year or more. Carnation pollen may be kept in closely stoppered vials for several weeks, and may be shipped from one part of the country to another. In preparing pollen for keeping, it should be thoroughly dried and placed in closely stoppered bottles. For plants grown in moist climates the drying should be done in the shade; for those growing in arid regions, it may be more quickly dried in the sun. It was stated that pollen of certain plants is commonly distributed through the West Indies on dry blotting paper inclosed in pasteboard boxes. In this way its vitality is retained for more than 3 weeks.

A paper giving Some Suggestions for the Classification of Hybrids, prepared by I. T. Lynch, curator of the Botanic Garden, Cambridge, England, showed the desirability of the classification of all results, so that reference can be had to previous work. A plan previously published by the author in the *Journal of the Royal Horticultural Society of London*, vol. 25, was briefly outlined. Investigators often want to know what plants have been found to respond in a certain way, or they may desire to reobserve from a new point of view, or carry further results in which they may be interested. This was cited to show the importance of classifying all experimental results, and action of the conference along this line was recommended. The writer requested that he be furnished with accounts of hybrids which at first were nearly barren and afterwards became fertile; also of hybrids which are less fertile than either of their parents. He also asked that suggestions be sent him regarding different systems of classification. In general, he proposes the classification of hybrids based upon their behavior, rather than upon the classification of natural orders, genera, or species.

The Principles of Plant Breeding were discussed in a paper by Luther Burbank, of Santa Rosa, California. The two influences or forces which control plant and animal breeding are heredity and environment. To guide the interaction of these two forces is the sole object of the breeder, whether of plants or of animals. A general knowledge of the relations and affinities of plants is not sufficient for the successful plant breeder. He must be a skillful biologist, and, having a definite plan, must be able to correctly estimate the action of the inherent and external forces which he would control. A plant breeder before attempting to make new combinations should select with great care the individual plants which seem best adapted to his purpose. This requires an exceedingly keen perception of minute differences, great patience, and extreme care in treating the organisms operated upon. This applies more particularly to annuals or those plants generally produced by seed. In breeding perennials the first deviations from the original form are often of an almost unappreciable

degree. By careful and intelligent breeding, any peculiarity may be made permanent, and there appears to be no limit to the improvement of plants. Cultivation and care may help plants temporarily, but by breeding plants may be produced which will do better work in all places and for all time.

W. A. Orton, of this Department, read a paper on the Breeding of Disease-Resistant Varieties, in which a résumé was given of work being carried on by the Bureau of Plant Industry. The wilt disease of cotton, cowpeas, and watermelon was described and photographs and material shown. As a result of continued selection of resistant varieties, it was stated, Sea Island cotton is now grown in regions which had been practically abandoned on account of the destruction caused by the wilt. No varieties are wholly resistant, but a number of strains have been found which are to a great degree able to resist the fungus. In general, upland cotton seems less resistant to wilt than Sea Island, and Egyptian varieties are more resistant than any of the others. The work so far has been one of selection, since hybridization is not practicable, as it tends to destroy the merchantable character of the fiber. Similar results in the selection of cowpeas and watermelons were cited, and the author believes that many other varieties of plants may yet be found that are resistant to disease.

W. M. Hays, of the Minnesota Station, presented a paper on Breeding for Intrinsic Qualities. He believed the value of plants and animals annually produced in this country could be readily increased 10 per cent at an expense of less than 1 per cent. The greatest financial gains would probably be secured by the improvement of a score of plants and about 4 species of animals. By carefully growing and testing many thousands of individuals there will frequently be found some one individual of such superior merit as to repay all expense. In any hybridization work a good foundation stock must first be produced upon which to base the new varieties. The importance of working with large numbers of individuals and the value of correlated qualities were pointed out. During the progress of the work various side lines may enter, but these must be held subordinate to the main idea which controls the experiment. In choosing varieties, often very perplexing problems arise. As a rule crosses should be made between individuals which closely approximate the ideal, and not between those which are too dissimilar. An illustration of the value of using large numbers was given in the experiments in breeding wheats. To begin with, 500 plants were examined for foundation stock and tested from 3 to 5 years to see that they came true to seed. After continuing the work this length of time, all were rejected but about 50, which were given a field trial. This work has been continued, large numbers of individuals being constantly grown, and as a result 2 or 3 varieties have been found which are intrinsically of great value. In wheat

breeding the author thinks that an increased yield, irrespective of distinguishing marks, should be the ideal sought.

A paper on the Correlation between Different Parts of the Plant in Form, Color, and Other Characteristics was read by S. A. Beach, of the New York State Station. By means of a number of specimens he showed the correlation which exists between different parts of plants. By the proper study of the correlation of form, color, vigor, etc., undesirable material may be eliminated to a great degree while the seedlings are still young. In this way much valuable time and space may be saved. Numerous examples were cited in which this early elimination is possible: Small foliage is said to be usually correlated with small fruit. The texture of the leaf and of the fruit are believed to be correlated to some degree. Dwarfed seedlings produce poor plants even when given good cultivation. Attention was called to the importance of considering groups of characteristics. In the case of the peach there seems to be a direct relation between the size of the foliage and the size of the fruit, and sufficient evidence is believed to be at hand to show that size and color of foliage and flowers may be depended upon in predicting the character of fruit. Pale or light colored blossoms are usually associated with small fruit in apples, while deep color is correlated with larger fruit. Pale foliage in the raspberry is correlated with yellow or light colored fruit, and dark fruit is obtained from plants having dark foliage and canes. Roses, cannas, and asters generally follow the same lines—pale colored foliage indicating light colored flowers. In comparing these factors, fully matured leaves should always be examined and even then exceptions will be noted. A correlation is said to exist between the color of the flowers and the seeds of beans, between the color of the roots and stems and the flowers of carnations, between the color of the seed coats and character of plants of peas, etc. There is apparently some correlation between the size of the different organs of plants and possibly between their size and color, but as yet the evidence is not sufficient to formulate definitely.

O. F. Cook, of this Department, discussed Evolution under Domestication, claiming that it is not rational to attribute to environment all of the changes found in plants and animals.

The Varying Tendency and Individual Prepotency in Garden Vegetables was the subject of a paper by W. W. Tracy, of Detroit, Michigan. The author's long experience has enabled him to examine an immense number of specimens of different vegetables and note some of their peculiarities. These variations will frequently be apparent only from a careful study of a great number of plants. It is stated that different plants of the same natural order tend to vary along parallel lines, and variations that are frequently attributed to hybridization are due to ordinary variation. Different natural orders of plants are

differently affected by soil, climate, etc. In some cases plants grown from seed from widely different regions did not show any appreciable difference; in others, marked differences may be noted in comparatively slight changes. An example was cited in which a variety of watermelon was grown in Michigan and in a Gulf State, the seed being from the same source, and the progeny was so similar as to defy any detectable differences. The effect of cultural and climatic influences is cumulative. This was illustrated by the simultaneous occurrence in widely separated regions of bush forms of Lima beans, sweet peas, etc. These plants ordinarily grow in climbing forms, but bush forms suddenly appeared in different parts of the United States, seeming to indicate that the influences had been simultaneously working in different regions. Stock produced by an individual grower will vary widely during different seasons. Seed from the same stock, equally well grown under precisely the same conditions, show marked differences in the tendency to adhere to type in different seasons. Seeds from individual pedigreed stock plants vary widely in their progeny, and the only way to secure uniformity is to define an ideal, select carefully, and propagate carefully, so as to secure a lineal descent of a single typical plant.

Dr. D. Morris, Imperial commissioner of agriculture for the West Indies, read a paper on the Cross Fertilization of the Sugar Cane, in which he described the experiments in the West Indies in the improvement of sugar cane. The subjects for consideration are a greater tonnage of cane, a greater yield of juice, a higher sugar content, and a cane immune to diseases. More than 60 varieties of canes have been imported from all parts of the world and tested at the various West Indian stations. Special attention has been paid to bud variation, and a few examples have been found, which were briefly described. Some of these are quite promising as improvements over the older varieties, and so far they tend to come true to color. Nearly all of the bud variations or sports which have been under investigation originated from the ribbon or striped cane. Planting from different parts of cane has not given results of any great value or improvement, and selection by analysis of the cane juice does not appear to offer promise of definite results, nor has selection proved of value when the richest canes have been taken individually. Where the richest clump in a field was tested there was some indication of value, and this is believed to warrant further investigation. A description was given of attempts to produce new varieties from seed. The fact that the sugar cane sometimes produced fertile seed was established about 1887. At that time fungus diseases had almost entirely destroyed many of the best varieties in Java and in the West Indies. A careful examination of the flowers, which are very small and very numerous, showed that occasionally a few seed in a panicle were produced, frequently only 2 or 3

being found in a panicle containing many thousand flowers. In the author's experiments the whole panicle was sown in boxes in the hope of the presence of some fertile seed. On account of the minuteness of the flowers and the rarity of the production of fertile seed, the ordinary method of cross fertilization could not be adopted. Staminate plants were planted to the windward of the pistillate ones, or in alternate rows. In another series the panicles were covered with bags and later dusted with pollen-bearing plants of known value. It was found that frequently the pollen was infertile, while the pistillate flowers were fertile. The most valuable varieties so far obtained through seed canes have followed the principal characteristics of the staminate parent.

So far as the writer's observation has gone, the seed canes tiller more extensively than the plants from the cane top. The Ribbon and White Transparent varieties have proved the best for mother plants, the mother plants governing the size, color, and to a considerable extent the sugar content of the cane. Purity of the juice has not been definitely determined as due to either parent. As to the yield of sugar, the average for the island of Barbados is said to be 1.7 tons per acre, while one variety shown by the writer, designated as No. 208, yields 3 tons of sugar per acre at Barbados, and its value has been further attested on the islands of Trinidad, St. Kitts, etc.

A paper on the Cytological Aspects of Hybrids, by W. A. Cannon, of Columbia University, New York, showed that the relation between the cytological and experimental studies could not be definitely stated in the present state of our knowledge on the subjects. A review was given of Mendel's laws in the light of modern cytological studies. So far these studies have been made on first-generation hybrids. It is said that the normal division of sex nuclei leads to fertility in hybrids, but abnormal division to sterility. Cytological studies on cotton and other hybrids, it is claimed, show (1) a possible cause of sterility, (2) that variation in the hybrid may or may not be associated with variation in spermatogenesis, and (3) that chromosomes tend to retain their respective individualities, as shown in many hybrids examined.

Improvement of Roses by Bud Selection was the subject of a paper by L. C. Corbett, of this Department, in which experiments were reported which were undertaken to determine the relative value of blind and flowering wood in rose production. It was shown that individual characteristics of a branch were perpetuated from generation to generation in plants asexually propagated, and also that cumulative results are not to be expected by the selection of parts showing like tendencies through successive generations. The flowering habit of plants produced from flowering wood through five generations was in no way increased, nor was it diminished when blind wood was

employed in a like manner. From the commercial side this has an important bearing, as it is more economical for the florist to produce his roses each season from blind wood.

Under the title of Improvement of Oats by Breeding, J. B. Norton, of this Department, gave a description of the work recently undertaken in the plant-breeding laboratory. This has included the selection and hybridization of oats to secure rust resistance, hardiness, increased yield, to prevent lodging, etc. As yet the results can not be definitely determined.

In experiments to increase the yield and hardiness of winter oats by selection, sowings were made at different dates late into the autumn, and the hardiness of the plants was tested by freezing out during the winter. It was found that the farther south seed oats are produced, the earlier the crop when sown at Washington; and there are apparently no varieties of oats which come absolutely true to type description. In experiments in crossing, only 5 to 10 per cent of successful fertilizations were ordinarily secured. If cool, moist days were chosen for pollination, better results would be obtained, in some cases almost 100 per cent of the pollinations resulting in the production of fertile seed. The presence of natural crosses was briefly commented upon, and it was stated that Rimpau in his work, covering many years, observed only 4 or 5 cases. This seems to indicate that oats are nearly always self-fertilized.

In commenting upon this paper, Director Saunders, of the Canada Experimental Farms, called attention to the Canadian work along the line of oats breeding, which has been carried on for about 10 or 12 years, and D. G. Fairchild referred to the work being conducted at the experiment station at Svalöf, Sweden, along similar lines. (E. S. R., 13, p. 814.)

The subject of Breeding Florists' Flowers was treated in papers by E. G. Hill, of Richmond, Indiana, C. W. Ward, of Queens, Long Island, and A. Wintzer, of West Grove, Pennsylvania. In Mr. Hill's paper notes were given on breeding experiments with roses, carnations, and geraniums. Of many thousand hybrids produced, but few of desirable quality were obtained. Not one in a thousand was said to in any way approximate to the value of the ideal which was sought. When the great number of hybridizers who are experimenting with roses is considered, the number of valuable new sorts is very meager compared to the amount of labor expended. While rose fertilization is said to be very easy, the most important part of the work is in properly maturing the seed and propagating it. A number of successful hybrid roses were cited as being recently introduced into the market. Somewhat similar results were reported with carnations, in which out of thousands of seedlings grown every year by hundreds of growers, only a few improved forms are annually obtained. In experiments with chrysan-

themums the best results have been obtained, it was said, when only double forms were used for parent stocks. The hybridizing of begonias was also commented upon, and the origin of a number of the finest new varieties was indicated. Attention was called to the fact that La France, claimed to be the parent of many new varieties, is absolutely sterile in some countries.

The results of experiments in crossing pumpkins were described by L. H. Bailey, of Cornell University, in a paper entitled A Medley of Pumpkins. The author began a series of experiments in 1857, which was continued for 10 years, to determine the immediate effect of pollen on fruit. After a number of years' investigation, no immediate effect of pollen could be recognized on cucurbit fruits. The experiments were continued, however, to see what would be the result of crossing 2 varieties of squash. These varieties were hand pollinated, the seed saved, and in the third generation the plants occupied between 8 and 10 acres. Of the product examined, fully 1,500 forms were noted which did not resemble either parent in form or shape. The plants seemed to be almost wholly self-sterile to their own pollen. The seed of one form, designated as Alpha, when planted, gave 110 distinct kinds of fruits and innumerable intermediates. The parent stock of this experiment was pedigreed and usually came true to type, but the progeny resulting from crossing was so variable as to give nearly as many types as there were individuals. New characters continually appeared in the second and third generations, and the confusion became so great that the experiment was abandoned. Another experiment was described, in which one of the small ornamental pear gourds was crossed with pollen from the typical Connecticut pumpkin. From the seed secured, 39 plants resulted and no two fruits were identical. Nineteen forms were found that were fairly well marked, and these were described as types. In all the experiments seedlessness seemed to be a common trait of crossed cucurbits, or if seed were produced they were ordinarily sterile. An attempt was made to reciprocally cross *Cucurbita pepo*, *C. maxima*, and *C. moschata*. Only 3 fruits were obtained, and those, species hybrids, were between *C. pepo* and *C. moschata*. The progeny grown from these seed were more uniform in character than those obtained by crosses in the varieties of *C. pepo*. Continuing this work through a number of generations, the *moschata* type entirely disappeared and the plants were to all appearances *C. pepo*.

Results of Hybridization and Plant Breeding in Canada was the title of a paper presented by William Saunders, director of the Canada Experimental Farms. He gave a brief résumé of 40 years' work in Canada along the line of production of new varieties of fruits, cereals, etc. His work with wheat, oats, barley, and various fruits was described, the methods of manipulation being given in considerable

detail. Specimens were exhibited which showed the results of a number of the crosses. Among them were crosses of *Pyrus baccata* with several varieties of Russian apples, of different species of barberry, of gooseberry and black currant, of *Pyrus maulei* and *P. japonica*, and of various cereals.

During an evening session a number of papers were presented which were illustrated by specially prepared lantern slides. The first of these was by W. B. Alwood, of the Virginia Station, in which an account was given of investigations in wine fermentation. The selection, propagation, and uses of pure cultures of yeasts in wine and cider making, and in brewing and distilling, were considered and the different methods of elimination and of cultivation described. Graphics were shown of the action of various wine ferments upon grape must.

The second illustrated paper was by W. Van Fleet, of Little Silver, New Jersey, on Hybridizing Gladiolus Species. In growing Gladioli, only summer-blooming varieties with good winter-keeping corms are desired in this country. Hybrids of large flowered species seldom prove valuable in the first generation but seem to improve in subsequent ones. Many species hybrids have been produced but few have proved of intrinsic value. As a rule, Gladioli do not grow well in clay. Sandy soil with an underlying of peat, if kept well wet, is the best soil for their growth. A number of hybrids were exhibited, one of which (Princeps) was said to have a flowering period of nearly 5 weeks, 4 or 5 of the huge flowers succeeding each other until the entire spike has blossomed. This same phenomenon occurs when flower stalks are cut and placed in water, if the water is frequently changed. During 16 years of active hybridizing, in which a number of species were used for breeding purposes and more than 150,000 seedlings produced, many new commercial varieties would have been expected, and although there were many promising novelties only 2, Princeps and Lord Fairfax, have been thought worthy of naming and commercial introduction.

The paper of C. W. Ward, of Queens, Long Island, on Breeding Florists' Flowers was also illustrated by lantern slides. He gave the results of 12 years' work in the hybridization of carnations. His work has been confined to 8 types of stock which were based on color differences. These have been subjected to various crossings, and it was said that the staminate parent showed its effect in the color of the progeny. If crossed upon another flower of the same color the resultant plant would show reversion to prominent ancestral types. The writer claims that when the commercial habit of the carnation has been established any desired color can be bred into it. In breeding carnations, if it is desired to heighten the color in no case should purple or similar colors be used, as those colors tend to dull the color of

the progeny. The most difficult colors to fix in hybrid carnations are the yellows and blues, and the variegated forms are almost impossible to fix. Of 60,000 seedlings grown to flowering, 36 have been considered of sufficient merit to continue propagation, and of this number 16 have been introduced to commerce. In the lantern slides accompanying this paper were shown the parentage and progeny of many of the hybrids produced by the writer.

N. E. Hansen, of the South Dakota Station, read a paper on the Breeding of Native Northwestern Fruits. The prairie regions of the Northwest require the breeding of new varieties of fruits, since all the Eastern varieties so far tested have proved too tender. The writer has been extensively engaged in originating new varieties and more than 100,000 seedlings have been under investigation. To induce variation he proceeded on Darwin's theory that excess of food induces variation, and the writer believes that selection and cultivation are the chief factors to be considered in his region. His work with the sand cherry (*Prunus besseyi*) was described at considerable length. Of this promising fruit between 4,000 and 5,000 seedlings of the third generation are under investigation. The quality of the wild fruit is known to be very variable, and this has been taken advantage of in his propagation work. He has at present 75 varieties budded upon plum stock. The results obtained so far have yielded a larger and better flavored fruit. The sand cherry is said to cross readily with many species of *Prunus*, and valuable hybrids may possibly be secured. Experiments with raspberries, strawberries, currants, gooseberries, and huckleberries were briefly reported, and promising crosses have been obtained of all of them.

T. V. Munson, Denison, Texas, gave the results of his investigations and observations on the selection and hybridization of grapes in a paper entitled Advantages of Conjoint Selection and Hybridization and Limits of Usefulness in Hybridization among Grapes. The author claims that the quality of grapes may be readily improved by increasing the vigor of the vine. To secure better varieties of fruit recourse should be had to selection and hybridization. Selection alone is considered too slow, and new flavors and characteristics can be obtained only in a limited degree through bud variation. On the other hand, indiscriminate crossing without selection may prove injurious, and it is only when crossing is followed by careful and continued selection that valuable results are obtained. The methods of securing crosses were described and the statement made that any method of crossing which is adapted to a genus of plants having many species will be found adapted to other genera possessing numerous species. Among the limits of crossing the author considered the possibility of double fecundation, stating that were it possible it would aid very materially in hybridizing so that in a single generation forms possess-

ing several desirable attributes could be obtained. In grape hybridizing, as well as with other plants, so far as possible pure races alone should be used. Seasonal changes, soils, and climates influence the character of hybrids. A hybrid adapted to a given region in which it has exceedingly valuable characteristics may utterly fail in other regions with different conditions. Special sorts of grapes and other plants should be produced for special conditions, and no attempt should be made to develop a variety that would be expected to contain all the desirable qualities and adapted to all regions and climates. A number of examples were cited of desirable parentage for new sorts for special qualities, conditions, and regions. The parentage of a large number of well-known varieties of cultivated grapes was traced at considerable length.

C. E. Saunders, of Ottawa, Canada, read a paper on the Variations in the Second Generation of *Berberis* Hybrids. In this paper the results of experiments in crossing *Berberis thunbergii* as a pistillate and *B. vulgaris purpurea* as a staminate parent, in which a large number of hybrids was obtained, are described. Some of the hybrids were intermediate in the size of the plant, and size, shape, and color of the leaves, while in others the different characters were widely divergent. As a result of his observations it was found that these hybrids tended to uniformity in the first generation and wide variation in the second and subsequent generations, as shown by more than a thousand seedlings. In the first generation little or no purple color was observed, but the color of the foliage came out well in many specimens of the second generation. The leaves, thorns habit of plant, etc., varied widely in the later generations.

Bud Variation in the Strawberry Plant was the subject of a paper by R. M. Kellogg, of Three Rivers, Michigan. This is said to be very common in the Strawberry Plant, and an account was given of 19 years' effort on the part of the writer to produce more vigorous types of strawberry plants by forcing growth through the use of fertilizers, by tillage, and continued selection. The effect of the different kinds of fertilizers in culture was shown, and an excess of nitrogen was used to stimulate vegetative growth and thus induce variation. The individual peculiarities of plants must be considered in producing new forms, and where valuable individual characteristics appear, as shown by bud variations, these should be eagerly sought and propagated.

G. T. Powell, director of the Briarcliff School, New York, gave the results of 10 years' experiments in propagating bud variations of the Sutton Beauty and Tompkins County King apple, his remarks being illustrated by specimens of fruits.

H. C. Price, of the Iowa Station, read a paper on Hand Pollination of Orchard Fruits. This is not difficult, but ordinarily the results obtained are very slow in development. The plan of cooperation

maintained by the Iowa Experiment Station with orchardists throughout the State, in which pollen of known varieties is distributed, was described. The seedlings resulting from the hand pollination of fruits are grown and carefully examined. In the cooperation it is, so far as possible, desired that the orchardist should produce his own seedlings rather than send them to the station. The effect of different kinds of emasculation of the flowers was described. Low emasculation, in which all the flower but the style was cut away, did not give as favorable results as high emasculation, in which only the corolla and anthers were removed. Studies on the time for operation showed that the immediate transfer of pollen after the emasculation of flowers gave the best results. Pollen applied to the stigmas by a camel's-hair brush gave slightly better results than where transferred by the fingers. Pollen taken from the anthers just before the opening of the flowers seems to be the most potent and gave the best results.

H. F. Roberts, of the Kansas Station, read a paper on Cereal Breeding in Kansas, in which he briefly reviewed some of the efforts that have been made in corn and wheat breeding. In breeding wheat for growth in Kansas, hardiness in winter, drought resistance, and increased production are the points sought. In a variety of wheat seeming to possess extreme hardiness a number of spikes appeared which showed a tendency toward the club-wheat form. These heads, to the number of 61, were collected and are to be studied during the coming season. Eleven of the heads were apparently of exceedingly great productivity. The grain will be planted and the results announced in due time. It is desired to secure a variety in which the spikelets and heads are more completely filled. Experiments in breeding macaroni wheats to secure greater drought resistance are also under way, and a number of other experiments were briefly mentioned.

William Fawcett, director of Public Gardens, Jamaica, gave a brief account of the plant-breeding work that is being conducted in Jamaica. Naturally the investigations have been conducted on tropical plants. The differences in the character of the different flower clusters of banana were pointed out. The lower or earlier ones are usually all female, and the ovary is twice the length of the rest of the style. Those next are both male and female, and the last ones to appear are all staminate. If the male flowers be cut from a bunch it results in early ripening and in uniformity of fruit. A number of attempts were made to artificially pollinize the banana, and some seeds were set but they failed to germinate. Experiments were reported in which the Smooth Cayenne and Ripley pineapples were crossed. The flowers of the pineapple are said to be almost wholly self-sterile. Many seedlings have been obtained, most of which were intermediate between the parents, but as yet they have not developed valuable characters. Experiments with mangoes have not yet proved success

ful. The investigations have shown that the Avocada, or alligator pear, may be budded with success.

The remaining papers of the programme, read by title, were as follows: Notes on New Hybrids, J. H. Wilson; Selection *v.* Hybridism, F. W. Burbidge; Some Laws of Plant Breeding, H. J. Webber; On Variation in Plants, J. B. Norton; Some Possibilities, C. L. Allen; Fertile Hybrids of Teosinte and Maize, J. W. Harshberger; A Study of Grape Pollen and What the Results Indicate, N. O. Booth; The Improvement of Corn by Breeding, C. P. Hartley; Improvement of Crops for Arid Regions and Alkali Soils, T. H. Kearney; Improvement of Cotton by Breeding, H. J. Webber; Practical Points from the Breeding of Strawberries and Bush Fruits, F. W. Card; Crossing Species of *Salix*, S. W. Fletcher; Notes on Breeding Hardy Apples, J. Craig; The Everbearing Strawberry, P. de Vilmorin; The Muskmelon, F. W. Rane; Results in the Breeding of Species of *Ricinus*, E. M. Wilcox; On Orchid Hybrids, O. Ames; Hybrid Beans, R. A. Emerson; Hybrid Plums, F. A. Waugh; Cross Breeding of Cinchonas, H. H. Rusby; Notes on Plant Breeding in California, E. J. Wickson; Plant Breeding in New Jersey, B. D. Halsted; The Wild Hybrids of the North American Flora, D. George; Plant-Breeding Work in Germany, J. C. Whitten; and Hybrids and Diseases, L. H. Pammel.

The afternoon session of October 2 was held at the New York Botanic Garden, Bronx Park, where the delegates to the conference were entertained as guests of the directors of the garden. On Friday an excursion was given the delegates up the Hudson to Poughkeepsie, in the vicinity of which a number of private estates were visited.

RECENT WORK IN AGRICULTURAL SCIENCE.

CHEMISTRY.

Manual of agricultural chemistry, H. INGLE (*London: Scott, Greenwood & Co., 1902, pp. 388, figs. 11*).—This volume “is based upon lectures delivered annually, for several years past, by the author, to classes of agricultural students, many of whom had already acquired some knowledge of general chemistry. . . . In all cases the writer has endeavored to avoid empiric statements, and to give, as far as possible, an explanation of the facts or phenomena described.” The introductory chapter deals with the distribution and relative abundance of the elements. Other chapters discuss the composition of the atmosphere, the materials from which soils are formed, the agencies active in soil formation, the constituents of soils as related to their chemical and physical properties, and the classification of soils; the reactions occurring in soils (chemical, physical, and biological nitrification, denitrification, action of gases and water, and electrolytic dissociation); analysis of soils (physical and chemical); natural manures and commercial fertilizers; analysis and valuation of manures and fertilizers; the constituents of the plant and the chemistry of the development of its different parts, including explanations of the assimilation of carbon dioxide through the stomata of the leaves based upon the generally accepted kinetic theory of gases, and of the essential differences between osmoses and diffusion as related to plant growth; the proximate composition of the principal farm crops (with methods of analysis); the chemistry of the animal organism and of its functions; foods and feeding; milk and its products (including analysis); miscellaneous products used in agriculture, including arsenic, mercuric chlorid and various plant poisons, bleaching powder, copper salts, iron sulphate, disinfectants, fungicides, and insecticides; and an appendix of useful tables.

Rapid volumetric method for determining phosphoric acid in fertilizers, A. L. EMERY (*Jour. Amer. Chem. Soc., 24 (1902), No. 9, pp. 895-897*).—A modification of the volumetric method adopted by the Association of Official Agricultural Chemists is described. The most important change proposed consists in shaking the solution vigorously by hand after adding the ammonium molybdate.

The determination of phosphoric acid by titration of ammonium phosphomolybdate, J. CÉZAR (*Bul. Assoc. Belge Chim., 16 (1902), pp. 247-253; abs. in Chem. Centbl., 1902, II, No. 12, p. 820*).—The author reports tests of Nyssens' method (*E. S. R., 13, p. 614*) and describes slight modifications of certain details of it.

On the determination of total phosphoric acid in Thomas slag, C. ASCHMAN (*Chem. Ztg., 26 (1902), No. 71, p. 823*).—The author describes a modification of his method (*E. S. R., 11, p. 507*), which consists in proceeding with the determination immediately after obtaining the filtered solution of the slag, instead of allowing the solution to stand 12 hours.

On the influence of potassium ferrocyanid on the precipitation of phosphoric acid by ammonium nitromolybdate, A. F. LEUBA (*Ann. Chim. Analyt., 7 (1902), No. 7, p. 257*).—It is shown that potassium ferrocyanid interferes with the precipitation of phosphoric acid by ammonium molybdate, due to the fact that it

yields a dense reddish-brown precipitate, to which the formula $\text{Mo}(\text{OH})_4$ is assigned. This precipitate dissolves in sodium carbonate solution, and when this is exactly neutralized with nitric acid and heated the yellow phosphomolybdic compound separates out.

Double ammonium phosphates in analysis, MARTHA AUSTIN (*Amer. Jour. Sci.*, 4. ser., 4 (1902), No. 80, pp. 156-160).—The author briefly reviews her own work (*E. S. R.*, 10, p. 419) and that of other investigators relating to the accuracy of the determination of magnesium, manganese, cadmium, and zinc by means of double ammonium phosphates, and calls attention to certain precautions which must be observed to insure accuracy, especially the use of anhydrous asbestos in filtering. The results obtained by Miller and Page^a in the determination of cadmium are stated to be unreliable by reason of their use of hydrous (serpentine) asbestos. The modification of the author's method for the determination of zinc and manganese proposed by Dakin^b is criticized as inaccurate on account of the error introduced by washing with ammonium phosphate and alcohol and by the use of hydrous asbestos in filtering.

Rediscovery of a process for rendering phosphoric acid available, C. BASKERVILLE (*Science*, n. ser., 16 (1902), No. 397, p. 215).—An abstract of a paper read before the North Carolina Section of the American Chemical Society at Raleigh May 17, 1902, in which the author's experiments in fusing insoluble phosphates with alkaline sulphates, sulphids, nitrates, and carbonates are briefly referred to.

The detection of nitric acid in presence of an alkaline ferrocyanid or ferricyanid, A. F. LEBEA (*Ann. Chim. Analyt.*, 7 (1902), No. 7, p. 258).—The test for nitric acid by adding sulphuric acid and a ferrous salt can not be made in the usual manner in the presence of alkaline ferrocyanids or ferricyanids, since these form dark blue compounds. When, however, a slight excess of concentrated solution of cadmium chlorid is added and the insoluble cadmium ferrocyanids and ferricyanids removed by filtration the test may be made as usual.

The determination of organic nitrogen in water, H. CAUSSE (*Compt. Rend. Acad. Sci. Paris*, 134 (1902), No. 25, pp. 1520-1522; *abs. in Chem. Centbl.*, 1902, II, No. 6, p. 475).—In the method proposed the organic compounds of nitrogen are precipitated by means of a saturated solution of baryta water containing 20 per cent of barium chlorid, the organic matter destroyed by digestion in sulphuric acid, and the nitrogen determined by nesslerizing the ammonia obtained by distilling the solution obtained, after addition of an excess of potash.

New apparatus in water analysis, A. G. WOODMAN (*Jour. Amer. Chem. Soc.*, 24 (1902), No. 9, pp. 897, 898).—A criticism of the apparatus of Thomas and Hall for collecting samples of water for the determination of dissolved oxygen or carbon dioxid (*E. S. R.*, 14, p. 10). The author explains why, in his opinion, the samples collected in the way proposed do not represent the exact character of the water being tested.

Gluten feeds, determination of fat and acidity, E. GUDEMAN (*Science*, n. ser., 16 (1902), No. 399, p. 287).—The author states that drying corn gluten feeds in hydrogen, vacuum, or air modifies them sufficiently to give low results for the percentage of fat and increases the acidity of the extracted fat. Gluten meals containing 5.16 per cent of fat before drying gave 3.56 after drying. The acidity of the fat extracted before drying was from 5 to 15 per cent and after drying from 20 to 40 per cent. The acidity as determined varies materially, according to the indicators used. The author claims that acidity of feeding stuffs is due to the presence of acid salts, and is no criterion of the quality of the feed or raw materials from which it was made.

Glucose determination, E. GUDEMAN (*Science*, n. ser., 16 (1902), No. 399, p. 288).—The author states that the polariscope gives incorrect results, due to the varia

^a School of Mines Quarterly, 22, p. 391.

^b Chem. News, 82, p. 101; 83, p. 37.

tion in the rotating power of glucoses between 80 and 198. He suggests determination by means of Fehling's solution after inversion at 67° C. and after treatment with malt. Invert sugar is determined by double polarization at 20 and 87° C. From these results the amount of reducing and nonreducing substances is directly calculated and the sum of the two taken as the actual amount of commercial glucose or grape sugar present in the mixtures.

The polarization of fruits, jellies, jams, and honeys, L. M. TOLMAN (*Jour. Amer. Chem. Soc.*, 24 (1902), No. 6, pp. 515-524, figs. 2).—The author investigated the action of hydrochloric acid upon the rotary power of invert sugar. Cane sugar was inverted with citric acid and hydrochloric acid added in different proportions to equal quantities of the solution. The change in rotation to the left due to the addition of hydrochloric acid was the same whether polarization was made immediately in the cold or after the solution had been heated to 67° C. and was proportional to the quantity of acid used. A correction for the hydrochloric acid is therefore necessary in the calculation of cane sugar in invert sugar by Clerget's method. The following formula in which S =sucrose, a direct reading, b invert reading, and t temperature, while not applicable to fruit products containing glucose, is given by the author as of special value in estimating small amounts of cane sugar in fruits, pure fruit jellies, jams, and honeys in which large amounts of invert sugar are present.

$$S = \frac{a - (b - 0.062 \frac{t}{2})}{141.79 - \frac{t}{2}}$$

The effect of the acid is represented by $0.062 b$. Readings should be made at about 20° C.

On the quantitative separation of maltose and lactose, C. I. BOYDEN (*Jour. Amer. Chem. Soc.*, 24 (1902), No. 10, pp. 993-995).—The method given is based upon the removal of maltose by *Saccharomyces anomolus*, which apparently does not affect the lactose.

Refractive indices of salad oils—correction for temperature, L. M. TOLMAN and L. S. MUNSON (*Jour. Amer. Chem. Soc.*, 24 (1902), No. 8, pp. 754-758).—The correction for temperature for the refractive indices of linseed, cotton-seed, peanut, corn, sesame, olive, and rape oils as determined was about 0.000365 for 1° C. and was practically uniform for the different oils.

The influence of growth of mold upon the chemical composition of oleomargarine and butter, C. A. CRAMPTON (*Science, n. ser.*, 16 (1902), No. 399, p. 288).—Analyses are given of a series of samples of oleomargarine which had been kept for 3 years and become infected with a growth of mold. These results show great variation in the composition of the fat, believed to be induced chiefly by the mold. The author believes they indicate that the rancidity of fats is brought about (primarily, at least) by the influence of the growth of micro-organisms or the enzymes produced by them.

Tables for use in the determination of fat in cream by the Gerber method, A. HESSE (*Molk. Ztg.*, 16 (1902), No. 23, pp. 406, 407).

BOTANY.

Fieldbook of American wild flowers, F. S. MATHEWS (*New York: G. P. Putnam's Sons*, 1902, pp. XX+552, col. pls. 24, figs. 263).—This book gives a short description of the character and habits of many of our best known wild flowers, together with a concise definition of their colors, and incidentally refers to the insect visitors which assist in their fertilization. The arrangement of the orders and genera is that adopted by Engler and Prantl, and a conservative treatment of specific nomenclature is followed. Species representative of 72 families of plants are

described in language as nontechnical as the subject will admit; and as a fieldbook the compactness of the volume, conciseness of the descriptions, and excellence of the illustrations make it easy to identify many of the more common species of wild flowers. The absence of any key to orders and genera may prove detrimental in the estimation of some, but through the popular instruction in nature studies many plants are known by their family affinities, and this work will be found valuable in supplementing the other studies.

The cultivated guavas and their botanical differences, J. B. DAVY (*California Sta. Rpt. 1899-1901, pt. 1, pp. 86-88*).—In view of the increasing interest which has been shown in the cultivation of guavas, the author has prepared a brief account of the botany and economic uses of the genus, together with a key of the species already introduced, by which they may be readily distinguished. Five species are described in considerable detail, the classification given being based on differences of the branchlets. A number of other species are mentioned which are insufficiently known, and notes given on others which might probably prove serviceable in plant-breeding experiments.

Some Australian vegetable fibers, J. H. MAIDEN (*Agr. Gaz. New South Wales, 13 (1902), No. 2, pp. 167-182*).—A list is given of some of the more important Australian fiber plants, together with notes on their distribution and economic value. The different plants are grouped according to orders.

The Geastræ, C. G. LLOYD (*Cincinnati: Author, 1902, pp. 44, figs. 80*).—A description is given of the Geastræ, in which different parts are defined, and a classification of the genera and species is given. Two genera are recognized—*Myriostoma*, with 1 species, and *Geaster*, with 22 species.

The origin of species by mutation, D. T. MACDOUGAL (*Torrey, 2 (1902), Nos. 5, pp. 65-68; 6, pp. 81-84; 7, pp. 97-100*).—An extended review is given of the origin of species by mutation, the theory and experiments of de Vries being described at considerable length (E. S. R., 13, pp. 324, 619).

The rheotropism of roots, F. C. NEWCOMBE (*Bot. Gaz., 33 (1902), Nos. 3, pp. 177-198; 4, pp. 263-283; 5, pp. 341-362, figs. 15*).—The results of investigations of the rheotropic movement of roots, as shown by the examination of 32 species of plants, are given. These 32 species include all plants but 2 that have been examined for rheotropism, and of the 34 that have been studied, 20 showed positively rheotropic movements and 14 have been found insensitive. It is concluded that rheotropism can not, therefore, be said to be a general phenomenon.

The transformation of proteids during germination, G. ANDRÉ (*Compt. Rend. Acad. Sci. Paris, 134 (1902), No. 17, pp. 995-998*).—Results of investigations in determining the transformation of proteids during the germination of beans are given. Of the proteid materials which enter into the seed, albumin disappears most quickly. Legumin, which represents about one-fourth of the total nitrogen of the unspouted seed, diminishes rapidly but never completely disappears. The amid nitrogen, such as asparagin, etc., remains in solution after the separation of legumin and albumin, and increases with the process of germination, so that the nitrogen, which is about 4.2 per cent of the total nitrogen of the seed, increases to more than 55 per cent during germination. The proteid materials which are insoluble in water form the greater portion of the substance called conglutin by Rittenhaus. At the time the total weight of the plant is about that of the seed, or when the plant begins to take up nitrogen from the soil, the insoluble nitrogen increases rapidly, and this period is characterized by the formation of new albuminoids. These, on the one hand, are formed from the nitrogen taken from the soil and on the other by the conversion of the soluble amids and albuminoids.

Observations on transpiration, C. C. CURTIS (*Bul. Torrey Bot. Club, 29 (1902), No. 6, pp. 360-373*).—An account is given of the variation of the transpiration due to differences in electric illumination, moisture, cuticular and intracellular transpira-

tion, periodicity of stomata, etc. It was found that on cloudy and stormy days, when the intensity of the light is uniform, the transpiration curve shows a pronounced maximum near midday. The illumination of an electric light of 900 candle-power under uniform external conditions demonstrated a periodicity in the transpiration of several plants that corresponded in the main with the curves determined on cloudy days. Slight variation in the humidity of the atmosphere produced no change in the amount of transpiration that could be definitely determined. An increase of 8 per cent in the humidity resulted in a marked drop in the rate of transpiration. The curve of transpiration in the dark was frequently characterized by marked variations in comparison with the periodicity of light. There is believed to be a cessation of the vital action of the plant in the dark, and the retarding of the rate, together with its more pronounced regularity, is in keeping with the loss of vigor in the plant. The transpiration in the dark indicates that the stomata may be sufficiently open to allow the escape of vapor. This may be brought about in connection with the interchange of the gases in respiration or possibly by the independent action of certain stomata that are especially affected by the increased turgor tension or vapor tension of intracellular transpiration. The physiological character of transpiration is indicated by the periodicity of the opening and closing of the stomata. They are more responsive to the stimulus of light in the morning than in the afternoon, and the increased physiological activity in the morning is manifested in the more pronounced after effect following the illumination in the forenoon.

Contributions to the chemistry of chlorophyll, E. SCHRECK (*Proc. Roy. Soc. [London]*, 69 (1902), No. 455, pp. 307-312; *abs. in Bot. Centbl.*, 89 (1902), No. 14, pp. 389, 390).—A report is given of the changes which chlorophyll undergoes in passing through the bodies of animals. The feces of animals fed green vegetable food did not contain any chlorophyll, but did show a number of substances that are apparently chlorophyll derivatives. One of these seems identical with phylloxanthin, while another resembles phyllocyanin, but is not identical with it. A third substance was found to which the name scatocyanin is given. The chemical and physical properties of scatocyanin are described.

The etiolation of plants, F. NOLL (*Sitzber. Niederrhein. Gesell. Natur. u. Heilk. Bonn*, 1901, pp. 9; *abs. in Bot. Centbl.*, 89 (1902), No. 13, pp. 363, 364).—In addition to the well-known action of the absence of light in producing the etiolation of plants, the author describes forms which are due to other causes. The action of water under special circumstances may result in etiolation, and an inadequate amount of nitrogen or other important food constituent may result in a similar condition. Another form of etiolation may be produced by propagating such plants as *Sempervivum* and other rosette-forming plants by their flowering shoots.

The action of light on etiolated plants, H. RICÔME (*Rev. Gén. Bot.*, 14 (1902), Nos. 157, pp. 26-40; 158, pp. 72-88; 159, pp. 120-137, pls. 3, figs. 10).—The result of a series of investigations on the influence of light upon etiolated plants is reported. Potatoes, beans, lentils, castor beans, and a number of other plants were germinated and part of the seedlings kept in the dark for several weeks and afterwards brought into the light, a check lot being grown under normal conditions. The effect of etiolation upon the subsequent development of the plants is shown in the modified morphological and anatomical structures of the plants. It is shown that etiolated plants are capable of considerable development when brought into the light, provided they possess sufficient reserve material when brought from darkness into light, and that their capacity to grow has not been destroyed by the sudden change. The ultimate development and differentiation of leaves produced in darkness when brought into the light depends upon the state of development at the time of the change. The same is true for the internodes, although these organs do not attain their maximum development in the light. This effect seems to be brought about by a loss of water due to the disturbance of the equilibrium between the transpiration by the leaves and

absorption through the roots. The organization acquired by a plant in darkness feebly affects its development in the light. The internodes of plants brought into the light are usually short and large and the leaves larger than normal, especially if in a dry atmosphere. This seems to be due to the activity of transpiration at the time and the leaves drawing the water from the internodes.

The influence of temperature on the absorption of mineral elements by etiolated plants, G. ANDRÉ (*Compt. Rend. Acad. Sci. Paris*, 134 (1902), No. 11, pp. 668-671).—In a previous publication (E. S. R., 12, p. 613) the author has shown marked differences which exist between etiolated plants of maize and lupine which are kept in darkness. In the present paper the experiments are continued with maize and beans, in which the effect of temperatures of 15 and 30° C. on the absorption of mineral elements by etiolated plants is shown. Lime, which is most abundant in plants etiolated at 15°, is absorbed less abundantly by those which have been kept at 30° C. Potassium is taken up in the same manner. Phosphoric acid does not show appreciable variation from the above, while sulphur in the form of sulphates, which is present in considerable abundance in beans, is found to be 2½ times as abundant in the etiolated plants as in the seed. In the case of maize the sulphates are 7 times as abundant. Comparing plants etiolated at 15 and 30° C. shows a remarkable increase in the silicates present at the higher temperature, which is correlated with an increase of cellulose.

METEOROLOGY—CLIMATOLOGY.

Report of the meteorologist, W. H. BISHOP (*Delaware Sta. Rpt. 1901*, pp. 200-206).—Monthly summaries of observations at 3 places in Delaware on temperature, pressure, precipitation, relative humidity, and prevailing winds during the year ended June 30, 1901, are given, with a summary of observations on temperature and precipitation during the calendar year 1900.

The summary for 1900 is as follows:

Annual summary of meteorological observations in Delaware, 1900.

Locality.	Temperature.			Total rainfall.	Number of days on which 0.01 in. or more of rain fell.
	Highest.	Lowest.	Mean.		
	Deg. F.	Deg. F.	Deg. F.	Inches.	
Newark	98 (July and August).....	4 (February)	53.3	40.74	92
Dover	108 (July)	3 (February)	54.8	37.71	85
Seaford	102 (August)	7 (February)	56.1	36.69	80

Meteorological tables, T. S. OUTRAM (*Minnesota Sta. Rpt. 1901*, pp. 341-349).—Tables prepared by the director of the Minneapolis office of the Weather Bureau are given, showing the monthly and yearly averages and departures from normal of temperature and precipitation, based on observations at some 64 places in Minnesota during the year ended June 30, 1901.

Rainfall variations (*Science*, n. ser., 16 (1902), No. 393, p. 75).—This is a brief note on a discussion by Hann^a of variations in rainfall during long periods, based on data for monthly and yearly rainfall at Padua, 1725-1900; Klagenfurt, 1813-1900,

^aSitzungsber. Wien. Akad., 111 (1902), IIa.

and Milan, 1764-1900. There is shown to be a 35-year periodicity as regards dry and wet years, corresponding with the 35-year climatic period of Brückner, as follows:

Periodicity of wet and dry years.

Wet	1738	1773	1808	1843	1878	(1913)
Dry	1753	1788	1823	1859	1893	(1928)

Black rain in North Carolina, C. BASKERVILLE and H. R. WELLER (*Science*, n. ser., 16 (1902), No. 397, pp. 215, 216).—An abstract of a paper read before the North Carolina section of the American Chemical Society at Raleigh May 17, 1902, which refers briefly to a chemical examination of a sample of black rain from Louisburg, N. C.

Cyclones and agriculture, L. DUMAS (*J. Ing. Agr. Gembloux*, 12 (1902), No. 11, pp. 523-531, figs. 2).—A general discussion of the movement and course of cyclones and of the damage which they do to agriculture.

WATER—SOILS.

Waters (*California Sta. Rpt. 1899-1901*, pt. 1, pp. 49, 50).—The results of examinations of 310 samples of water from different parts of the State, with reference to their adaptability for domestic or irrigation purposes, are briefly summarized. It was found that 70 per cent of the lake and stream waters, 56 per cent of the spring waters, 56.7 per cent of the common well waters, 47.8 per cent of the reservoir and ditch waters, and 31.6 per cent of the artesian well waters were unsuitable for domestic and irrigation purposes.

The purification and sterilization of water, S. RIDEAL (*Jour. Soc. Arts*, 50 (1902), Nos. 3591, pp. 717-725; 3592, pp. 729-737; 3593, pp. 741-750; 3594, pp. 755-767).—A series of lectures giving a very complete discussion of the subject.

Studies of the subterranean hydrology of the region of Cadereyta Méndez, State of Querétaro, 1901, J. DE D. VILLARELLO (*Bol. Sec. Fomento [Mexico]*, 1 (1901), No. 5, IV, pp. 75-91; 1 (1902), No. 6, IV, pp. 135-152).

Soil analyses, C. L. PENNY (*Delaware Sta. Rpt. 1901*, pp. 77-82, fig. 1).—"As a preliminary step to a general study of the soil, analyses were made for potash, phosphoric acid, and lime in 7 soils selected from various places in Kent County, all in the vicinity of Dover." The results of these analyses, as well as of mechanical analyses of the soils, are reported with a description of the methods used in sampling the soils and in determining potash. In each case the surface soil was sampled to the line of demarcation between surface and subsoil, the depth varying from 6 to 10 in. in different cases. The subsoil was sampled to a total depth from the surface of 36 in., or 25 to 30 in. below the bottom of the surface soil. The samples were taken either with a brass tube sampler or by means of a spade. The method of determining potash was substantially that described in previous publications (E. S. R., 10, pp. 134, 514), except that the rotary device used in the acid digestion of the soils was modified so that the steam chest containing the flasks is inclined toward the horizon at an angle of 22°, the flasks being placed in the chest with their necks parallel to the axis of rotation. In this way the necessity for tightly closing the flasks, with the consequent danger of collapse, is avoided, and it is claimed that while the agitation is not so violent as in the original device, the conditions are quite as favorable for the solvent action of the acid. The soil solutions were made with hydrochloric acid of 20.26 per cent strength (1 liter of acid to 500 gm. of soil), the digestion being maintained at steam heat for 12 hours. Parallel determinations were

made in samples of soil ignited to bright-red heat and those not so ignited. It was found that the amount of potash soluble in strong acid at steam heat was in most cases more than doubled by ignition. A slightly larger percentage of potash was found in the subsoil than in the surface soil, the reverse being true in case of lime.

The soils of Dorset, D. A. GILCHRIST and G. A. LUXMOORE (*Jour. Reading Col. [England]*, 1900, *Sup. 10*, pp. 28; 1902, *Aug.*, pp. 34).—Reports are here given of results of examinations of the second and third installments of 20 samples each of Dorset soils investigated under the terms of an agreement explained in an earlier report (*E. S. R.*, 11, p. 327). The reports give the results of laboratory examinations and field observations.

Gooselands of Glenn and Colusa counties, R. H. LOUGHRIDGE, T. L. KNOCK, and J. B. DAVY (*California Sta. Rpt. 1899-1901*, pt. 1, pp. 21-83).—A brief account is given of mechanical and chemical examinations, and studies of alkali conditions, physical characteristics, and distinctive flora of these lands, which derive their name from the fact that they are the resort of large flocks of wild geese which are attracted by the accumulation of water on the surface of the soils during the winter rains. The soils cover a large area in the counties of Glenn and Colusa, bordered by the alluvial belt of the Sacramento River on the east and the valley plain of the Sacramento Valley on the west, and reach from Willows on the north to within a few miles of Arbuckle on the southeast. The region varies in width from about 15 miles in its widest place on the north to about 6 miles on the south. It has a length of about 30 miles. The accumulation of water is due to an impervious subsoil, and the soil is strongly impregnated with alkali, the predominant ingredient of which is sodium sulphate. The alkali is believed to be derived mainly from the alkali waters and sediments of Willows Creek, which empties into this area. A combined system of warping and drainage is suggested as a possible means of correcting the present unsatisfactory condition of these lands. "The most abundant and distinctly characteristic plants of the gooselands proper are, in order of prevalence: Alkali heath (*Frankenia grandifolia*), gum weed (*Grindelia camporum*), salt grass (*Distichlis spicata*), gold fields (a species of *Baria* or *Lasthenia*, especially prevalent on adobe patches), cressa (*Cressa cretica truxillensis*), sida (*Sida hederacea*), long-winged pepper cress (*Lepidium latipes*), tissa (*Tissa leucantha*), and prostrate saltbush (*Atriplex fruticulosa*)."

Study of the climate and soil of the Polder region of Belgium (*Monographie agricole de la région des Polders. Brussels: Ministry of Agriculture, 1902*, pp. 1-14).—The subject is treated in the same manner as in previous reports of this series on other regions (*E. S. R.*, 13, p. 723). The soils of the region are compact, tenacious, and of marine or fluvio-marine origin. They contain from 20 to 30 per cent of clay. In virgin state they are rich in fertilizing constituents, but have in many cases become impoverished by continuous cropping without manure, especially as regards nitrogen and phosphoric acid.

An investigation of soil sediments, as formed under arid conditions, with regard to their plant-food value, L. M. TOLMAN (*California Sta. Rpt. 1899-1901*, pt. 1, pp. 33-42).—Chemical analyses of the different sediments obtained in mechanical analyses of a number of California soils are reported and compared with similar analyses of sediments obtained in analyses by Loughridge of soils from humid regions. The results indicate that the clay of arid soils is not so important a factor in plant nourishment as that of humid soils and that there is a rather general distribution of plant food through all the sediments, the plant food being in about the same condition in all of them.

A contribution to the action of fertilizer salts on the physical properties of soils, A. MITSCHERLICH (*Fühling's Landw. Zig.*, 51 (1902), No. 16, pp. 580-588).—The most marked effect of the use of salts on soils is to cause them to become more compact; the influence on moisture content is thought to be of no great importance.

The sugar beet as a reclamer of arid and alkali regions, H. C. MYERS (*Jour. Soc. Chem. Ind.*, 21 (1902), No. 12, pp. 834-838, figs. 4).—This is the second article on this subject by the same author (E. S. R., 13, p. 641), and gives results of observations on the growth of sugar beets on virgin alkali soil in West Weber, Utah, where cultivation has never been attempted, the land being irrigated from artesian wells. Analyses of soils, water, and beets are given.

Studies on the distribution of lime in the soils of vineyards, J. DUFOUR and H. FAES (*Chron. Agr. Canton Vaud*, 15 (1902), Nos. 15, pp. 437-445; 16, pp. 480-487).

Occurrence and importance of soluble manganese salts in soils, E. E. EWELL (*Science*, n. ser., 16 (1903), No. 399, p. 391).—An abstract of a paper presented to the American Chemical Society at its summer meeting, which briefly reports the results of an examination of a soil which failed to grow leguminous plants and which was found to contain a very considerable amount of manganese compounds soluble in water, more in fact than of lime.

Agriculture in its relations to bacteria and other ferments, H. W. WILEY (*Jour. Franklin Inst.*, 154 (1902), Nos. 2, pp. 81-90, pl. 1, figs. 3; 3, pp. 161-169, pl. 1, fig. 1).—This article deals almost exclusively with the transformations of nitrogen in the soil under the influence of micro-organisms—nitrification, denitrification, and assimilation of nitrogen by plants—incidentally describing the methods followed in the Bureau of Chemistry of the Department in sampling and examining various soils used in studies on nitrification. In discussing the problem of exhausted soils the author takes the somewhat unusual position "that the leguminous crops will not grow except in a reasonably fertile soil and hence it is useless to expect the restoration of fertility to an exhausted soil by a natural means. . . . With such soils the best recourse is to nitrogen already available, that is, some form of nitric acid. The cheapest source at present is sodium nitrate or Chile salt-peter."

Development and distribution of nitrates in cultivated soils, F. H. KING and A. R. WHITSON (*Wisconsin Sta. Bul.* 93, pp. 39, figs. 6).—This is a detailed account of investigations more briefly reported elsewhere (E. S. R., 13, p. 930). The additional data include the results of a study of the variation in nitrification in soil and subsoil, which show greatest development of nitrates in the surface 6 in. of soil and the least in the third 6 in.; also the results of observations on the transformation of nitrogen in a galvanized iron lysimeter 5 ft. deep and having an area of 37.5 sq. ft., and on the development of nitrates in fallow and immediately adjacent soil under crops.

Investigations on the determination and composition of humus, and its nitrification, C. LIMBACH (*California Sta. Rpt.* 1899-1901, pt. 1, pp. 43-48).—Laboratory experiments on the rate of nitrification of humates of lime and magnesia prepared from soils are reported, which verify "the assumption made heretofore by Professor Hilgard and others that Grandean's *matière noire* is a direct source of nitrogen through nitrification." They also tend to confirm Hilgard's conclusion "that humus containing a high percentage of nitrogen, such as is found in the soils of the arid regions, will yield larger amounts of nitrates in the same time than will that of lower nitrogen percentages, and that conversely, low nitrogen percentages may fail to supply a sufficiency for plant growth." Grandean's method for the determination of humus and of nitrogen in humus was investigated, with the following results:

"By leaching with chlorhydric acid and water a certain quantity of humus, varying in the different soils, is lost to the subsequent extraction with ammonia.

"The content of nitrogen of the soda extract, being different from that of the ammonia extract, can not be directly referred to the content of organic matter of the latter.

"In the determination of organic matter and nitrogen in the ammonia extract, the quantity of combined ammonia must be considered. . . . It is evident that the percentages of humus heretofore determined are too high, inasmuch as the combined

ammonia, which is about 5 per cent of the ash-free ammonium humate, has been erroneously calculated as organic matter. . . .

"The question still remains whether sodic or ammonic solution, and in what strength, satisfy best the requirements of a solvent for humus substance, regarded as the sum of organic substances, decomposed or not, that are immediately available for the plants."

Studies in soil bacteriology, F. D. CHESTER (*Delaware Sta. Rpt. 1901*, pp. 50-73).—This is a preliminary report on uncompleted investigations relating mainly to the study of methods of determining the number of bacteria in soil samples, the numerical distribution of bacteria in soil, and the conditions (acidity, influence of lime and other fertilizers, etc.) affecting the number and distribution of the soil organisms. The results of pot experiments with lime and other fertilizers indicate that—

"(1) Lime diminishes the acidity of the soil as measured by the method of Wheeler [E. S. R., 11, p. 1003], but not in the degree which would be expected. It would, therefore, appear that soil acidity must in a measure be due to substances which the lime does not neutralize. The basic slag slightly reduced acidity, while the muriate of potash was without effect.

"(2) The study of pots to which nothing was applied shows that the number of bacteria undergoes fluctuations. In other words, death of bacteria and multiplication are concurrent phenomena, and there may be gain or loss dependent upon conditions, favorable or unfavorable, during certain intervals.

"(3) In the pots which received no treatment a general level of bacteria was maintained throughout the experiment.

"(4) The addition of lime had a marked tendency to increase the number of bacteria in the soil, which was most marked when the larger quantities were applied.

"(5) Neither Thomas slag nor muriate of potash had any appreciable effect in increasing the number of bacteria in the soil."

Elements of agricultural geology; a scientific aid to practical farming, P. McCONNELL (*London: Crosby Lockwood & Son, 1902*, pp. X + 329, pls. 8, figs. 25, map 1).—This book, which is stated to represent 25 years' systematic study of the subject, contains chapters on the great ice age (introductory), origin and formation of soils, mineralogy of soils, physiography of soils, water supply, formations and farming, and evolution of live stock. The statements and conclusions are based on observations not only in Great Britain but in other countries, including America. As a result of his observations in New England the author supports Johnston in maintaining that an intimate relation exists between rocks and soil in that region, contrary to the very recently accepted views supported by Merrill and others that such a relation seldom exists. Five chapters, covering 115 pages, are devoted to the relation of geological formations in the British Islands to the kind of farming practiced, the thesis upon which the discussion of this phase of the subject is based being "that every rock formation has a soil peculiar to itself, and wherever rocks throughout the world have similar lithological characters the soils derived from such will be similar, and with a corresponding influence on the farming thereof—provided that no disturbing agencies have been at work and the materials have been allowed to accumulate in situ." Special attention is also given to the evolution of live stock (horses, cattle, sheep, and swine) as traced through geological remains and influenced by geological formations, four chapters covering 55 pages being devoted to this subject. In discussing this topic the author proceeds upon the theory that "similarity of formations has produced similarity of breeds, just as differences of formations have produced differences among breeds. The converse of this, again, is true, for we find on the American continent, on the prairies, a region of land very similar to Eastern Europe, and this similarity tends to wipe out the differences between breeds. British breeds have a tendency there to lose their characteristics, and would in time, if

allowed freedom, revert back to some common form when continuously bred under one set of geological surroundings. . . . Even the 'original variety or breed,' if it can be traced to its beginning, will be found to have been influenced or 'developed' by the geological conditions of its habitat." In method of treating the subject this book differs essentially from Risler's *Géologie agricole* and the various available treatises on origin, formation, and characteristics of soils.

FERTILIZERS.

A study of the phosphorus nutrition of plants, T. SCHLOESING, JR. (*Compt. Rend. Acad. Sci. Paris*, 134 (1902), No. 1, pp. 53-55).—A study was made of soils, one of which was comparatively rich in soluble phosphates, the other quite poor. The plant experimented with was maize, and the amount of phosphoric acid taken up from the different soils is shown. In the soil rich in phosphates the phosphoric acid soluble in water was 1,012 mg. per 26 kg. of soil; while that taken up by the plants grown in pots containing this amount of soil was 1,115 mg. In the soil poor in this constituent the amount of soluble phosphoric acid was 199 mg., while the plants obtained from the soil 451 mg. This shows that while the soluble phosphates are readily absorbed it is not necessary that they should be entirely in a state of solution, as the roots of the plant are able to dissolve the compound without the intervention of soil water.

The fertilizing value of deep-stall and yard manure, M. GERLACH (*Jahresber. Landw. Vers. Stat., Jersitz-bei-Posen, 1900-1901*, p. 24; abs. in *Chem. Centrbl.*, 1902, II, No. 11, p. 764; *Centrl. Agr. Chem.*, 31 (1902), No. 8, p. 599).—The deep-stall manure used in the pot experiments here reported contained 0.521 per cent of total nitrogen and 0.086 per cent of water-soluble nitrogen. The yard manure contained 0.446 per cent of total nitrogen and 0.022 per cent of water-soluble nitrogen. The results of the experiments showed that weight for weight the deep-stall manure gave a much larger yield than the yard manure, but the addition of potash and phosphoric acid increased the yield in both cases. The nitrogen of the yard manure was much less effective than that of the deep-stall manure.

The influence of additions of straw, peat, manure, etc., on the action of nitrate nitrogen and the action of Alinit, M. GERLACH (*Jahresber. Landw. Vers. Stat., Jersitz-bei-Posen, 1900-1901*, pp. 23-25; abs. in *Chem. Centrbl.*, 1902, II, No. 11, p. 763).—Applications of straw diminished the action of nitrate nitrogen to a considerable extent; peat with nitrate nitrogen reduced the yield of grain (barley) somewhat, but increased that of straw; cow manure with straw and nitrate had almost no influence on the yield. Alinit in presence of an application of carbonaceous matter was without effect on barley.

Note on the effect of manuring upon the milling property of the grain, F. B. GUTHRIE and G. W. NORRIS (*Agr. Gaz. New South Wales*, 13 (1902), No. 7, pp. 727-729).—A preliminary report on the milling quality of wheat grown on plats fertilized with sulphate of ammonia, nitrate of soda, dried blood, superphosphate, and sulphate of potash in various combinations.

The preservation of manure with superphosphate-gypsum, kainit, and sulphuric acid, T. PFEIFFER, F. MOSZEIK, O. LEMMERMAN, and E. WÄLNTZ (*Arch. Deut. Landw. Gesell.*, 1902, No. 73, pp. 49).—A large number of experiments on this subject are reported. The general conclusions reached are that there is a considerable loss of nitrogen from manure in the stall. With daily removal of the manure the loss was less than when it was allowed to remain for 7 days under the animals. This, however, should not be taken as contradictory to the favorable results obtained in the deep-stall method. The loss of nitrogen both in the stall and in the heap was greater in the summer than in winter. Kainit and superphosphate-gypsum in

amounts of from 1.5 to 2 kg. per 1,000 kg. of live weight of animal were without effect in preventing loss of nitrogen. The addition of sulphuric acid reduced the loss of nitrogen, but not to a sufficient extent to make the practice profitable. The indications are that the nitrogen escaped from the manure mainly in elementary form.

Conservation of cow dung, D. N. MOOKERJI (*Ann. Rpt. Burdwan Expt. Farm 1900-01. Dept. Land Records and Agr., Bengal, 1902, pp. 12, 13*).

On sawdust as fertilizer, G. LOGES (*Deut. Landw. Presse, 29 (1902), No. 76, p. 622*).—The objections to sawdust as a fertilizer are pointed out.

Chemical-agricultural investigations on the fertilizing value of beans, E. DE CILLIS (*Staz. Sper. Agr. Ital., 35 (1902), Nos. 2-3, pp. 85-128, fig. 1; 4-5, pp. 289-308; 6, pp. 441-495, figs. 5*).—A discussion based upon a large amount of analytical and experimental data of the extent to which soils are enriched in nitrogen by the growth of beans, the influence on the succeeding crop, and the possibility of increasing the fertilizing capacity of beans.

Studies in denitrification, E. B. VOORHEES (*Jour. Amer. Chem. Soc., 24 (1902), No. 9, pp. 785-823*).—The plan, scope, and some of the results of the investigations here reported have already been noted (*E. S. R., 13, p. 727*). The first part of the article is a review of other investigations on the subject, containing a list of references of 80 entries; the second part summarizes the results of experiments during 3 years at the station, in cylinders of galvanized iron 4 ft. long and 23.5 in. in diameter, on the availability of the nitrogen of fresh and leached solid and liquid cow manure, of sodium nitrate, of ammonium sulphate, and of dried blood alone and combined. The amounts of nitrogen applied and recovered in the crops (corn, oats, and millet) were used as a measure of the availability. The results, which are reported in detail, indicate that with applications of manure not exceeding 20 tons per acre there was no denitrification in the cylinder tests, although laboratory work had shown "clearly that nitrates when in contact with manure are destroyed by the organisms contained in the latter; that this destruction of nitrates is essentially a reducing process; that the larger portion is set free as gaseous nitrogen, and that a part of it is converted into ammonia and part of it into insoluble organic nitrogen, not suited to supply the immediate nitrogen requirements of the growing crop."

By-product of ammonia and soda manufacture as fertilizers, A. M. GRIMM (*Ztschr. Landw. Versuchsw. Oesterr., 5 (1902), pp. 918-920; abs. in Chem. Centbl., 1902, II, No. 11, p. 761*).—This material contains 32 per cent of lime in air-dry condition and 20 per cent in the fresh condition.

On the use of calcium-carbid residue in agriculture, M. GERLACH (*Fühling's Landw. Ztg., 51 (1902), No. 3, pp. 81-87; abs. in Chem. Centbl., 1902, II, No. 11, p. 764*).—This material, which contains in moist condition 49.52 per cent of free water, 7.33 per cent of calcium carbonate, 40.69 per cent of calcium hydrate, and 0.43 per cent of insoluble matter, is recommended as a useful lime fertilizer.

Analyses of commercial fertilizers and manurial substances, C. A. GOESSMANN (*Massachusetts Sta. Bul. 83, pp. 24*).—Analyses are reported of 175 samples of fertilizers collected in the course of regular fertilizer inspection during 1902, and of 58 samples of fertilizing materials sent to the station for examination, including mixed fertilizers, wood ashes, lime ashes, cotton-hull ashes, coral formation, dry ground fish, ground bone, sulphate of potash, carbonate of potash, nitre lime, vegetable potash, acid phosphate, tobacco stalks, wool waste, castor pomace, and soils.

Analysis of commercial fertilizers, J. L. HILLS, C. H. JONES, and B. O. WHITE (*Vermont Sta. Bul. 93, pp. 83-126*).—This bulletin contains a report of analyses and valuations of 136 brands of fertilizers, the output of 8 companies, sampled and examined during the spring of 1902; a discussion of the results of the inspection; a comparison of the average composition of fertilizers in 1902 and in previous years; and formulas and directions for making home mixtures of fertilizers. Nine-tenths of the

brands examined were up to or above the guaranty, and none failed to furnish the commercial equivalent of the guaranty. As a rule the quality of the crude stock used was apparently good. Nearly a third of the brands contained no water-soluble nitrogen. Sulphate of potash, claimed to be present in five-sixths of the brands, was actually found in only one-sixth. In some cases the phosphoric acid was largely in insoluble or reverted forms. The average selling price approximated \$28.23, the average valuation \$20.18. The average composition of the fertilizers was somewhat higher than that of last year. Tables are given containing formulas in which relatively small, medium, and large quantities each of nitrogen, available phosphoric acid, and potash are combined with varying quantities of the other ingredients, and their use in the preparation of home-mixtures for different purposes is explained.

Licensed commercial fertilizers, F. W. WOLL and A. VIVIAN (*Wisconsin Sta. Bul. 92, pp. 3-12*).—Analyses of 9 samples of fertilizers licensed for sale in Wisconsin in 1902 are reported, with notes on the sources and forms of nitrogen, phosphoric acid, and potash in fertilizers; the purchase and use of fertilizers; the valuation of fertilizers; and the value of inspection.

Fertilizers, T. MACFARLANE (*Lab. Inland Rev. Dept. Ottawa, Canada, 1902, Bul. 81, pp. 41*).—Analyses and valuations of 106 samples of fertilizers furnished by manufacturers and importers, and 85 collected in the open market in Canada, are reported, with notes on the nature and use of natural manures and commercial fertilizers.

Results of fertilizer control, 1900-1901, G. THOMS (*Die Ergebnisse der Düngerkontrolle, 1900-1901. Riga: Jonck & Poliewsky, 1902, pp. 55*).—This is the usual annual summary of the results of the fertilizer control of the experiment station at Riga, Russia, with a discussion of various phases of the fertilizer question which have been the subjects of studies by different investigators during the period referred to, including denitrification, soil inoculation, Alinit, etc.; conservation and care of manure; phosphatic, nitrogenous, and potassic fertilizers; the occurrence of pure Peruvian guano; poudrette and similar manures; liming and manuring; change in weight of certain fertilizers on exposure to the air; the influence of water and fertilizing on the composition and ash of potatoes; determination of the fertilizing requirements of typical soils; the surface treatment of upland moor soils; the importance and possibility of partially replacing barnyard manure with commercial fertilizers in grape culture; fertilizers for field culture of cucumbers; commercial fertilizers for potatoes; fertilizing meadows with kainit, superphosphate, and Thomas slag; fertilizing potatoes with poudrette. All of the more important articles referred to have been noted in the Record.

FIELD CROPS.

The [California Culture] substations, C. H. SHINN (*California Sta. Rpt. 1899-1901, pt. 1, pp. 124-142, figs. 4*).—Notes are given on the results obtained with different crops at the Foothill, Southern Coast Range, San Joaquin Valley, and Southern California Culture substations during a series of years. Macaroni wheats grown in the different localities varied considerably in quality, the greatest change and increase in starch being observed at Amador. The hardy Algerian wheats under test deteriorated less at some stations than at others. At Tulare the hardy wheats on trial tillered more and yielded better from year to year. Vetches have been tested from 3 to 10 seasons. The following are recommended: *Vicia villosa*, *V. sativa cordata*, *V. sativa*, *V. narbonensis*, *V. bythinica*, and *V. fulgens*. A yield of over 17 tons of green forage per acre was obtained from one cutting of *Atriplex nummularia*, the plants being 2 years old. *A. pamparum* has also given promising results. *Rhagodia spinescens inermis* and *R. limifolia* have shown great forage value and great endurance of drought and frost. Their leaves contain less salt than species of *Atriplex*. *Rhagodia limifolia*

is considered adapted to the foothills of the Coast range. The African stock melon, also called Tsama or Khama melon, yielded over 19 tons per acre as against 10 tons produced by Kansas stock melon. This variety has given a good yield with an annual rainfall of 5.7 in.

Fertilizer experiments, C. H. SMITH (*California Sta. Rpt. 1899-1901*, pt. 1, pp. 89-95, figs. 4).—Tests with fertilizers for wheat, oats, and barley on several different soils were made at the Foothill Substation, and with wheat at the Southern Coast Range Substation. The fertilizers consisted of nitrate of soda, alone or with muriate of potash and Thomas phosphate. There were increased yields with the fertilizers, which were profitable in every case, whether the cereal was grown for grain or hay.

Report on cultural tests in 1900, A. DAMSEAUX (*Bul. Agr. [Brussels]*, 18 (1902), No. 1, pp. 9-22).—The results of variety and cultural tests with wheat, oats, sugar and forage beets, colza, and lupines are briefly considered. The culture of abutilon for fiber is discussed and the results of a culture test briefly given.

Cooperative field trials with cereals, potatoes, and root crops in Norway, 1901, B. LARSEN (*Christiania*, 1901, pp. 34).—The trials were conducted, under the direction of the Agricultural College at Aas, Norway, on 129 plats located on farms in different parts of the country, and on 9 plats on the college grounds. Comparative variety tests were made with oats, barley, potatoes, root, and hay crops. The varieties which produced the best average yields during the years 1889-1900 were as follows: *Oats*—Baseler, Lühneburger Kley, Duppaner, with average yields of about 56 bu. per acre; *barley*—Malum, Björneby, and Finne, six-rowed square varieties, yielding about 40 bu. per acre; *potatoes*—Bodö Original, Juvel Gra. and Lydia Gra. with the highest average yield, of over 400 bu. per acre. The best varieties of the root crops were Dale Hybrid yellow turnip, Greystone white turnip, Bangholm and Lawson ruta-bagas, Hvid Pål and Red Oberndorfer fodder beets; Breustedt Neuere Zucht and Schreiber Specialty sugar beets; and Altringham and Red carrots.—F. W. WOLL.

Analyses of root crops at different times during storage, H. P. LARSEN (*Landthömmen*, 12 (1901), No. 18, pp. 282-284).—Monthly analyses of fodder beets, ruta-bagas, and turnips from the time of harvesting until the end of May showed steadily decreasing contents of dry matter. The average results for fodder beets were as follows: October, 13.64 per cent; November, 13.06 per cent; December, 12.82 per cent; January, 12.52 per cent; February, 11.88 per cent; March, 11.37 per cent; April, 11.07 per cent, and May, 10.64 per cent. This represents a loss of 3 per cent in seven months, or of 22 per cent of the original dry matter in the beets. Ruta-bagas contained 12.47 per cent dry matter in November and 8.58 per cent in May, and turnips 9.53 per cent and 5.84 per cent for the same months, respectively. The larger the roots the lower the percentage of dry matter and the yield of dry matter per acre from the same number of plants. Data obtained with the "brine test" showed that in general a high, specific gravity is found in beets low in dry matter. Lots of 40 beets each having a specific gravity of 0.81, 1.06, 1.12, 1.30, and 1.31 contained 14.12, 13.13, 13.19, 12.41, and 12.82 per cent of dry matter, respectively. Analyses of different parts of beets and of smooth and irregularly shaped beets are also given.—F. W. WOLL.

Chemical composition of some leguminous plants at different stages of development, H. G. SÜDERBAUM (*K. Landt. Akad. Handl. Tidskr.*, 40 (1901), No. 5-6, pp. 354-381).—Analyses of *Astragalus glycyphyllos*, *Lathyrus pratensis*, *Medicago sativa*, *Melilotus alba*, *Orobis niger*, *Trifolium pannonicum*, and *Vicia dumetorum* are reported. The samples for analyses were taken June 7, when the flower buds were forming; June 21, at the beginning of the blossoming period; July 5, when the plants were in full bloom, and August 15, after the blossoming period had ended. Moisture, ash, total nitrogen, ether extract, crude fiber, pentosans, and albuminoids were determined. In all cases but two the percentages of pentosans, like those of

crude fiber, increased regularly with the age of the plants. The content of pentosans in *Astragalus* was 11.05, 14.01, 15.20, and 17.47 per cent in samples taken on the 4 different dates respectively. The pentosan content for the entire period varied from 8.07 to 12.10 per cent in *Lathyrus*, from 13.93 to 16.79 per cent in *Medicago*, from 11.15 to 16.88 per cent in *Melilotus*, from 12.12 to 18.78 per cent in *Orobus*, from 11.80 to 13.86 per cent in *Trifolium*, and from 11.02 to 15.81 per cent in *Vicia*. In the 2 cases where a cutting showed a lower content of these substances than that immediately preceding, the differences amounted to less than 0.1 per cent. The most rapid increase in the content of pentosans was found in case of *Astragalus*, with almost 3 per cent in 14 days, while the greatest increase during the whole period occurred in *Orobus*, with 6.66 per cent, and the smallest in *Astragalus*, with 2.13 per cent.

As a general rule, with the advance of the growing period a decrease was found in ash materials, nitrogenous constituents, amids, albuminoids, and digestible and indigestible albuminoid nitrogen, while an increase occurred in crude fiber and pentosans. In the ether extract and nitrogen-free extract no definite regular changes were observed. As the age of the plants increased the coefficient of digestibility of the protein decreased—in *Astragalus* from 88.9 to 82 per cent, in *Lathyrus* from 72.4 to 57.7 per cent, in *Medicago* from 90.2 to 81 per cent, in *Melilotus* from 90.3 to 84.8 per cent, in *Orobus* from 89.5 to 72.5 per cent, in *Trifolium* from 87.1 to 78.1 per cent, and in *Vicia* from 88.7 to 79.2 per cent. The author calls attention to the fact that in many cases the relative rank of these plants, as determined by their contents of digestible crude protein, digestible albuminoids, or by the digestion coefficients for the nitrogen compounds, changed radically only within 14 days, and further dwells upon the importance of accompanying all analyses of forage plants with exact information as to the time of cutting and the stage of development of the crop at the time of cutting.—F. W. WOLL.

Barley, L. GRANDEAU (*Jour. Agr. Prat.*, n. ser., 3 (1902), No. 7, pp. 213-215).—The conditions required for the successful culture of barley are described. The plant food removed from the soil in crops of 2-rowed and 6-rowed varieties is shown in a table.

Fertilizers for barley, L. GRANDEAU (*Jour. Agr. Prat.*, n. ser., 3 (1902), No. 9, pp. 276-278).—The author reviews the results of fertilizer experiments and variety tests with barley. Chevalier Richardson and Hanna barley yielded 20 per cent more than the Champagne variety.

Observations on the culture of beets, BERTHAULT and BRÉTIGNIÈRE (*Ann. Agron.*, 28 (1902), No. 1, pp. 30-56).—The results of experiments with beets in 1899, 1900, and 1901 are reported. A comparison of 4 varieties in 1899 resulted in the best yields for the varieties ordinarily grown for the manufacture of alcohol, and commonly called distillery beets. In total amount of dry matter produced the fodder-beet variety *Jaune Ovoïde de Barres* stood lowest, with a yield of 4,271 kg. per hectare, and the variety *Brabant à collet vert* stood highest—6,165 kg. Planting in drills 40 cm. apart with 35 cm. between plants in the drill gave best results. It was noticed that close planting had raised the sugar content of the fodder-beet variety, still it contained nearly 5 per cent less sugar than either intermédiaire *Desprez* or *Brabant à collet vert*. The authors conclude that even in a dry season and on an inferior soil the varieties used for distillery purposes are to be preferred to the fodder-beet varieties, and that close planting should be practiced. The different varieties did not give similar results when grown at varying distances. The variety *Jaune Ovoïde de Barres* gave the smallest yield with the closest planting, while *Brabant à collet vert* gave the smallest yield with the widest planting. The question of distance was further investigated in 1900 with the result that 40 cm. between rows, from 35 to 40 cm. between plants in the row, gave the best returns in the largest number of cases. These

distances represent from 6 to 6½ plants per square meter, or 60,000 to 65,000 plants per hectare.

The results of 1901 indicate that the varieties producing a long-shaped beet may be grown in rows 50 cm. apart and the plants narrowed down to 25 cm. in the row, while the ovoid-shaped varieties may be planted in rows at closer intervals, but giving the plants more space in the row. Close planting, owing to the increase in the number of beets, was found to increase the cost of production, but in most cases this was more than compensated for by the increase in yield.

Observations on beet culture, BERTHAULT and BRÉTIGNIÈRE (*Ann. Agron.*, 28 (1902), No. 2, pp. 65-102, figs. 10).—The work here reported consisted of a study of beet-seed production and variety tests of beets grown for the manufacture of sugar and alcohol and for feeding purposes. The tabulated results of the variety tests show the yield of beets and sugar per hectare, together with the financial returns for each variety. In studying the seed production of beets in 1899, 1900, and 1901, the methods of growing the mother beets from seed and from cuttings, grafts, or by division were compared. A beet allowed to seed in the ordinary way in 1899 yielded 93 gm. of seed, while from 30 cuttings and two sections made from another beet 222 gm. of seed were obtained. Although 30 cuttings were made, only 7 grew, and of these 4 produced seed. The 4 seed-producing beets contained an average of 13.73 per cent of sugar and the other 3, which did not throw up seed stalks, contained an average of 15.52 per cent. The original beet from which the cuttings and sections were made had a sugar content of 15.12 per cent. The following year the three remaining beets were permitted to seed, producing 100.4 gm., and the beets obtained from the two sections of the original were each cut into three pieces and planted for seed, yielding for the 6 plants 23 gm. This made a total of 345.4 gm. of seed from one beet in 2 years.

The seed obtained in 1899 was sown in 1900, but the results were quite irregular. This season tests were carried on with three beets, the first being grown for seed in the ordinary way, the second was used to furnish cuttings, grafts, and sections for growing seed beets, and the third was cut into four sections for the same purpose. The beet grown in the ordinary way produced 69.7 gm. of seed. Of 24 cuttings of the second beet, 22 beets were obtained perfectly homogeneous in foliage and form, but only one produced seed, which, however, was of no value. The cutting which produced seed contained the central bud. In grafting, a cylinder 7 mm. in diameter and about 3 cm. long, with a growing bud at the top, was taken from the upper part of the beet and inserted on the upper surface of the beet used as a stock after the crown had been removed. This procedure is described in detail, and the value of top and side insertion of the scion on the stock beet discussed. The grafts grew with varying success, but no seed is reported to have been obtained. After the cuttings and grafts had been secured from the second beet, it was divided into four sections, which were planted, but did not yield seed. The third beet was divided into four sections, which were planted separately. Three plants were obtained, and these yielded 77.5 gm. of seed.

In 1901 the seed obtained by the different methods of propagation was tested and the results obtained are reported. A second seed production by a beet which had furnished cuttings the previous year did not seem profitable. The seed obtained from the main seed stalk was found much superior to seed produced on the branches. Grafting is not considered a satisfactory method of propagation for seed beets. In the case of cuttings it is necessary to determine the conditions which assure their seed production.

The influence of distance between plants in the row on the yield of forage beets (*Deut. Landw. Presse*, 29 (1902), No. 11, p. 33).—Forage beets were grown from 8 to 9 in. apart in 14-in. drills, and from 10 to 12 in. apart in 16-in. drills. The results were in favor of the closer planting.

The influence of distance on the yield and quality of fodder beets, A. VON KÜTTERITZ (*Fühling's Landw. Ztg.*, 51 (1902), No. 4, pp. 155, 156).—A number of varieties of beets were grown in 14 and 16 in. rows with the plants about 8 in. apart in the 14-in. rows and from 10 to 12 in. apart in the 16-in. rows. The yield was slightly and the quality largely in favor of the narrow planting.

Comparative tests of forage beets and varieties of a medium sugar content, DESPREZ (*Semaine Agr.*, 22 (1902), No. 1084, pp. 59, 60).—A summary of results is given which shows that varieties of a medium sugar content are more profitably grown for feeding purposes than the ordinary varieties of forage beets.

Broom corn, W. R. DODSON (*Louisiana Stas. Bul.* 67, 2. ser., pp. 806-816, figs. 4).—This bulletin is a brief popular treatise on the growing and curing of broom corn.

The improvement of the castor plant, W. R. SHAW (*Oklahoma Sta. Bul.* 54, pp. 10).—This bulletin discusses the improvement of the castor plant and suggests methods by which this object may be attained. It is pointed out that the relative value of varieties depends mostly upon the percentage of oil in the seeds, the quantity of seeds produced, the cost of harvesting, and the simultaneous ripening of the pods on a spike and on the different spikes of a plant. Upon the equality of ripening depend the cost of harvesting and the percentage of seed of the total product which may be gathered. In summing up the discussion of seed selection the author recommends to "select the best and earliest seed of a crop for planting, and when practicable select this seed from the best plants of a stand." The method of grading castor seed on the market is described.

The culture of the castor bean in Algeria, C. RIVIÈRE (*Agr. Prat. Pays Chauds*, 1 (1902), No. 6, pp. 747-751).—The culture of the castor bean in Algeria is described and the varieties grown are briefly noted.

Cotton culture, C. FARMER (*La culture du cotonnier*. Paris: J. André, 1901, pp. 375).—A general treatise on cotton culture dealing largely with the industry in America and India. In addition to the culture of cotton, ginning, baling, insect enemies, diseases, and the value of cotton seed for feeding purposes are discussed.

The cowpea (*Southern Pines: North Carolina State Hort. Soc.*, [1902], pp. 63, figs. 12).—A pamphlet treating of the origin, history, culture, and uses of the cowpea. The utilization of cowpeas for grazing, soiling, renovating, and fertilizing soils and for hay and silage is described.

Cowpeas, soy beans, and winter vetch, J. D. TOWAR (*Michigan Sta. Bul.* 199, pp. 165-176).—This bulletin gives a general description of cowpeas, soy beans, and winter vetch, together with directions for their culture and uses. The discussions consist largely of quotations from experiment station bulletins and from articles presenting the experience of practical farmers. The tabulated data given in the bulletin consist of analyses showing the percentage of digestible nutrients and fertilizing elements of feeding materials, including the crops under discussion, analyses of the soy bean made at the station, and the yield and composition of hairy vetch cut on different dates republished from a bulletin of the Alabama Station (E. S. R., 11, p. 921).

Alfalfa, cowpeas, and crimson clover as factors in reducing feed bills, A. T. NEALE (*Delaware Sta. Bul.* 55, pp. 3-8; *Rpt.* 1901, pp. 8-13).—A discussion on the relative quantities of protein produced by alfalfa, cowpeas, and crimson clover based on data obtained in different experiments is summarized as follows: "Maximum crops of alfalfa of average tests yield 1,230 lbs. of protein per acre, equivalent to the amount contained in approximately 1½ tons of cotton-seed meal. Maximum crops of cowpeas and maximum crops of crimson clover of average test contain each not more than 725 lbs. of protein per acre. But a crop of clover and one of peas may be grown and made into hay annually from one and the same acre of land. Hence where alfalfa fails to thrive, peas and clover may be found to be a profitable substitute."

A critical study of Getty's method of raising cowpeas for silage purposes, A. T. NEALE (*Delaware Sta. Bul.* 55, pp. 8-23; *Rpt.* 1901, pp. 13-28).—This method

consists in growing corn and cowpeas together and ensiling the combined crop. The advantages of the method are enumerated and discussed. The results of testing the method are summarized as follows: "The total crop per acre was very slightly influenced by the seeding of peas with corn, but the quality of the crop, from the protein standpoint, was improved thereby to the extent of 25 per cent. With the exception of the cost of the pea seed and the expense of labor in the seeding, the mixed crop of corn and peas can be worked and harvested at the cost entailed by the corn alone. The density of the silage is so modified by the peas that in comparison with corn alone an increase in capacity of from 35 to 40 per cent may be credited to a silo when filled with the mixed crop." The cost per ton of material in the silos amounted to \$1.46. The method was also tested by a number of farmers and desirable results were obtained. No serious difficulties were encountered in harvesting the crops by means of corn harvesters or in the use of silage cutters. The value of peas included in the crop per acre is estimated at \$2.50 based on results obtained in the most favorable case at an outlay of 50 and 20 cts. per acre for seed and labor respectively.

The depth of plowing in flax culture, KÜHNERT (*Mitt. Deut. Landw. Gesell.*, 17 (1902), No. 11, pp. 69-71).—Cooperative tests were made to determine the effect of different depths of plowing on the growth of flax. The land was plowed 12, 16, 20, and 24 cm. deep. The results for this experiment were in favor of plowing 16 and 20 cm. deep, but the author does not draw definite conclusions from this single test.

Hemp from the higher latitudes cultivated in France, E. GAIN (*Ann. Agron.*, 28 (1903), No. 2, pp. 103-110).—Observations are reported on a comparison of Swedish and French hemp at Nancy. The seed of the Swedish hemp had been produced in Sweden at 63° north latitude, while the French hemp was originally from Piedmont, which is at 45° north latitude. The results of experiments carried on for three years show a constant proportion of 65 to 71 female plants to 100 male plants in the French hemp, while in the Swedish hemp the proportion of female to male plants was much larger, but decreased each year. The indications are that this decrease in the number of female plants is due to the change in climate and environment. The seed from the higher latitude produced precocious and rapidly developing plants, but rather light in weight. The author believes that by crossing the French with the Swedish hemp a variety ripening earlier, having a shorter period of growth, and producing a larger proportion of female plants may be obtained, but that by such a process the size of the variety might possibly be reduced.

Grasses and clovers in Idaho, H. T. FRENCH (*Idaho Sta. Bul.* 33, pp. 87-107).—This bulletin describes briefly the value of orchard grass, tall meadow oat grass, English rye grass, Italian rye grass, meadow fescue, Canadian blue grass, redtop, timothy, brome grass, alfalfa, and the most common species of clover, and gives directions for preparing the soil and seeding these different crops.

A number of field and plat experiments are reported. Two fields of about 6 acres each and each seeded down with a mixture of 40 lbs. of common red clover, 6 lbs. of alsike clover, 25 lbs. of orchard grass, 6 lbs. of meadow fescue, 5 lbs. of English rye grass, 10 lbs. of timothy, and 4 lbs. of tall meadow oat grass at the rate of 16 lbs. per acre gave good yields of hay and pasturage. A plat each of orchard grass, tall meadow oat grass, meadow fescue, English rye grass and brome grass sown at the rate of 20 lbs. per acre produced a good stand the first season and withstood the winter perfectly. Sheep were pastured on part of these plats to determine what grasses would be eaten first and how they would recover from close cropping. The grasses were eaten in the following order: Orchard grass, meadow fescue, brome grass, rye grass, tall meadow oat grass. Orchard grass was the first to start a new growth, followed by oat grass, meadow fescue, brome grass, and English rye grass in the order given. The hay harvested on the remainder of these plats showed that orchard grass and meadow fescue yielded 5,280 lbs.

per acre, tall meadow oat grass, 5,760 lbs., brome grass, 5,600 lbs., and English rye grass, 4,000 lbs.

Vermont grasses and clovers, L. R. JONES (*Vermont Sta. Bul.* 93, pp. 139-184, figs. 32).—A general description is given of grasses and grass-like plants, together with economic notes on a number of species occurring in Vermont. The relative value of hay, pasture, and lawn grasses of the different species is discussed, and the clovers and their allied plants are treated in a similar manner. Directions are given for the cultivation of the grasses and clovers, and a chapter is devoted to the impurities which are found in grass and clover seeds.

Economic notes on some of the grasses of southwest Missouri, S. A. HOOVER (*Missouri State Bul. Agr. Rpt.* 1902, pp. 449-456).—The results of a study of grasses and forage plants in four counties in the southwest part of the State are given. A number of cultivated and wild grasses are described and their relative value for hay and pasture indicated.

Kentucky forage plants, H. GARMAN and A. M. PETER (*Kentucky Sta. Bul.* 98, pp. 61, pls. 16).—In addition to other matter this bulletin discusses the appropriation of free nitrogen by leguminous plants, together with methods of soil inoculation. A list of Kentucky Leguminosae is given with brief descriptive notes, but the most important ones, including the soy bean, alfalfa, sainfoin, velvet bean, serradella, cowpea, and the principal species of clover are considered more in detail. Notes on 11 varieties of cowpeas grown on plats at the station in 1901 are presented. In addition the results of plat experiments with 22 species of grasses in 1900-1901 are briefly given. The results of an experiment with blue grass seed gathered on different dates indicated that this seed should be harvested from about June 12 to June 20. One hundred and eight analyses of forage plants from the plat experiments are reported in a table.

Kentucky blue grass seed, A. J. PIETERS and E. BROWN (*U. S. Dept. Agr., Bureau of Plant Industry Bul.* 19, pp. 19, pls. 6, figs. 3).—This bulletin describes the production of Kentucky blue-grass seed and gives an account of methods of harvesting, curing, and cleaning the same. The industry is confined to areas in Kentucky where much the greater portion is produced and to localities in southern Iowa and northern Missouri.

A study of the effect of curing on the vitality of the seed was made and the results of germination tests of samples of seed taken at different stages of the curing process are reported. The following conclusions are drawn from the results: "Green seed of Kentucky blue grass when put in ricks will ferment and reach a temperature of 130 to 140° F. in less than 16 hours. A temperature of 130 to 140° F. for 16 hours or less will greatly damage if not entirely destroy the vitality of the seed. Under the present methods of handling green seed it must be stirred at short intervals. The seed must not be stripped until mature, as it is much harder to prevent fermentation in the immature seed. Seed should always be put in small ricks, not over 18 in. high. Seed can be cured to better advantage under cover in bad weather and outdoors in clear weather." The authors believe artificial curing feasible and recommend that tests be made to demonstrate the practicability of this method.

The use of corn fertilizers on meadows, E. ZACHAREWICZ (*Prog. Agr. et Vit. (Éd. L'Est)*, 23 (1902), Nos. 2, pp. 40-46; 3, pp. 83-88).—The subject of fertilizing meadows is considered at some length and the results of cooperative experiments in this connection are reported. It was found that commercial fertilizers were more profitably used on meadows than barnyard manure. Fertilizer formulas for different kinds of meadows are given.

The time of applying potash salts on moorland meadows, B. TACKE (*Landw. Wehnbl. Schleswig-Holstein*, 52 (1902), No. 5, pp. 69-71).—The experiments here described led to the conclusion that when there is danger of flooding, potash salts

should be applied when vegetation is dormant and not too short a time before it begins to grow. This practice has not affected the stand of grasses unfavorably.

Experiments with oats, J. N. HARPER and A. M. PETER (*Kentucky Sta. Bul.* 99, pp. 65-78).—The results of a test with 27 varieties of oats in 1901 are given in a table. The yields of grain and straw are reported and the color of the grain, character of the straw, and date of ripening are given. The yields of grain and straw for 4 successive years and the weight per measured bushel for 3 successive years are also shown for the different varieties. In 1901 the yields of the varieties ranged from 29.4 to 49 bu. of grain per acre, the leading varieties being White Russian, Improved Welcome, Negro Wonder, White Belgian, and New American, in the order given. The average weight per measured bushel for 3 years was 32.5, 31.1, 30.8, and 30.3 lbs. for Pringle Progress, Probsteir, Hopetown, and Imported Welcome, respectively. All other varieties gave an average weight of less than 30 lbs. per bushel.

The results of a fertilizer test with 160 lbs. per acre of nitrate of soda and muriate of potash applied separately showed a material increase in yield.

Analyses of the different varieties made to determine their relative value for feeding are tabulated. The average yield of protein was 293 lbs. per acre and the average percentage 6.77. Basing the selection on the production, varieties yielding 300 lbs. or more of protein per acre and having a protein content of over 7 per cent in the dry matter are the best for feeding purposes. Analyses of samples of all the varieties cut on July 5, 6, 7, and 8 indicate that the crops harvested on July 5 would have been slightly richer in protein, but would have given a smaller total yield. In general, the percentage of protein in the dry matter decreased and the quantity of dry matter increased as the plants reached maturity. The difference in composition of young and ripe oat plants is shown by analyses of samples taken June 16 and July 19.

Directions for the treatment of seed oats against smut are given and the meteorological conditions for 1898-1901, inclusive, are summarized in tables.

Fertilizers for oats, L. GRANDEAU (*Jour. Agr. Prat., n. ser., 3 (1902), No. 6, pp. 177, 178*).—This article discusses the use of fertilizers for oats on poor soils. Several fertilizer applications to suit various conditions are recommended.

Plant breeding, M. FISHER (*Fühling's Landw. Zig., 51 (1902), No. 2, pp. 411-415*).—The results of experiments in breeding winter oats are reviewed.

Variety and fertilizer tests with potatoes, W. J. GREEN and C. W. WAID (*Ohio Sta. Bul.* 133, pp. 71-87).—Similar work has been previously reported (E. S. R., 11, p. 42). The yields of 55 varieties tested in 1901, together with the average yields of varieties grown for 3 and 5 years, are tabulated. Each variety tested in 1901 is described. The following varieties, in the order named, were most productive in 1901: Northern Beauty, Quick Crop, Maule Early Thoroughbred, Early Norwood, Early Fortune, Pingree, Roberts, Early Rose, and Pat Choice. Among the varieties tested for 3 years, Vigorosa, Maule Early Thoroughbred, Early Rose, Whiton White Mammoth, Livingston, Sir Walter Raleigh, Sir William, Uncle Sam, Pat Choice, and Pingree produced the best yields, while of those grown for 5 years, Enormous, Livingston, Early Trumbull, Uncle Sam, Sir William, Sir Walter Raleigh, Bovee, Maule Early Thoroughbred, Suffolk Beauty, and Carman No. 3 were the leading ones in point of production. Early Trumbull, Early Thoroughbred, Bovee, Early Harvest, and Early Ohio are recommended as early market varieties, and Livingston, Whiton White Mammoth, Enormous, Sir Walter Raleigh, and Carman No. 3 as late market varieties. Early Trumbull, Early Harvest, Livingston, Pat Choice, and Uncle Sam are considered especially adapted for home use.

The results of the fertilizer test show that superphosphate alone was much more profitable than either nitrate of soda or muriate of potash used singly. The most profitable application in this test consisted of 160 lbs. superphosphate and 80 lbs. nitrate of soda. All the applications tested proved profitable, with the exception of

480 lbs. superphosphate, 300 lbs. muriate of potash, and 320 lbs. of nitrate of soda per acre.

Variety tests of potatoes, E. GROSS (*Fühling's Landw. Ztg.*, 51 (1902), No. 4, pp. 121-123).—This article summarizes the results of variety tests with potatoes, which were carried on for 3 years. The varieties under test were originated by a seed firm in Galicia. A number of these varieties gave good results under rather unfavorable climate and soil conditions. For moist soils the varieties Skarbek, Dolega, Perkun, and Kmit are recommended.

Potato experiments at Garforth, R. S. SETON (*Yorkshire Col., Leeds, and East and West Ridings Joint Agr. Council, Pamphlet 21, 1902, pp. 7*).—In a test of 9 varieties of potatoes, British Queen gave the best yields in 1900 and 1901, and produced tubers of better quality than any other variety. Cut sets for seed gave better yields than whole tubers. Tubers greened in the fall by exposing them to sunlight produced a larger yield than ungreened seed. Planting in rows 28 in. apart and placing the sets about 15 in. apart in the row is recommended.

Sand lucern, J. D. TOWAR (*Michigan Sta. Bul. 198, pp. 147-160*).—This bulletin gives a description and the botanical history of sand lucern (*Medicago media*), with directions for its culture and uses. The results of a number of experiments conducted at other stations and showing the value of alfalfa for feeding and soil renovation are reviewed, and the experiences of Michigan farmers with sand lucern are reported.

Culture experiments with this plant have been in progress at the station since 1897. A sixth-acre plat yielded at the rate of 6,800 lbs. of cured hay per acre in 1898, 10,580 lbs. in 1899, 12,310 lbs. in 1900, and 13,839 lbs. in 1901. In 1898 three cuttings were made, while in the succeeding years four crops were obtained each season. The dates of cutting averaged about June 10, July 12, August 15, and October 1.

An analysis of the hay made in 1901 is reported in a table. The crop produced per acre 1,529 lbs. of digestible protein, 4,307 lbs. of digestible carbohydrates, and 140 lbs. of digestible fat, as calculated with the coefficients of digestibility for alfalfa. As to the fertilizing value of the hay, the crop contained 330 lbs. of nitrogen, 62 lbs. of phosphoric acid, and 426 lbs. of potash per acre. For green forage, hay, and pasture sand lucern is considered equal to common alfalfa. As a cover crop in orchards it is said to rob the trees of plant food and moisture.

Sorghum in 1901, C. L. PENNY (*Delaware Sta. Rpt. 1901, pp. 74-76*).—Analyses of the sorghum crop for 1901 made on different dates from October 8 to November 20 are given in a table, together with analyses of the crops grown during the last four seasons. The crop of 1901 showed the highest percentage of sugar in the juice except that of 1898, and gave a larger yield of cane, of total sugar per acre, and of available sugar per acre than any other crop except that of 1900. The purity of this season's crop was the lowest of all.

Beets and sorghum compared on the basis of sugar production, A. T. NEALE (*Delaware Sta. Rpt. 1901, pp. 32-35*).—The comparison of sugar beets and sorghum was made on 2 plats, one-half of each being devoted to sugar beets and the other half to sorghum. The season was favorable to sorghum but unfavorable to beets. The average yield of total sugar in the sorghum was 5,653 lbs. per acre, and in the sugar beets, 1,045 lbs. It was observed that cane still standing November 20 had deteriorated by apparently 1,000 lbs. of sugar per acre, and since the specific gravity of the juice was practically as high as it was on October 8, it is concluded that the test was lowered by the presence of inverted sugar in canes which had been mutilated by windstorms. Sugar beets dug on December 2 were still in good condition, indicating that the working season for sugar beets is longer than the season for sorghum. Owing to the use of modern machinery, sorghum culture is considered as being placed upon a practical basis.

The sugar beet in Delaware, A. T. NEALE (*Delaware Sta. Rpt. 1901, pp. 30-32*).—

An account is given of experiments in sugar-beet culture undertaken by the station. The results were not quite satisfactory and no conclusions are drawn.

Sugar-beet experiments, C. L. PENNY (*Delaware Sta. Rpt. 1901, pp. 76, 77*).—This year experiments in growing sugar beets were undertaken by the station for the first time. Sample beets to the number of 393 were produced by 29 growers. The results with reference to the weight of the sample beets, their sugar content and purity are tabulated and briefly discussed. Owing to inadequate attention given to the crop the results are not considered decisive.

Sugar-beet experiments in 1901, J. D. TOWAR (*Michigan Sta. Bul. 197, pp. 117-144, figs. 6*).—In a test of 8 varieties, Austrian B. A. produced the highest value of crop per acre, amounting to \$59.69. This same variety showed a sugar content of 13.51 per cent in the beet, being the highest in the test. The average sugar content of all varieties was 11.91 per cent and the purity 79.8 per cent. A seed test to determine the number of sprouts from 100 seed balls was made in connection with this experiment, and the results are reported.

A report is given on an experiment carried on for three successive years with beets planted on different dates. Planting on May 8 gave the highest yield of sugar, and the yields decreased as the planting departed from this date, although there was but little difference in the results from planting on May 8 and May 1. The author believes that the time of profitable planting is not very limited, and that planting may be done as early as the middle of April if the ground can be properly prepared. Planting after May 20 gave decided decreases in the results. In some cases early planted beets were attacked by leaf blight which lowered the sugar content, while varieties planted later thus escaping the disease and growing continuously throughout the season gave better returns. Early planting gave no indication of early maturity.

A distance of 18 in. between rows gave better results than 21 or 24 in. The value of crop per acre from the 21-in. rows was only \$2.21 less, and owing to the greater facility in cultivating wide rows, the author considers 21 in. a favorable distance.

The results for three seasons, and their averages, obtained in experiments with maximum, minimum, and normal amounts of several fertilizing elements are reported in a table and briefly discussed. The normal application consisting of 200 lbs. each of nitrate of soda and muriate of potash and 400 lbs. of dissolved phosphate rock per acre, gave nearly as good average results as an application containing 800 lbs. of dissolved phosphate rock. As a rule, double applications of the different elements gave no appreciable gains over the normal application, and omitting an element entirely resulted either in a small crop of beets or a low sugar content. The results of another test with excessive amounts of fertilizing elements in addition to the normal fertilizers were in favor of increasing the nitrogen, the yield being greater and the percentage of sugar higher. The general results favored nitrate nitrogen as compared with ammonia nitrogen. In a soil test the average increase in yield from nitrate nitrogen over organic nitrogen was 18 per cent, and the average quantity of sugar produced for three years in a special comparative test was 2,394 lbs. per acre for nitrate nitrogen and 2,154 lbs. for ammoniacal nitrogen. "The general conclusion [from soil test experiments with fertilizers] is that for the best results no single element or 2-element fertilizer will do as well as our complete fertilizers, and that stable manure increases the tonnage but does not increase the total number of pounds of sugar in a similar proportion." In another comparison of barnyard manure with other fertilizers the manure produced the lowest average percentage of sugar, although the tonnage was nearly the highest.

The exhaustive effects of the sugar-beet crop were observed by comparing results obtained on fertilized and unfertilized plats. The decrease in yield on the unfertilized plats as compared with plats receiving annually a normal application of fertilizers was 1.25 per cent the first year, 11.25 per cent the second year, and 13.85 per cent the third.

Results of analyses of sugar beets from plantings made weekly from April 13 to June 5, inclusive, and sampled on alternate days from September 11 to November 16, together with weekly averages of the same, are shown in a table. In these tests it was observed that heavy rains and cloudy weather from October 14 to 25, lowered the sugar content. Beets sampled the first week in November showed the highest percentage of sugar.

Beets stored in piles in the field with sufficient protection to prevent freezing weighed 5,345 lbs. October 26, 4,655 lbs. November 27, and 4,478 lbs. December 31, the total loss in weight amounting to 16.22 per cent. All varieties stored in this way September 1 showed a gain in the percentage of sugar, the average increase for the different varieties being 6 per cent. The loss in weight was not commensurate with the gain in the percentage of sugar, for during the first month of storing there was an actual increase of 82½ lbs. of sugar or practically 14 per cent, while during the second month the decrease in the sugar content was so great that the beets at the end of the period showed a loss of 9.37 per cent. The average coefficient of purity for the different varieties was 78 October 26, 80 November 27, and 72 at the close of the experiment.

Sugar-beet seed 1, 2, 3, and 4 years old showed practically no difference in vitality, indicating that the seed is not injured when kept under favorable conditions. Soaking the seed was of no advantage and proved an inconvenience in sowing with the drill. A test of home-grown seed demonstrated the possibility of growing sugar-beet seed in that locality. Beets from seed accidentally sown in the fall gave promising results and led to further experiments along that line. Imported seed gave better results both as to sugar content and purity than commercial seed obtained from a seedsman.

The leaf curl of beets is discussed and several tests of diseased beets reported. The sugar content in the beets affected with leaf curl ranged from 5 to 7½ per cent. In studying the influence of the size of beets on the sugar content, it was found that in every case except one the percentage of sugar in each variety increased as the size decreased. The average difference between 32 oz. and 8 oz. beets was 2 per cent and the 16 oz. beets were nearly ¾ per cent richer than the 32 oz. beets.

The influence of lack of plant food on the sugar beet (*Dent. Landw. Presse*, 29 (1902), No. 11, p. 84).—A summary of results is given. It is shown that an insufficient potash supply decreases the sugar content and when a large quantity of nitrogen is present the percentage of sugar in the beet sometimes drops to below 1 per cent and the beet itself has a tendency to become diseased. A small nitrogen supply under these same conditions produces a much richer and healthier beet. In connection with a lack of phosphoric acid the effect of nitrogen is not so marked. Lack of potash increases leaf growth. A subnormal quantity of phosphoric acid produces a perfectly healthy beet with a fair sugar content and a subnormal nitrogen supply produces a healthy beet with a very high percentage of sugar.

Green manuring for sugar beets, H. BRIEM (*Bll. Zuckerrübenbau*, 8 (1901), Nos. 9, pp. 133-139; 10, pp. 155-159; 11, pp. 165-168).—A general discussion of the subject in which the results of experiments in this connection are reviewed.

The history of sugar-beet culture and beet-sugar manufacture with legislation affecting the industry in France during the nineteenth century, J. HELOR (*La sucre de betterave en France de 1800 à 1900; culture de la betterave, législation, technologie*. Cambrai: Fernand and Paul Deligne, 1900, pp. 220, pls. 15).

Experiments in cultivating sugar cane, W. C. STUBBS (*Louisiana Stas. Bul.* 66, 2. ser., pp. 780-802).—This bulletin presents a short treatise upon the principles involved in the preparation and cultivation of the soil, and reports the results of experiments in cultivating sugar cane carried on during the past few years. Previous work in this line has been reported in a former bulletin (*E. S. R.*, 12, p. 438).

In these experiments cultivation was performed with the plow alone, the plow supplemented by the disk and middle cultivator, and the cultivator without the use of the plow. The aggregate yields of sugar cane for four years in five different systems of cultivation are reported, and it is shown that the use of the plow alone gave the smallest tonnage of cane. The best yield was obtained from the use of the disk and middle cultivators alone. These implements can be adjusted to make small or large ridges and the depth can be regulated so that only a minimum amount of roots are cut in cultivating. This method was found to conserve moisture and to increase microbic action, greater numbers of microbes being found in a soil finely pulverized by the cultivators than in a cloddy soil worked with the plow.

Fertilizing experiments with sugar cane, J. D. KOBUS (*Meded. Proefstat. Oost-Java, 3. ser., 1901, No. 31, pp. 25*).—The purpose of this series of tests was to determine whether three successive crops of sugar cane can be economically taken from the same soil and in what fertilizing elements the soil was deficient. The cane was grown in 60 large boxes containing soil which had already produced two crops. These boxes were divided into 5 series of 12 each. The first was a check series and received no fertilizers; the second received sulphate of ammonia, and the third, phosphatic slag; the next, sulphate of potash; and the last, sulphate of potash and phosphatic slag. In addition to these fertilizers, the last three series received sulphate of ammonia. As compared with the check test, sulphate of ammonia increased the yield by 53 per cent, showing that the soil was deficient in nitrogen. The lack of phosphoric acid was even more apparent, since the plants receiving both these fertilizers yielded 20 per cent more than the plants receiving only the sulphate of ammonia. The addition of lime proved injurious, especially when applied in connection with phosphoric acid, in which case it reduced the yield and the sugar content.

Chemical analyses of the cane revealed no material difference in the composition due to the fertilizers applied. The plants which received sulphate of ammonia contained more potash and sulphur and less phosphoric acid than the check plants. Lime, although it affected the yield, did not change the composition.

The following season showed that the application of nitrates generally increased the yield, while the use of lime was injurious to the yield and the quality of the juice. The unfertilized plants produced a juice of superior quality. The chemical analyses of the plants grown the second year indicated that the fertilizers had no effect on composition. However, the plants which did not receive sulphate of ammonia were poorer in nitrogen, potash, sulphur, and lime, and richer in phosphoric acid than those receiving different treatment.—H. M. PIETERS.

New method of preserving sweet potatoes, J. S. NEWMAN and J. S. PICKETT (*South Carolina Sta. Bul. 71, pp. 6*).—This method consists essentially in boiling the sweet potatoes before evaporating them. Tests were made with a number of varieties, and the results are shown in the following table:

Yield of sweet potatoes and evaporated product.

Varieties.	Yield per acre.		Evaporated product.	Yield per acre of the evaporated product.
	<i>Bushels.</i>	<i>Pounds.</i>	<i>Per cent.</i>	<i>Pounds.</i>
Pumpkin Yam.....	222	13,920	24	3,840
Hanover Yam.....	329	19,740	26	5,132
Extra Early Caroline.....	146	8,760	25	2,190
Red Nose.....	228	14,280	24	3,427
Nansensmond.....	222	13,320	22	2,930
Bunch Yam.....	165	9,900	18	1,782
Georgia Sugar Yam.....	211	12,660	23	2,911
Vineland Bunch Yam.....	136	8,160	22	1,795
Jersey Big Stem.....	357	21,420	29.5	6,318
Pierson Yam.....	328	19,680	22	4,329
Jersey Red.....	261	15,660	29	4,542

The evaporated product "will keep for an indefinite time and bear transportation to any part of the world at any season." An analysis of air-dry evaporated sweet potato gave the following results: Moisture 3.42 per cent, crude ash 2.48 per cent, crude protein 5.06 per cent, crude fat 0.80 per cent, crude fiber 2.08 per cent, nitrogen-free extract 86.16 per cent. It was observed that all varieties showed losses from rotting when stored from November until March.

Tobacco culture on the east coast of Sumatra, W. WESTERMAN (*De tabaks-cultuur op Sumatra's oostkust*. Amsterdam: J. H. de Busey, 1901, pp. 300, pls. 30, figs. 10, map 1, dgms. 14).—An extensive treatise on the culture of tobacco on the east coast of Sumatra, including a description of its preparation for market, and a consideration of labor, commerce, and other economic phases of the industry.

Sumatra tobacco, H. DENTZ (*Sumatra Tabak*. Amsterdam [1901], vol. 7, pp. 70+XV).—Notes on the commerce of Sumatra tobacco, with ratings of different companies trading in the product.

Fertilizers for tobacco, P. WAGNER (*Mitt. Deut. Landw. Gesell.*, 17 (1902), No. 14, pp. 81-84).—The subject of fertilizing soil in tobacco culture is considered and a number of different methods to suit certain conditions are suggested. According to the author tobacco should be grown on soil rich in potash, and fertilizing substances containing chlorin should not be used. The dry substance of the leaves should not contain more than 0.6 per cent of chlorin and not less than 6 per cent of potash.

The sovereign herbe; a history of tobacco, W. A. PENN (*London: Grant Richards; New York: E. P. Dutton & Co.*, 1901, pp. 326, pls. 5).—A history of tobacco, including its cultivation and manufacture, the making of pipes, the use of cigars and cigarettes, and statistics on the consumption of tobacco since its use has become common.

HORTICULTURE.

Field experiments with nitrate of soda on market garden crops, E. B. VOORHEES (*New Jersey Stas. Bul.* 157, pp. 20, pls. 2).—The author made a study of the effect of different quantities of nitrate of soda for carrots, cabbage, celery, tomatoes, peppers, turnips, and sweet corn, and of the relative advantages of two and three applications. In all cases the plats were first liberally fertilized with acid phosphate and muriate of potash. The data as to the yields obtained with the different crops are tabulated and the proportion of primes and culls shown in each instance.

Carrots.—Applications of 300 and 400 lbs. per acre, respectively, of nitrate of soda were applied to carrots cultivated in different plats. With this crop the increased yield obtained was only just about sufficient to pay for the increased cost of the fertilizers used. This result was thought to be due to some untoward condition of the season.

Cabbage.—When 400 lbs. of nitrate of soda per acre, applied in three different applications, was used the gain in the total yield was 13,810 lbs. or 156 per cent. On the other plats where only 300 lbs. of nitrate of soda was used, or only two applications made, the increase while very large was in no case in excess of 100 per cent. The average gain for all the plats by the use of nitrate of soda was 1,287 heads. When 400 lbs. of nitrate of soda per acre was used there was a gain of 1,450 heads, and when 300 lbs. was used there was a gain of 1,125 heads. The larger application resulted in the more satisfactory yield, though the plants did not economically use the larger amounts applied. When two applications were made there was a gain of 945 heads per acre; when three were made there was a gain of 1,630 heads, thus making the increase 685 heads per acre due to the third application. The three applications were more effective than the addition of 100 lbs. of nitrate of soda. The most profitable crop

was obtained by the use of 400 lbs. of nitrate of soda applied in three equal dressings, since the heads in this crop were much firmer and sold for 50 per cent more than the heads grown on the other plats.

Celery.—The total additional yield of celery due to the use of nitrate of soda was 17,810 lbs., or 132 per cent. The value of the crop when the nitrate of soda was used averaged \$378.10 per acre, at a cost of but \$7 for fertilizers. This was \$54.01 gain for each dollar invested in nitrate of soda. The amount of nitrate of soda used was 300 and 400 lbs. per acre, respectively. When these amounts were given in two equal applications the average yield obtained was 14,500 roots, and from three applications 14,995 roots, or a gain of 495 roots, worth \$31.19, for the third application. The gain from the third application was considerably larger when the 400 lbs. was used per acre than when the 300 lbs. was used.

Tomatoes.—Owing to an unfavorable season there was an imperfect setting of this fruit. The amount of nitrate of soda applied varied from 200 to 300 lbs. The increase in yield obtained from the different plats varied from 3,220 lbs., when the nitrate of soda was applied in two equal applications at the rate of 200 lbs. per acre, to 5,880 lbs., when the same amount of fertilizer was applied in three equal distributions. The average gain for all plats where the nitrate of soda was used was 4,564 lbs., or 62 per cent. There was a gain on the average of 475 lbs. of fruit when 200 lbs. of nitrate of soda was used over the yield obtained when 300 lbs. was used. The third application tended to produce a larger growth of vine and later maturing fruit, and this materially reduced the yield.

Turnips.—The use of nitrate of soda with turnips increased the yield, on the average, 5,230 lbs., or 63.3 per cent. There was an increase of 2,960 lbs., or about 20 bbls. per acre, when nitrate of soda was used at the rate of 300 lbs. per acre, over the yield obtained when only 200 lbs. per acre was used. With this crop two dressings, whether of the larger or smaller amount, were much more effective than three dressings. The third dressing seemed to increase growth of top rather than root, and thus decreased the yields. The increased value of the crop, due to the use of nitrate of soda when 300 lbs. was used in two equal applications, was \$38.85 per acre.

Peppers.—The use of nitrate of soda considerably increased the yields in every instance with this crop. When 200 lbs. was applied per acre in two equal dressings the increased cash value of the crop due to the use of the nitrate was \$16.70. When this same amount was applied in three equal dressings the increased value of the crop was \$25.90. When 300 lbs. of nitrate of soda was used in two applications the increased value of the crop was \$30.20, and in three applications \$29.50.

Sweet corn.—Earlier experiments at the station have shown that this crop responds better to applications of nitrogen in ammonia or some organic form than in nitrate of soda. There was a considerable gain, however, in the yield and value of the crop from all the different plats where nitrate of soda was used. The most profitable gains were made when 300 lbs. of nitrate of soda was used in three different applications. The gain in the value of the crop in this instance over the plat where no fertilizer was used was \$18.10.

Conclusions.—The results of the season's work with nitrate of soda, in the author's opinion, justify the following conclusions:

"That both the yield and quality of vegetable crops are improved by a liberal supply of available nitrogen. That large quantities of nitrogen (300 to 400 lbs. of nitrate of soda per acre) are, on the whole, preferable to smaller quantities. That where large quantities of nitrate of soda are used fractional dressings are likely to result in a greater proportionate use of the nitrogen. Three dressings proved, on the whole, more profitable than two. When the growth is satisfactory the third dressing may be withheld."

Home-grown v. purchased seed, W. C. STUBBS, F. H. BURNETTE, and E. WATSON (*Louisiana Stas. Bul.* 68, 2. ser., pp. 820-846).—The author states that there is a general belief that southern-grown seed is inferior to more northern seed. Experiments have therefore been undertaken at the station and substations to determine the truth of the matter. Tests have been conducted now for four years with a large number of vegetables, which show that, in the main, nearly all varieties of home-grown vegetable seed are equal, and in some instances superior, to northern-grown seed. Difficulties were sometimes encountered in properly curing the home-grown seed, owing to the dampness of the climate, inexperience, weevils, etc. The following crops gave as good results with home-grown seed as with northern-grown, and in some instances better: Bush beans, Lima beans, pole beans, garden beets, cauliflowers, carrots, cucumbers, eggplants, sweet corn, endive, lettuce, muskmelons, watermelons, mustard, okra, onions, peppers, potatoes, sweet potatoes, tomatoes, radishes, spinach, squashes, pumpkins, and turnips. No success has been attained in raising home-grown cabbage seed.

Tests of varieties of vegetables were made at the same time. In addition to tests of the vegetables mentioned above, the following were grown: Artichokes, asparagus, Brussels sprouts, broccoli, kale, kohlrabi, leeks, shallots, parsley, Chinese cabbage, and a large number of Japanese vegetables, obtained from the U. S. Department of Agriculture.

Tests were also made of the following varieties of fruits: Apples, pears, peaches, plums, figs, oranges, mulberries, raspberries, blackberries, dewberries, strawberries, gouni, and jujube. Of the 45 varieties of apples grown, Rhodes Orange Moultrie, Killagiskie, Yates, Shockley, and Pear or Palmer bore large crops that kept well. At Audubon Park sand pears were the only ones that succeeded. At Baton Rouge 46 varieties were grown, of which the Le Conte bore a large crop. From present experience it is not possible to recommend the most suitable varieties of pears for Louisiana. Peaches were not a success at Audubon Park. The Peento type have been destroyed by frost each year at Baton Rouge, and have therefore been discarded. Of the other varieties grown, Elberta has proven the most productive. Some of the varieties recommended for culture at Calhoun are Triumph, Champion, Smock, Crosby, Troth Early, Austen Late, etc. Plum growing has not been a success at any of the stations. The gouni bushes planted at the stations bear enormous crops of fruit each year. They also rank high as an ornamental shrub. The jujube produced its first crop of fruit in 1899 and is still growing well.

Preliminary account of variation in bean hybrids, R. A. EMERSON (*Nebraska Sta. Rpt.* 1901, pp. 30-49, pls. 3).—An account is given of the variation occurring in hybrids and their progeny of a number of races of kidney beans (*Phaseolus vulgaris*). The work was begun in 1898, and in some cases has been carried through five generations. Combinations have been made between varieties with yellow, green, and blue-green pods; stringy and stringless pods; long and short pods; round and flat pods; white, red, brown, black, and variously mottled seeds; oblong and nearly round seeds, etc. The method of work observed is given in detail. The hybrid seed used for planting in the field was grown in a greenhouse, since the climate of the station does not permit a successful outdoor hybridization of this crop. Kidney beans are perfectly self-fertile, and in the author's observations only 4 per cent of hybrid forms were found in lots of bean plants the preceding generation of which was grown in a field with over 100 races, the most of which were in blossom at the same time.

In the author's experience all the racial hybrids of beans produced showed little variation in the first generation, but pronounced variation in the second and third generations. They appeared fairly well fixed in the fourth and fifth generations.

The characters of the two parents were usually reproduced in the hybrids, though occasionally new or atavistic tendencies were notable. Characters differentiating the parent forms were usually blended together in the hybrids, or united unchanged in mosaics of small or large pattern. Of the blends, Blue Pod X Davis is cited. The brown color of the seeds of Blue Pod united with the white color of the Davis seed, to form light brown seeds. Golden Wax, a nearly stringless podded sort, united with the Mohawk, a stringy podded variety, to produce a hybrid with pods less stringy than Mohawk and more stringy than Golden Wax. The ratio of the length to the thickness of seed of Stringless Green was found to be about 2.21, and of Warwick, 1.92. In the hybrid Stringless Green X Warwick, the ratio was 2.11. A number of other examples of blends are cited.

Mosaics were obtained when the white-seeded Davis was crossed with the red-seeded Scarlet Flageolet, the hybrid seed being spotted red and white. A like mixture of colors occurred in hybrids of Currie X Golden Wax and Wardwell X Challenge Black, etc. Cases are also cited in which hybrid seeds took all their characters, such as color, shape, size, etc., from one parent, while the characteristics of the pods, such as color, shape, stringiness, etc., were taken from the other. Keeney X Davis is cited as an example of this kind. This hybrid had white seeds like the Davis and pods like the Keeney. Sometimes the characters of one parent were found mixed with the blended characters of the two parents. Thus some individuals of the third generation hybrid Blue Pod X Davis had leaves and stems like the Davis, brown seeds like Blue Pod, and flowers in which the dark bluish purple of the Blue Pod was plainly diluted by the white color of the Davis. Instances are cited in which hybrids could not be differentiated from one of the parents. Thus, "In second and third generation hybrids of Blue Pod X Davis numerous individuals were so nearly like Blue Pod that they could scarcely be distinguished from those races by any characters of plant, pod, flower, or seed. The considerable number of reversions in this case is specially noteworthy because of the fact that the two parent races differ in nearly all their characters."

Those characters which were transmitted entire or almost unchanged in first generation forms, and termed "dominant" by Mendel (E. S. R., 13, p. 744), were found, as in Mendel's experiments with beans, to be green-colored pods and a long plant axis. Other characters which tended to impress themselves strongly in the first generation hybrids were dark seed colors and stringless pods. When green and yellow podded races were crossed, the first generation hybrids had green pods, yellow and intermediate colors not appearing until later generations. When semidwarfs and dwarfs were crossed, the first generation hybrids were all semidwarfs, strictly dwarfs not appearing until the second generation. Atavistic tendencies were found especially prominent in the pod colors whenever Davis or Mohawk was used as one of the parents. This fact suggests that these races probably came originally either directly or indirectly from such varieties as Horticultural, Goddard, etc.

Investigation as to the cause of pithiness in celery. E. P. SANDSTEN and T. H. WHITE (*Maryland Sta. Bul.* 83, pp. 110-119, figs. 5).—In 1900 two samples of American and one of French celery seed were sown in similar seed beds and 200 plants from each seed bed selected for planting in an open field June 14. The plants in every case were given the same kind of cultivation and attention. When the celery was dug in December it was found that 40 per cent of the plants grown from American seed were pithy, while not a single stalk of the plants from the French seed was pithy. These results were so striking that the experiment was continued in 1901, seed being obtained from five different seed firms. The experiment that year divided itself into two phases, early transplanted and late transplanted. One hundred plants were used in each instance. The results obtained during the season are shown in the following table:

Pithy celery stalks from seed of different origin.

Kind of seed.	Pithy stalks.	
	Early trans-planted.	Late trans-planted.
	<i>Per cent.</i>	<i>Per cent.</i>
A's French-grown seed	1	00
A's American-grown seed	43	46
B's French-grown seed	38	26
B's American-grown seed	40	43
C's French-grown seed	00	00
C's American-grown seed		38
D's American-grown seed	31	
D's Select American-grown seed		10
E's Selected XX	20	

The author makes the following comments on these results: "The stalks from A's and C's French-grown seed were very uniform and alike in all particulars, and were evidently procured from the same source in France. B's French grown was in no way different from B's American grown. The stalks were not of uniform color or size. It was evidently a mixed lot, or else the seed plants had not been carefully selected and 'rogued.' The stalks from A's American grown, from B's American, from D's American grown, from E's Selected XX were of the same general character, both as to habit of growth and mixture of colors. The plants from the American-grown seeds were not uniform in their growth or in their color."

These experiments, taken as a whole, it is believed show the superiority of French-grown celery seed over American-grown seed. This superiority, however, is thought to be due more to the careful selection of seed by the French than by American seedsmen. With the same care in selection, American seed would probably be as good as foreign seed.

Detailed directions are included in the bulletin on celery culture in Maryland from the planting of the seed to the storing and marketing of the crop.

Experiments in hybridizing (*Indian Gard. and Plant.*, 10 (1902), No. 13, p. 218; *abs. from Standard*).—It is stated that on Sutton's trial-seed grounds one plant each of Dwarf Green Curled kale, Brussels sprouts, broccoli, Red Variegated kale, Purple-colored kale, Thousand-colored kale, Portugal cabbage, Sutton Favorite cabbage, Dwarf Blood Red cabbage, and Drumhead Savoy were all planted in one bed together to see if they would cross. Plants grown from the resulting seeds showed remarkable variation, thus proving the necessity of keeping these plants separated in the seed grounds.

The book of vegetables, G. WYTHES (*London and New York: John Lane, 1902, pp. 106, figs. 17*).—This is the seventh of the series of handbooks of practical gardening edited by H. Roberts, and deals with the culture and varieties of vegetables grown in England, such as cabbage, broccoli, Brussels sprouts, spinach, various roots and tubers, onions, beans, etc. Chapters are also given on the history and cookery of vegetables, by the editor. Like many of the other books in the series, the directions regarding methods of culture, varieties, etc., are particularly adapted to English conditions, and hence will be found of but minor value to American gardeners.

The agave; memoir on its culture and the value of its products, J. C. SEGURA (*El maguey; memoria sobre el cultivo y beneficio de sus productos. Mexico: Mexican Agr. Soc., 1901, 4. ed., pp. 411, pls. 22*).—This is a manual of the agave and its various productions. It includes the history of the plant, botanical classification and descriptions of varieties, methods of nursery and field culture, insect enemies, methods of securing the juice, and the manufacture of pulque and mescal, with an

account of the uses of those products as beverages and medicines. A bibliography of about 200 references is included in the work.

Report of the horticulturist, C. H. POWELL (*Delaware Sta. Rpt. 1901, pp. 83-126, figs. 12*).—This report presents the results of the season's investigations with the Chinese Cling group of peaches (published as a bulletin, E. S. R., 13, p. 1049) and with the pollination of apples and pears. The studies with the latter fruits are in continuation of those reported last year (E. S. R., 13, p. 245). The work with apples during the season indicates that practically all the more important varieties grown on the Chesapeake Peninsula are probably self-sterile. July and Bough, both of little commercial importance, were the only varieties that set any considerable amount of fruit when self-pollinated. Astrachan, Early Harvest, and Yellow Transparent were more or less self-fertile and under favorable conditions might produce crops. The varieties that were found self-sterile, or nearly so, were Early Ripe, English Russett, Fanny, Gilpin, Gravenstein, Grimes, Lilly of Kent, Missouri Pippin, Nero, Paragon, Red Streak, Stark, Stayman, Strawberry, William Favorite, and Winesap. The self-fertile kinds were confined almost exclusively to summer sorts. Gilpin, a winter sort, set a few fruits, but they dropped as the season advanced. The season's work with apples strongly indicates the advisability of mixing varieties in commercial orchards.

Experiments in intercrossing varieties of apples indicate that Paragon, Stayman, Winesap, and Lilly of Kent, all weak pollen bearers except the latter, are intersterile and should not be planted together in commercial orchards for the purpose of cross-pollination.

In a study of the blooming period of varieties of apples it was found that good tillage, spraying, fertilizing, etc., extended the period of flower-bud formation in the fall and seemed to prolong the blossoming period in spring, while on poor, uncultivated soils the blooming period was shortened. Diagrams are given showing the blossoming period in 1901 of 9 varieties of apples grown at Denton, Md., 16 varieties at the station, and 32 varieties in Kent County, Del. Lists are also given of the varieties of apples introduced into Delaware by the station since 1897.

Further experiments with the Keiffer pear indicate that it is practically self-sterile in Delaware and that varieties used for pollination exert little if any influence on the size or appearance of the fruit.

The experiments of two years have shown "that the Keiffer is not more fertile with pollen from a distant orchard than with pollen from the tree on which the crosses were made; that the Keiffer may be somewhat more self-fertile in one orchard than in another; that a cross-fertilized pear starts into growth with more vigor and develops more rapidly than a self-fertilized one; that the crosses with different varieties do not show differences that can be attributed to the pollinizer. . . . Garber and Le Conte are the most satisfactory pollinizers [for Keiffer], though the characteristics of either one leave much to be desired. A pollinizer is needed with the quality of the Seckel and the vigor and prolificacy of the Keiffer."

The record of 1901 showed that if 2 blossoms of Keiffer out of 100 set fruit the resulting crop was a heavy one.

Experiments with deciduous fruits at and near the Southern Coast Range Substation, C. H. SHINN (*California Sta. Bul. 141, pp. 48, figs. 18*).—An account is given of the results secured in 13 years' experimental work with deciduous fruits at the Southern Coast Range Substation. The results secured are supplemented by concise accounts of the results secured by a large number of the most successful deciduous fruit growers in the vicinity of the station. The data obtained cover a territory of about 40 miles long by 20 wide. The substation work shows that in that climate successful culture of most deciduous fruits is impossible. It is practically useless to plant almonds, cherries, prunes, and apricots, except in a few sheltered spots on good, well-watered soil. The most successful fruits throughout the district

have been pears and hardy American plums. On the better soils, free from hardpan, pears are likely to bear well 4 years out of 5, apples 3 years out of 5, and peaches and nectarines 2 years out of 5. Persian mulberries will bear nearly every year, and grapes yield fairly well 4 years out of 5. These figures are based on orchards given every attention as regards spraying, pruning, cultivation, etc. Pears are likely to come nearest to being profitable and are considered the safest fruit for the entire district. The general conclusion is reached that the growing of fruit, except in especially favored localities should be only a secondary resource in the region east of the Salinas. Large plantings and costly experiments should be avoided. Grapes may be grown with a little expense over a large area for the home table and wine use, but not for high-class raisins.

Thinning fruits, E. P. SANDSTEN (*Maryland Sta. Bul. 82, pp. 97-99*).—The purpose of this bulletin is to call the attention of the fruit growers of Maryland to the value of thinning orchard fruits. According to the author peaches and plums should be thinned after the "June drop," peaches to not less than 5 in. apart, and plums to from 2 to 3 in. apart. Apples and pears should be thinned when they have attained the size of small crab apples. Pears should be thinned to about 4 or 5 in. apart, and apples to the same distance as peaches. The advantages of thinning are more regular crops, stronger and more shapely trees, less disease, and larger, better colored, more uniformly ripened, and more salable fruit. Thinning, however, will not pay unless pruning, spraying, fertilizing, and cultivation have been properly attended to.

Improving an orchard, F. W. CARD (*Rhode Island Sta. Bul. 83, pp. 143-152, figs. 8*).—This is a popular account of an attempt made by the station to bring up one of the worthless orchards in the vicinity of the station into a profitable bearing condition, by means of proper cultivation, spraying, pruning, fertilizing, etc. As a result of 3 years' work it has been quite definitely proven that neglected orchards can be easily brought into good bearing conditions by the methods above mentioned. The orchard under consideration contains only 0.86 of an acre. In 1901 only part of the trees were in bearing, yet about \$80 worth of fruit was harvested. It is believed that few parts of the farm offer better chances for profitable returns than the orchard, when well managed.

The value of improved methods in the propagation of fruit trees, G. T. POWELL (*Proc. New Jersey State Hort. Soc., 27 (1902), pp. 135-135, figs. 2*).—The author reports that he has successfully grown the King apple in New York by using the Northern Spy as a foundation stock. In this work choice buds, taken from trees that regularly produced an excellent quality of fruit, were used. No canker has appeared on these trees during the past 10 years, the trees have shown unusual thrift and vigor, and the fruit has been uniformly fine. In propagating peach trees selected buds have been taken from mature trees. Buds thus set in stock not over 20 in. in height and scarce half an inch in diameter have produced fruit within 13 months from the time the trees were set, 50 to 139 peaches being obtained from each tree. The Giant prune, one of the finest varieties grown in California, is being successfully grown on Lombard stock in New York, where the thermometer sometimes goes down to 25° below zero.

Relative to the use of cover crops in orchards, the author states that there is a limit beyond which it may not be safe to use clover. He believes that after 3 years of crimson clover in an orchard, a crop of rye or some other nonleguminous plant should be sown. Too much nitrogen in the soil appears to make lighter colored fruit and lessens the keeping qualities of the fruit.

Renewal pruning, E. S. GOFF (*Amer. Gard., 23 (1902), No. 335, pp. 302, 303*).—The author points out that as apple trees increase in age the size of the fruit tends to become smaller. This he believes is due to the increased difficulty of sap circulation in the fruit-bearing twigs. An instance is pointed out in which water sprouts on part of an apple tree were allowed to develop in place of a large limb that had been

broken off. The fruit on this portion of the tree was much larger than on the remaining older portions of the tree. The question is therefore raised whether the size of fruit on old apple and pear trees cannot be maintained by a careful system of renewal pruning.

Two new apricots, P. MOUILLEFERT (*Jardin*, 16 (1902), No. 360, pp. 56, 57, col. pl. 1).—Two seedling apricots, which are considered of considerable merit, are described and the fruit and leaves illustrated with a colored plate.

Stringfellow method of planting peach trees, H. M. COLLINGWOOD (*Proc. New Jersey State Hort. Soc.*, 27 (1902), pp. 52-60).—An account is given of the successful growth of peach trees when planted on steep rocky hillsides in New York, which were capable of producing fair crops of rye, potatoes, and grass. The trees were pruned to straight stubs and the holes made for setting them were dug with a crowbar. A cup of water was poured in each hill, the stub put in place, loose sand poured in, and the soil firmly packed about the trees. Out of 100 trees thus set, 96 made a favorable growth the first season, the roots making a strong downward growth.

Moderate v. severe thinning of peaches, A. T. JORDAN (*Amer. Agr. (ind. ed.)*, 69 (1902), No. 21, p. 700).—The effect of thinning peaches was observed in 1901 on two trees that were set out in 1897. The set of fruit on one tree was 862 peaches and on the other 852 peaches. From the first tree 69.5 per cent of the total set of fruit was removed, leaving to mature 263 peaches. From the second tree 31.9 per cent of the fruit was taken, leaving to mature 580 peaches. From the tree which had been most heavily thinned 2.83 baskets of fruit were obtained. The average weight of the peaches from this tree was 4.48 oz., the price offered per basket by leading grocers \$1, and the total value of the peaches from the tree \$2.83. From the tree less severely thinned 3.92 baskets of fruit were obtained. The fruits from this tree averaged 2.81 oz. each, for which leading grocers offered but 45 cts. per basket, making the total value of the fruit from this tree but \$1.76. The immediate financial result of thinning in this case was \$1.07. Further observation of the two trees showed that 46.6 per cent more fruit buds matured on the tree severely thinned during the season than on the other tree. Figured out on the basis of an acre and allowing 160 trees to the acre, there was an advantage in thinning of \$171.20.

Fertilizer experiments with sour cherries and plums (*Deut. Landw. Presse*, 29 (1902), No. 29, p. 25, figs. 2).—The greater growth of the trees, heavier fruit production, and greater profits obtained by adding potash to the fertilizers used in growing cherries and plums, are brought out in tables and illustrations.

Notes on strawberries, H. C. PRICE and E. E. LITTLE (*Inna Sta. Bul.* 64, pp. 186-208, figs. 5).—Results are reported of a test of 75 varieties of strawberries for 1899, and of 92 varieties for 1901. Each of these varieties is briefly described and in addition directions are given for the culture of strawberries, including location of the bed, cultivation, winter protection, protection from spring frosts, and from insect and fungus enemies. The opinions of 22 prominent strawberry growers in the State as to the best varieties for market and home use, the distance apart plants should be set, winter protection of plants, and the number of years a plantation should be fruited, have also been brought together in tabular form. In the station experiment the 5 heaviest yielding varieties were Lovett, Kansas, Bederwood, Afton, and Warfield. The varieties oftenest recommended by growers throughout the State were Warfield, Bederwood, Crescent, Clyde, and Lovett, mentioned in the decreasing order of their importance. In the station tests the average yield of 60 staminate varieties fruited in 1901 was 2,059 qts. per acre and the average yield of 29 pistillate varieties 2,351 qts. When, however, the 10 heaviest yielding staminate varieties were compared with the 10 heaviest yielding pistillate varieties the average yield was slightly in favor of the perfect or staminate varieties.

Some strawberry books, C. H. PAYNE (*Gard. Chron.*, 3. ser., 32 (1902), No. 816,

pp. 109, 110).—A list is given of a number of books on strawberries published in England, France, Germany, and America.

The cranberry industry (*Sci. Amer.*, 86 (1902), No. 12, pp. 206, 207, figs. 6).—A general article discussing methods of growing, with illustrations of modern ways and an account of the cranberry districts, yields, etc.

Field grafting and bench grafting (*Pacific Rural Press*, 63 (1902), No. 20, p. 228).—The advantages of bench grafting grapes over field grafting are discussed.

Stocks for calcareous soils, L. RAVAZ (*Prog. Agr. et Vit. (Éd. 1^{re} Est)*, 23 (1902), Nos. 3, pp. 73-75, pl. 1; 4, pp. 100-102, pl. 1; 5, pp. 134-136, pl. 1; 8, pp. 230-233, pl. 1; 13, pp. 369-371, pl. 1; 17, pp. 482-484, pl. 1).—A short descriptive review is given of the stocks that may be profitably employed on calcareous soils.

Electricity for cultivation of plants (*Tradesman*, 47 (1902), No. 12, p. 65).—A brief note on experiments by J. Fuchs in the use of atmospheric electricity in grape culture.

Instantaneous bleaching liquid for nuts, G. E. COLBY (*California Sta. Rpt. 1899-1901*, pt. 1, pp. 57-61).—The recent enormous crops of walnuts in California have made it necessary to provide rapid-acting bleaching solutions in order that great numbers of carloads of nuts may be simultaneously brought into marketable condition. Tests have therefore been made at the station of different bleaching solutions to determine their relative values. In the experiments walnut culls two years old were used. The stains on these were dried, hard, and more fixed in character than those ordinarily found on fresh nuts.

The first formula used consisted of 6 lbs. of chlorid of lime, 12 lbs. of sal soda, and 50 gal. of water. Walnut culls treated with this solution for 5 minutes were made acceptable in appearance and salable. When to this same formula dilute sulphuric acid (0.15 per cent of acid in 50 gal. of water) was added, the nuts were bleached in from 5 to 10 seconds, and after washing presented a clean appearance and were acceptable to the trade. The nuts were not injured in the least by this method of treatment. When dilute acetic acid (0.22 per cent in 50 gal. of water) was substituted for the sulphuric acid, the results were equally good and there was no development of rancidity in the nuts with perfect shells after they had stood a month. These same percentages of sulphuric acid and acetic acid were also used with another formula made up of 25 lbs. of bleaching powder, 18 lbs. of sal soda, and 50 gal. of water. This formula without the acids cleaned the nuts in 5 minutes, and with the acids in from 5 to 10 seconds. Treatment for 5 minutes with a 1 per cent solution of bisulphite of calcium failed to remove the stains, even when a little dilute sulphuric acid was added. Laboratory experiments with both bleaching powder formulas showed that they could be used successively as many as four times, and it is recommended to use them until exhausted, which is shown by failure to evolve chlorine gas when fresh sulphuric acid is added.

The results of the station's work with the instantaneous bleaching formulas suggest the following formula as being most satisfactory for commercial use: Sal soda, 12 lbs.; chlorid of lime, 12 lbs.; water, 45 gal. dilute sulphuric acid as noted above. The method of preparing and using it on a large scale is described. By having proper drain boards to save the bleaching solution, 4 to 5 tons of walnuts can be bleached with 50 gal. The cost of the material for bleaching nuts by this method is about 40 cts. per ton. It is stated that certain persons in the State have claimed to hold patents for instantaneous methods of bleaching nuts, but the above processes are not patentable, since they were given to the public by the station in 1896. Their use is believed to be perfectly harmless and to have no other effect than that desired.

Distribution of seeds, plants, cuttings, etc., E. J. WICKSON (*California Sta. Rpt. 1899-1901*, pt. 1, pp. 96-123).—An account is given of the seed distributed during the year, with short reports by farmers from different sections of the State as to the

manner in which they have succeeded. These reports are similar in character to those of previous years (E. S. R., 12, p. 936).

The paper mulberry (*Broussonetia papyrifera*) has been found to be about as hardy as the orange. The Asia Minor willow (*Salix salmomi*) planted from cuttings in 1895 was 32 ft. high in October, 1897, with trunks 22 in. in circumference. *S. alba* under like conditions was but 12 ft. high with a trunk 8 in. in circumference. A number of species of Eucalyptus are promising in certain sections of the State. Acacias have succeeded well in the university plantations and are strongly recommended. Sallywood of Lord Howe Island (*Lagunaria patersonii*) appears to be a desirable ornamental for the shrubbery or home gardens. The English oak (*Quercus robur*) seems to be one of the most rapidly growing hard wood trees thus far grown in California. The tree tomato (*Solanum betaceum*) seems to be about as tender as the lime. The edible pod pea has given quite general satisfaction. The asparagus pea (*Tetragonolobus purpureus*) has not proved satisfactory as a green manuring plant but is gaining favor as an edible pea. The Kansas Standard tomato has given good satisfaction and was the first variety to ripen seed at the station for a number of years. Turkestan winter muskmelons have proved four times as prolific as common garden varieties of muskmelons planted under similar conditions. The Khama melon, a stock melon, yielded at the rate of 22 tons per acre at the Pomona Substation. Cows and horses ate them readily. Hairy vetch not only made a fine winter growth but proved exceptionally resistant to drought and in many places grew during the dry season without irrigation. *Modiola* (*Modiola decumbens*), a forage plant, grew especially well on alkali lands in Kern County, and was eaten by sheep and cows in preference to alfalfa.

Other plants mentioned are the New Zealand oil tree, strawberries, vegetable marrow, various beans, kale, Jerusalem artichokes, pumpkins, watermelons, cereals, field peas from Russia, bitter vetch, various lupines, fenugreek, Australian saltbushes, and a number of pasture grasses.

FORESTRY.

Handbook of the trees of New England, L. L. DAME and H. BROOKS (Boston: Ginn & Co., 1902, pp. XV + 196, pls. 87).—This volume gives descriptions and full plate illustrations of the trees of New England, and while primarily prepared for that region it is applicable to a much wider range, most of the species being quite widely distributed over the eastern United States. In order that the descriptions may be readily compared, the text is arranged under conspicuous paragraph headings, and in addition to the botanical description and illustration of all the important features, every species is discussed in its horticultural aspect, its value for park and other planting being shown. As far as could be done with conciseness and clearness popular terms have been adopted, and the book will be found of value to all who are in any way interested in trees.

The [California] forestry substations, C. H. SHINN (*California Sta. Rpt. 1899-1901*, pt. 1, pp. 142-144).—A brief report is given of the progress made at the forestry substations in California during the 3 years covered by the report. The principal improvements have been made at the Santa Monica and San Joaquin Valley stations. New tree plantations have been made and a number of species of forest trees have been tested under the conditions existing at these stations. The present condition of a large number of species of trees planted in the San Joaquin Valley is briefly indicated.

Forestry in Iowa, W. GREENE (*Proc. Iowa Park and Forestry Assoc.*, 1 (1901), pp. 46-51).—The author believes that forestry plantings are not to be recommended as individual efforts but should be carried on by corporations or the State, the investment and time being too great for the individual. While it is not expected that

large areas of Iowa land will be used for timber culture, yet the steep slopes along streams should be replanted with the most valuable forest trees suitable to the location. Most of the forest trees when planted on exposed places in the western part of the State need protection from the strong westerly winds by wind-breaks, for which purposes cottonwood, maple, willow, red cedar, Austrian pine, and white spruce are recommended. Of the forest trees most desirable for planting, the author enumerates the black walnut, butternut, white and green ash, black cherry, hackberry, catalpa, honey locust, sugar maple, hickories, oaks, cedars, spruce, and pine. In addition to the aesthetic consideration and as a permanent investment, a number of the species will produce rapid growth, and willow and catalpa will make posts in 10 years, cottonwood will produce logs in 25, and larch and cedar will be fit for telephone poles in from 25 to 50 years, while oaks will make fence posts and railway ties in about the same length of time.

Trees of the Big Horn forest reserve, A. ESTELLA PADDOCK (*Proc. Iowa Park and Forestry Assoc.*, 1 (1901), pp. 75-77, pl. 1).—The deciduous trees of the Big Horn forest reserve are said to be *Populus angustifolia*, *P. tremuloides*, green ash, box elder, and various species of willow. Of the coniferous species represented, the yellow pine is most abundant, and associated with it are *Pinus flexilis*, Douglas spruce, lodge pole pine, and Engelmann spruce, balsam fir, and mountain cedar.

Trees of the Priest River forest reserve, J. C. BLUMER (*Proc. Iowa Park and Forestry Assoc.*, 1 (1901), pp. 77-80).—The principal species of trees occurring in this forest reserve are said to be the western white pine, yellow cedar, tamarack or western larch, Douglas spruce, yellow pine, Engelmann spruce, western hemlock, white fir, lodge-pole pine, white pine, yew, red cedar, together with a few deciduous trees such as cottonwoods, maples, and birch.

Special report of the forestry bureau, Philippine Islands, G. P. AHERN (*Spec. Rpt. War Dept.*, 1901, pp. 60, pls. 33).—A report is given of the activity of the forestry bureau of the Philippine Islands from April, 1900, to July, 1901. The personnel of the bureau is described and the system of regulations and licenses is reported upon at considerable length. The methods of procedure and forms prescribed by the regulations are shown. The number of licenses granted for timber, firewood, dyewood, rubber, etc., during the time covered by the report amount to 580. The different kinds of timber have been classified and arranged into groups, the popular and scientific names of which are given. A brief description is given of the forests of the Philippines, and the amount of different kinds of timber taken during the time covered by the report is indicated. The author believes that if the proper safeguards be adopted the Philippine forests will not only be a source of great revenue, but may be maintained without serious depreciation.

Forestry in Saxony, E. L. HARRIS (*U. S. Consular Rpts.*, 69 (1902), No. 261, pp. 244, 245).—The forests of Saxony are divided into 12 principal districts, which are again subdivided into 100 minor districts. The author gives a report on the value and income derived from these forests, arranged according to the different districts. The total value of the forests is about \$80,000,000, and the income for the year reported was \$3,246,976.42, with expenses amounting to \$1,005,364.85, making a net average income of 2.71 per cent.

Report on forest administration in Burma for 1900-1901 (*Rpt. Forest Admin. Burma, 1900-1901*, pp. 173).—The forest reserve area of Burma was increased during the period covered by this report by 684 square miles, the total being now 17,836 square miles. The reserve forests of Burma are divided into four circles, each of which is reported upon in detail. Preliminary surveys have been made of a considerable portion of the reserves, but as yet working plans for extensive areas have not been begun. The principal forest product exploited is teak timber, but a number of secondary timber products are mentioned and during the year sanction was given for the planting of 10,000 acres in para rubber (*Hevea brasiliensis*), work

on which has been begun. A number of other experimental plantations are reported upon and tables given showing the financial returns from the different regions. During the year covered by this report the total income from the forests amounted to 7,706,324 rupees, equivalent to more than \$2,500,000, a decrease of about \$100,000 from the revenue of the previous year. This decrease is said to be attributed to a prolonged dry season, which prevented the marketing of a large amount of timber.

Report on forest administration in the Punjab for 1900-1901, C. F. ELLIOTT (*Rpt. Forest Admin. Punjab, 1900-1901, pp. 80*).—The forest area of the Punjab, under the administration of the authorities, amounts to 6,408,272 acres, which is classified as reserve, protected, and unclassified. The increase during the year covered by the report amounted to 353,320 acres. During the year covered by the report the cultural operations and exploitation were seriously hindered by the prevailing drought. The number of forest fires decreased from 227 to 140, and the area burned over diminished in nearly equal proportion. The net income received from the various forest products was 36 per cent of the gross receipts. Detailed reports are given of the natural results and operations in the different districts.

Report of forest administration in the Hyderabad assigned districts, 1900-1901, C. BAGSHAWE (*Rpt. Forest Admin. Hyderabad, 1900-1901, pp. 41*).—During the year covered by this report 223 square miles were removed from the forest area of the Hyderabad district, which at present consists of 3,953 square miles. Owing to the drought the income from grazing was greatly reduced and the net receipts of the commissioner of forests were about 50 per cent less than the previous year. The working plants of the different divisions are described and discussed in detail. The area of state forests in different districts is shown in tabular form, as well as the production of timber, fuel, and other forest products.

City forestry, L. A. GOODMAN (*Missouri State Bd. Agr. Rpt. 1902, pp. 439-448*).—The desirability of tree planting in cities is pointed out and suggestions given for the growing, planting, and handling of trees, as well as for their protection.

Winter aspect of the woods, CHARLOTTE M. KING (*Proc. Iowa Park and Forestry Assoc., 1 (1901), pp. 71-74, fig. 1*).—Brief notes are given on the winter condition of a number of the more common forest trees.

The cork oak, J. H. MAIDEN (*Agr. Gaz. New South Wales, 13 (1902), No. 2, pp. 187-190, pls. 2*).—A description is given of the growth of the cork oak (*Quercus suber*) in New South Wales. Several specimens are described, which are said to have made a satisfactory growth, and the tree is believed to be adapted to a number of localities throughout the country. Young trees are offered for planting in different regions to test the suitability of different regions for the growing of this important tree. Notes are given relative to the growing of the cork oak in Queensland, California, and elsewhere.

The comparative temperature of birch, fir, and pine, V. T. LUGUININE (*Izv. Moscow Selsk. Khoz. Inst. [Ann. Inst. Agron. Moscow], 7 (1901), No. 2, pp. 71-84*).—Two series of experiments were carried on by the author between April, 1889, and December, 1892, in which the internal temperature of birch, fir, and pine was investigated. The first series of experiments was conducted on birch and fir which grew on clay soil, the trees having attained a diameter of 30 cm. The birch and pine in the second experiment grew on sandy soil and were all about the same average size. The thermometers used were bent at right angles, the shorter limb carrying the mercury bulb inserted into the interior of the trunk on the north side, the longer limb remaining parallel to the trunk. Readings were taken in the first series three times a day during the vegetative period of the trees and once a day during the remainder of the year. In the second series the readings were made daily at 1 p. m. The results of investigations are shown in curves which indicate the differences in temperature between the birch and fir on the one hand and the birch and pine on the other. The curves show that during the summer months the temperature fluctuated with

the temperature of the surrounding atmosphere. The differences between the fir and birch were greater than between the pine and birch, the maximum variation being 6.9° C. when the temperature of the air was 25° C., the difference between the pine and birch being 3.3°.—P. FIREMAN.

SEEDS—WEEDS.

Annual report of the seed-control station at Vienna, T. VON WEINZIERL (*Ztschr. Landw. Versuchsw. Oesterr.*, 5 (1902), No. 3, pp. 515-548).—A report is given of the investigations conducted at the seed-control station in Vienna for the year ended July 1, 1901. During this period 27,238 samples of seed were examined, and 11,356 packages of seed were attested and sealed, the most of which were red clover and alfalfa seed. A detailed report is given, showing the maximum, minimum, and average purity and germination of all of the principal seeds tested. The investigations of forage plant seeds for the presence of dodder is reported upon, in which a slight increase in the percentage of samples containing this parasite is reported. Separate reports are given of the investigation of beet seed, flaxseed, forest tree seed, and cereals. Notes are also given on a number of plant diseases which were identified at the station during the year. The laboratory and field experiments with various culture crops are briefly described.

A study on the germination and growth of Leguminosæ, especially with reference to small and large seed, F. G. MILLER and L. H. PAMMEL (*Iowa Sta. Bul.* 62, pp. 155-177, pls. 5).—This is a reprint from an article in the proceedings of the twenty-second annual meeting of the Society for Promotion of Agricultural Science, 1901 (E. S. R., 14, p. 52).

Plants injurious in agriculture and horticulture, E. MENAULT and H. ROUSSEAU (*Les plantes nuisibles en agriculture et en horticulture. Paris: Octave Doin, 1902, pp. XVII+314, pls. 80*).—Illustrations and descriptions are given of a number of the more troublesome weeds occurring in France, together with parasitic phanerogams, and a number of plant diseases. Among the plant parasites those described are the principal fungi which attack cereals, the grape; the mildews of potato, lettuce, beets; and several species of *Cuscuta* and *Orobanche* occurring on various leguminous plants. The third part of the work is taken up with methods for the destruction of these various pests, in which cultivation, treatment with chemicals, the growing of heavy crops which smother out the weeds, and the use of fungicides for the prevention of plant diseases are described.

The broom rapes, R. ROGER (*Jour. Agr. Prat.*, n. ser., 4 (1902), No. 32, pp. 186, 187, fig. 1).—Brief descriptions are given of *Orobanche epithymum*, *O. rapum*, and *O. minor*, and suggestions given for the eradication of these pests.

Broom rape, G. MARTINET and A. ESTOPPEY (*Chron. Agr. Canton Vaud*, 15 (1902), No. 14, pp. 402-404, fig. 1).—A description is given of the common broom rape (*Orobanche minor*). This is parasitic on alfalfa and also other species of clover. For its destruction the authors suggest the pulling up of the plants before the maturity of the seed, but where that is impracticable the covering and burning of the affected plants, both host and parasite.

Dodder—its life history and remedies, D. MCALPINE (*Jour. Dept. Agr. Victoria*, 1 (1902), No. 3, pp. 325-329).—A description is given of *Cuscuta epithymum*, a species of dodder which affects alfalfa, clover, and other plants. The life history, local characteristics, and distribution of this parasite are given and various suggestions offered for its control. Among the remedies offered are cutting the crop before the dodder matures its seed, burning over affected areas, spraying with a 5 per cent solution of iron sulphate, or watering the area affected by the parasite with sulphuric acid at the rate of 1 part to 200 parts of water.

Concerning the destruction of mustard by spraying, F. SMYERS and J. VANDERVAEREN (*Rec. Gén. Agron. [Louvain]*, 11 (1902), No. 6, pp. 309-312).—A brief account is given of experiments in which solutions of sulphate of copper, sulphate of iron, and nitrate of copper were sprayed over oat fields for the destruction of mustard. The relative efficiency and cost of application of these different herbicides are shown, and comparing the cost the nitrate of copper is in some respects to be preferred. It is less expensive than the sulphate of copper, and when sprayed at the rate of 900 to 1,000 liters per hectare the amount of nitrogen present has a fertilizing value equal to an application of 8.5 kg. of nitrate of soda upon the same area.

Experiments on the destruction of charlock by spraying (*Dept. Agr. Cambridge Univ. Rpt. 1902*, pp. 15, 16).—Experiments were carried on in barley and oat fields sown with clover and grasses to test the efficiency of solutions of nitrate of soda for the destruction of charlock. This chemical has been recommended as a valuable herbicide as well as having recognized value as a fertilizer. In May plats of an acre each were sprayed with different amounts of 10 and 20 per cent solutions of nitrate of soda, and comparisons are made with the results obtained from a plat of 7 acres sprayed with copper sulphate. In no case did the nitrate of soda show any appreciable effect upon the charlock. The area sprayed with a 4 per cent solution of copper sulphate at the rate of 40 gal. an acre was almost completely cleared of charlock without any injury to the barley, oats, or clover plants. The areas treated with the nitrate of soda were so infested with weeds that it was resolved to spray them when the charlock had come into flower with a 4 per cent solution of copper sulphate. Even at this advanced stage of growth the effect was quite marked and but few charlock plants survived the treatment.

A brier and blackberry bush eradicator, H. W. PORTS (*Jour. Dept. Agr. Victoria*, 1 (1902), No. 1, p. 27).—It is said that the sulphuric acid left in the flasks used in testing milk samples is of practical value for destroying briars, blackberry bushes, wild roses, etc. Half a pint of this waste acid poured about the stem of a plant and the main roots will destroy the bushes within a few days.

DISEASES OF PLANTS.

Report of the mycologist, F. D. CHESTER (*Delaware Sta. Rpt. 1901*, pp. 36-50, figs. 9).—A report is given of some diseases of cantaloupes, treatment for pear canker, experiment in bagging plums for the prevention of plum rot, and spraying for the treatment of plum rot. Among the diseases of cantaloupes 2 leaf blights, one due to *Macrosporium cucumerinum*, and a second due to an undetermined species of *Cercospora*, are described. These leaf blights are reported as being associated with each other and have caused considerable losses by checking the growth and preventing the ripening of fruit. In one locality it is estimated that half the crop was lost, due to these diseases. The technical characters of the fungi are described at considerable length. In the case of the leaf blight due to the *Cercospora*, efforts to obtain cultures from which inoculation experiments could be conducted have failed, but further investigations will be made in this direction.

A third disease of the cantaloupe, called stigmonose, is characterized by a bleaching of the chlorophyll along the veins of the leaf. It is believed that this is caused by aphid punctures and recourse should be had to insecticides to keep the melon vines free from plant lice.

The experiments for the treatment of pear canker are in continuation of the description of the disease previously given (*E. S. R.*, 13, p. 254). The canker was generally prevalent during the year covered by the report, being especially troublesome among Keiffer trees. The disease apparently became chronic and a number of trees were

entirely destroyed. Prior to the death of the trees the foliage assumes a yellowish appearance and the diseased bark becomes cracked and loosened from the trunk. Experiments were conducted for the prevention of the disease, in which the loose bark was removed from the affected portions of the trees, after which the scraped areas were covered with a copper-whale-oil soap mixture, a mixture of formaldehyde and glycerin, and a Bordeaux-resin soap mixture. The directions for the preparation of the different fungicides are given, and as a result of the treatment the formaldehyde-glycerin mixture is recommended as promising and worthy a more extended trial.

An experiment is reported in which the protection of pear trees against blight by spraying with a lime-sulphid solution was investigated. As there was only a slight amount of blight observed during the season, the results obtained are of a negative nature. The same experiment is to be repeated during the coming season.

On account of the frequent rotting of plums, even when thickly coated with Bordeaux mixture, an experiment was conducted in which the fruit was incased in paper bags some time before ripening, the object being to ascertain the time of infection of the fruit and the efficiency of this method of protection. Covering the plums with bags slightly diminished the amount of rot, but not to any material degree. Plums covered by bags and protected against insect punctures during the susceptible period of infection showed from 36 to 91 per cent rotten fruit. In a number of experiments the fruit was thickly covered with *Monilia* spores before bagging but this treatment did not markedly increase the amount of rot. From these experiments it is concluded that plums become infected through other channels than by the direct infection of the fruit itself, and this explains why the fruit so frequently rots when thickly covered with Bordeaux mixture or other fungicide. A cooperative experiment is reported in which a Bordeaux-resin mixture was sprayed over plum trees to protect against the rot. After spraying, the trees were inspected at intervals, and although the fungicide was plainly visible covering the fruit, the percentage of rotten plums was very high, the fungicide offering little if any protection.

Notes and observations on plant diseases, 1901, J. PERCIVAL (*Jour. South-east. Agr. Col., Wye, 1902, No. 2, pp. 81-89, figs. 3*).—The author reports the observation of a number of plant diseases during the season of 1901. Among those mentioned are the barley smuts, due to *Ustilago nuda* and *U. jensenii*, for the prevention of which soaking the seed in copper solutions or the hot-water treatment is recommended. The leaf scorch of cherries, caused by the parasitic fungus *Gnomonia erythrostoma*, is described. Only cherries of the Bigarreau and Heart types were affected. The fungus attacks the leaves, diminishing their vitality, and later sometimes attacks the fruit, which is developed irregularly. Malformed pears, due to attacks of a species of *Cladosporium*, are also briefly described, and the occurrence of a leaf scorch of orange and lemon trees grown in a hothouse is mentioned. The cause of the leaf scorch is said to be an attack of the fungus (*Glaucosporium hendersonii*). The chrysanthemum rust (*Puccinia chrysanthemi*) is mentioned and a disease of the apple in which the 1-year-old twigs are attacked by a species of *Melanconium* is described. A wilt disease of hops due to *Fusoma parasiticum* and an eelworm of hops (*Heterodera schachtii*) are described.

Plant diseases, G. MASSEE (*Jour. Roy. Hort. Soc. [London], 26 (1902), No. 4, pp. 724-744, figs. 11*).—This paper consists of a résumé of a series of lectures treating of the general conditions regarding plant diseases, and gives descriptions of a number of the more common fungus diseases of herbaceous plants, fruit and other trees.

New heteroecious rust fungi, H. KLEBAHN (*Ztschr. Pflanzenkrankh., 11 (1901), No. 4-5, p. 193*).—Brief notes are given upon a number of heteroecious rust fungi in which the alternate hosts are mentioned. The *Æcidium* of *Coleosporium pulsatilla* is

said to occur on the needles of *Pinus silvestris*, where the fungus is known as *Peridermium jaapii*. *Melampsora allii-salicis* has for its *Ceoma* host different species of Allium, and the uredo and teleutospores occur on *Salix alba*. *Melampsora allii-populina* forms its *Ceoma* on species of allium, and uredo and teleutospores on *Populus nigra*. *Melampsora galanthi-fragilis* occurs on *Galanthus nivalis*, with the uredo and teleutospores upon *Salix fragilis*, and also *S. pentandra*. *Ecidium elatinum* is said to be associated with *Melampsorella cerasii*. *Puccinia cari-bistortae* is said to be identical with *P. angelicae-bistortae*. The teleutospores of *Ecidium pastinacae* are reported as occurring upon *Scirpus maritimus*.

On the hot-water treatment of cereal grains for the prevention of smut, H. ROMMETIN (*Jour. Agr. Prat., n. ser., 3 (1902), No. 14, pp. 440, 441*).—Directions are given for the hot-water treatment of cereals for smut prevention, and the value of such treatment is pointed out. The cost of treating the seed required for sowing 1 hectare (about 2½ acres) by the method suggested by the author need not exceed 20 cents. In the case of oats so treated, it is claimed that a loss of 5 to 10 per cent could be avoided and the treatment much more than paid for.

The difference between smut and bunt, E. DRYCE (*Queensland Agr. Jour., 10 (1902), No. 2, pp. 86, 87*).—The differences between the bunt or stinking smut and the loose smut of wheat, oats, barley, and rye are popularly indicated, and the treatment of the seed by soaking in solutions of copper sulphate is recommended.

The wilt disease of the cowpea and its control, W. A. ORTON (*U. S. Dept. Agr., Bureau of Plant Industry Bul. 17, pp. 22, pls. 4*).—The results of investigations of the wilt disease of the cowpea (*E. S. R., 11, p. 944*) are given. The disease first makes its appearance when the plants are about 6 weeks old. Growth is checked and the stem shows a faint reddish-brown tinge. The affected plants drop their leaves, the lower ones falling first. The spread of the disease is gradual, and it usually makes its appearance in spots throughout a field, spreading from these centers. The cause (*Neocosmospora vasinfecta tracheiphila*) is described, and the manner of infection and spread indicated. While resembling the wilt of cotton and watermelons, the diseases are not intercommunicable. So far it is known to occur in North Carolina, South Carolina, and Alabama, and it is thought probable that it occurs elsewhere. As yet the disease has not caused serious loss except in a few localities, but there is great danger anticipated from its future spread. Land affected by this disease is said to be peasick, but the real reason for the failure of the growth of the peas is the presence of the fungus in the soil. How long the land remains infected in the case of the cowpea wilt is unknown.

For the prevention of this disease the rotation of crops and the substitution of other leguminous crops which are not subject to the fungus are recommended, or the growing of resistant varieties, one of which (the iron pea) is said to be immune to disease. The results of experiments with a large number of varieties of cowpeas and other leguminous plants are given, and the relative susceptibility to disease is indicated.

A cowpea resistant to root knot, H. J. WEBBER and W. A. ORTON (*U. S. Dept. Agr., Bureau of Plant Industry Bul. 17, pp. 23-38, pls. 2*).—While investigating the subject of the wilt disease of cowpeas the authors discovered that one variety (the iron cowpea) was almost entirely free from attacks of the nematode *Heterodera radicicola*, the other varieties being almost destroyed by it. Notes are given on the development and distribution of root-knot nematodes, largely compiled from Alabama Station Bulletin 9 (*E. S. R., 1, p. 185*) and Massachusetts Station Bulletin 55 (*E. S. R., 10, p. 1055*). The use of resistant varieties in stocks for the prevention of attacks of various diseases and insect pests is commented upon and attention called to the freedom of this variety from attack. The possibility of breeding nematode-resistant plants is commented upon.

A new disease of potato, S. GUÉRAUD DE LAHARPE (*Jour. Agr. Prat.*, n. ser., 3 (1902), No. 15, pp. 481, 482).—A summary is given of the investigations of Delacroix on the bacterial disease of the potato due to *Bacillus solanincola*. This disease has been under investigation for some time. For its prevention the planting of sound tubers and 4-year rotation, the use of entire tubers which are to be treated before planting with a 1:20 solution of formalin, and the planting of the potatoes as late in the season as possible, allowance being made for the harvesting of the crop, are recommended.

A new disease of potato, R. ROGER (*Rev. Hort. [Paris]*, 74 (1902), No. 4, pp. 94, 95).—A summary is given of the previous publications of Delacroix and others relating to the bacterial disease of potatoes caused by *Bacillus solanincola*.

The brown disease of potatoes, C. E. BESSEY (*Science*, n. ser., 15 (1902), No. 372, p. 374).—For several years the potato crop of Nebraska is reported as having been seriously damaged by a disease which caused the fibrovascular bundles of the tubers to turn brown. This disease is said to be widely distributed in America and Europe, but as yet no satisfactory cause for it has been discovered. A series of experiments was begun in the laboratory of the University of Nebraska to determine, if possible, what produced this disease. Cultures made from diseased tubers soon showed tufts of mold filaments projecting from the diseased bundles. These, upon development of their fruits, proved to be the filaments of *Stysanus stemonites*. Repeated experiments were made in which, in every case, cultures of the brown bundles produced the fungus, while those which were not discolored were wholly free from the fungus. Tubers examined from a number of parts of Nebraska, as well as from other States, showed the presence of the fungus. These experiments have been continued for a number of months, and it is believed that *Stysanus stemonites* is the cause of the disease.

The snow mildew, P. SORAUER (*Ztschr. Pflanzenkrank.*, 11 (1901), No. 4-5, pp. 217-228).—Under this name the author describes a disease of rye which he says has been known for a long time, but has been given but little consideration. The cause of the disease is said to be *Fusarium nivale*. The history and systematic relationship of the disease is discussed at considerable length and the action of the fungus when freely growing in the field and in inoculation experiments is described.

A new parasite of sugar beets in Egypt, V. MOSSEY (*Ann. École Nat. Agr. Montpellier*, n. ser., 1 (1902), No. 3-4, pp. 310-319).—*Orobanche tinctoria*, or *O. lutea*, as it is sometimes called, is reported as growing parasitically on the roots of sugar beets in Egypt. The plant has long been known in that country, but was first noticed as occurring destructively on beets in 1900.

Diplodia cacaoicola, a parasitic fungus on sugar cane and cacao in the West Indies, A. HOWARD (*Ann. Bot.*, 15 (1901), No. 60, pp. 683-701, pls. 2).—While pursuing the study of the rind fungus of sugar cane, reported in E. S. R., 13, p. 466, the author frequently distinguished a second fungus which exhibited little difference from that which is considered the Melanconium stage of the rind fungus *Trichosphaeria sacchari*. This disease is commonly called the rind fungus or root disease wherever it occurs, and subsequent investigations have shown that the predominant fungus on canes examined from a number of localities is identical with that just mentioned, and experiments were undertaken to develop the fungus under artificial conditions. Pure cultures were successfully grown, and inoculations made showed that the fungus was truly parasitic on the sugar cane.

An investigation of the fungus found on the pods and branches of the cacao tree showed that, so far as the characters of the pycnidia and spores are concerned, it agrees exactly with the form described on the sugar cane. Artificial cultures from the cacao were carried out in a similar manner to those made with the sugar-cane fungus, pure cultures being made from the fungus obtained from the pods as well as from the cacao trees. The infection experiments showed that the fungus could live as a parasite on the cacao pods and is a dangerous wound parasite of the tree itself.

On account of the resemblance between the two, infection experiments were conducted in which mycelium from cacao trees and pods was transformed to sugar cane and the sugar-cane fungus to the cacao. The cross-infection experiments were very successful and leave no doubt as to the identity of the two fungi. In suggesting remedial measures for checking the ravages of this fungus, it is stated that all cacao pod husks should be removed and burned, and all the diseased pods noticed on trees should be similarly destroyed. In the cultivation of sugar cane, the diseased canes should be regularly collected and burned. In this way there will be less chance for infecting a new crop. The systematic position of the fungus is discussed at some length.

Observations on the mosaic disease of tobacco, A. F. WOODS (*U. S. Dept. Agr., Bureau of Plant Industry Bul. 18, pp. 24, pls. 6*).—A summary is given of the author's investigations on the cause of the mosaic disease of tobacco and similar diseases of other plants. The work of a number of other investigators is reviewed, and the author's publications relative to this disease (*E. S. R.*, 12, pp. 216, 217) are summarized. The author claims to be able to artificially produce the disease, and that it is due to a disturbance of the normal physiological activity of the cells. The reduction of the available nitrogenous reserve food may cause the disease, and rapid growth caused by too much nitrogenous manure is favorable to it. It may also be caused by a severe cutting back of plants or by transplanting when rapidly growing. When once started the disease is believed to be continued by the action of the oxidizing enzymes as previously noted.

Black rot of ginger, A. HOWARD (*Bul. Bot. Dept. Jamaica, 9 (1902), No. 3, p. 42*).—The occurrence of black rot on a number of specimens of ginger roots is reported. In continuation of the suggestions of the paper mentioned above, the author calls attention to the necessity of isolating the diseased patches by trenches, throwing the soil on the affected areas, and destroying the diseased plants by burning. In planting, care should be taken to select perfectly healthy rhizomes from the best fields and to soak these for a few hours in Bordeaux mixture.

A new banana disease in Egypt, A. PREYER (*Jour. Khediv. Agr. Soc. and School Agr., 3 (1901), No. 5, pp. 242, 243*).—For about three years a peculiar disease has been noticed spreading among the bananas cultivated in the vicinity of Alexandria, Egypt. The first symptoms of the disease are observed in a sudden checking of the growth, after which the tips of the leaves and the young central leaves become black and die. The stem does not die immediately but is rendered unfit to bear fruit. The great damage done by the disease led to its investigation. A badly infected stem was dug up and together with its roots cut in longitudinal direction. In the upper part the youngest leaves were all black and rotten, while the outer layers were white and seemed sound. The lower part of the stem and root stalk showed no sign of disease. The roots themselves exhibited toward their ends small excrescences usually accompanied by a resin-like material. Sections of these knob-like growths were examined and found to be filled with nematodes, and further investigations showed that the banana disease was due to infection of the roots by the nematodes which in this case belonged to the genus *Tylenchus*, the species resembling *T. acrocaudatus*. The nematode was found to be not only present in the roots, but was met with in considerable numbers in the upper parts of the stem. Experiments are being conducted for the prevention of the disease, but as yet no definite results have been obtained.

Observations on the mulberry dwarf troubles, a widely spread disease in Japan, U. SUZUKI (*Bul. Col. Agr. Imp. Univ. Tokyo, 4 (1902), No. 5, pp. 359, 360*).—In a previous publication (*E. S. R.*, 13, p. 866) the author reported on the relation between oxidizing enzymes in healthy and diseased mulberry leaves. Numerous tests have been made in continuation of his previous investigations, and as a result the author concludes that oxidase and peroxidase are present in larger quantities in

diseased leaves than in the healthy ones. Peroxidase is always more prevalent than oxidase in the diseased leaves. Catalase seemed present in a majority of cases in greater quantity in the diseased leaves.

Experiments in the prevention of *Peronospora* of grapes, F. ZWEIFLER (*Weinlanbe*, 1901, No. 15, p. 176; *abs. in Centbl. Agr. Chem.*, 30 (1901), No. 12, pp. 818-820).—On account of the high price of copper sulphate, experiments have been conducted with greatly diluted solutions of Bordeaux mixture and with other fungicides in combating the downy mildew. The author reports upon his experiments made with Bordeaux mixture of strengths varying from 2 per cent down to 0.1 per cent. The results obtained where the vines were sprayed with 0.5, 0.75, and 1 per cent solutions were equal to those where the 2 per cent solution was used. The grapes were well protected against disease, but where weaker strengths were applied there was undoubted infection. The effect of the stronger solutions on the sugar and acid content of the grapes was quite marked, containing much higher percentages than in the case where weaker solutions were used. Experiments are also reported in which zinc sulphate, manganese sulphate, and alum, in combination with lime and soda, were investigated, but these fungicides were all decidedly inferior to Bordeaux mixture. The use of the 3 per cent solution of iron sulphate was tried, and when sprayed twice during July and August the leaves and shoots receiving this mixture were decidedly injured.

Coulure, or non-setting of grapes, E. H. RAINFORD (*Queensland Agr. Jour.*, 10 (1902), No. 1, pp. 41, 42, pls. 2).—This disease, which is known in this country usually by the name of shelling or rattling, is described and is said to occur under two forms—one the failure of the flower to set fruit in any or all parts of the cluster, another in which the fruit sets increase in size for a time, after which they fall off in greater or less quantity. The causes of the disease are said to be accidental and constitutional. The accidental causes are adverse meteorological conditions at flowering time, too great vigor of vegetation, and fungus attacks. Each of these causes is described at some length, and brief suggestions given for their prevention so far as means are known.

The American gooseberry mildew in Ireland, E. S. SALMON (*Jour. Roy. Hort. Soc. [London]*, 26 (1902), No. 4, pp. 778, 779).—The first outbreak of the gooseberry mildew (*Sphaerotheca mors-uvæ*) was reported in 1900, and in the following year the disease appeared in the same locality and proved more destructive than in the previous season. The conditions seemed to indicate that the fungus was becoming somewhat widely distributed throughout Europe, and the author recommends spraying the plants with a potassium sulphid solution at 10-day intervals, beginning as soon as the buds begin to unfold.

Diseases of the tea plant, G. DELACROIX (*Jour. Agr. Trop.*, 2 (1902), No. 9, pp. 67-72).—A list is given, together with brief descriptions of the principal animal and vegetable parasites which attack the tea plant. Among the insects are various borers, leaf miners, and other leaf-eating insects, scale insects, red spiders, etc. The author also describes attacks of nematodes upon the roots of plants, 2 species (*Tylenchus acutocaudatus* and *Heterodera radicolica*) being described. Among the plant diseases described are the following: Blister blight, due to *Exobasidium vexans*; anthracnose, caused by *Colletotrichum camelliae*; gray blight, due to *Pestalotzia guepinii*; thread blight, caused by *Stilbum nanum*; and root rot, due to attacks of *Rosellinia radiciperda*. The effect of the alga, *Cephaleuros virescens*, in producing what is known as red rust is described, as well as the attack of a number of undetermined species of mistletoe upon the plant.

The parasites of the tea plant, A. ZIMMERMANN (*Centbl. Bakt. u. Par.*, 2. Abt., 8 (1902), Nos. 1, pp. 16-23; 2, pp. 46-55).—A list is given of animal and plant parasites destructive to the tea plant. Compiled notes are given regarding many species, and a brief bibliography is appended.

Diseases of timber, H. VON SCHRENK (*Forestry and Irrig.*, 8 (1902), No. 2, pp. 60-63, figs. 5).—Notes are given on some of the means by which timber is destroyed, particular attention being paid to the attacks of *Trametes pini*, *Polyporus schweinitzii*, and other species on living coniferous trees. Attention is called to the rapid decay of railway ties, bridge and other construction timbers, and suggestions are offered for the prevention of this destruction by the application of various chemical agents.

The disease of larch, J. SIMPSON (*Gard. Chron.*, 3. ser., 31 (1902), Nos. 798, pp. 233, 239; 799, pp. 256, 257).—On account of the proposed investigation into the larch disease in England, the author calls attention to some of the more important facts relating to it. The distribution of the disease throughout Great Britain is indicated, and attention called to the difference between the larch blister or blight, which is due to species of aphids, and the disease of larches caused by attacks of the fungus *Peziza willkommii*.

A disease of the American ash, H. VON SCHRENK (*Abs. in Science*, n. ser., 15 (1902), No. 376, p. 406).—Mention is made of a disease of the common ash (*Fraxinus americana*) which is caused by attacks of *Polyporus fraxineus*. Where this disease is prevalent it is said that a large percentage of the trees are affected.

Carnation anthracnose, M. C. COOKE (*Gard. Chron.*, 3. ser., 31 (1902), No. 795, pp. 193, 194).—A description is given of a disease that has recently appeared among the carnations in England, in which the leaves are first spotted with small purple roundish spots. These gradually enlarge and become confluent and indeterminate, and at length brownish in the center. In the meantime the leaves become weakened and begin to die at the tip. The general character of the disease is that commonly described as an anthracnose, and the author has described the fungus causing it as a new species to which the name *Glaeosporium dianthi* is given. The technical characters of the fungus are mentioned and it is believed that dilute Bordeaux mixture, together with the picking off and destroying of the diseased leaves, would prevent its spread.

Sterilized soil for carnation stem rot, W. R. PIERSON (*Gardening*, 10 (1902), No. 228, pp. 179-181).—A report is given of investigations made by the author and others on the prevention of stem rot, which is due to *Rhizoctonia* sp. The soil of benches in which carnations were grown was sterilized by steam heat. The expense of sterilizing the soil in a house 16 by 300 ft. was about \$25. In the sterilized soil only about half a dozen plants were lost out of 1,500 planted. This loss is so slight that it is believed the difficulty was overcome. While not claiming that sterilization is a cure for stem rot, the author thinks that, if properly managed, it will secure the prevention of attack. In addition to destroying the fungus, nematodes and other troublesome pests will be likewise eradicated.

Fungus pests of the carnation family, M. C. COOKE (*Jour. Roy. Hort. Soc. [London]*, 26 (1902), No. 4, pp. 649-656, pls. 2).—A summary and list is given of the parasitic fungi which attack the carnation family of plants. They are divided into the leaf-spotting fungi, molds, smuts, rusts, and the bacterial diseases. The fungi causing each of these diseases are described at some length, and a list is given of all the parasites known to occur upon species of Caryophyllaceæ, whether cultivated or uncultivated. The total number of species reported is 60.

Observations on the bacterial rot of the calla lily, C. O. TOWNSEND (*Abs. in Science*, n. ser., 15 (1902), No. 376, pp. 404, 405).—A bacterial rot of the calla lily is briefly described, which is characterized as a soft brown rot with offensive odor that usually attacks the bulbs, but may appear on the roots or leaves. It is reported as having destroyed all the plants in greenhouses in the vicinity of Washington, D. C. As a rule, the bulb shows the disease most frequently near the top, but it often happens that the attack is made below the surface of the ground, in which case the bulb is almost entirely destroyed before the leaves indicate that the plant is diseased. Cultures made from diseased areas usually give pure cultures of a rod-shaped motile bacteria. The action of the organism in various nutrient media is briefly described.

Diseased plants have been treated with lime, sulphur, and dilute formalin with some success. The best treatment thus far found, however, consists of changing the soil in the beds or in growing the plants in pots, and in the proper management of greenhouses.

The toxic properties of some copper compounds with special reference to Bordeaux mixture, J. F. CLARK (*Bot. Gaz.*, 33 (1902), No. 1, pp. 26-48, figs. 7).—Studies are reported on the toxic effect of a number of copper compounds in preventing the growth of fungus spores, etc. Based upon his investigations, the author concludes that the solution of that part of the Bordeaux mixture which under orchard conditions is of fungicidal value is chiefly accomplished by the solvent action of the fungus spores themselves. The amount of copper necessary for the destruction of the spores of parasitic fungi is probably not more than 1 part of soluble metallic copper to 80,000 parts of water. The host plant has a greater or a less power of dissolving copper hydroxid deposited on its leaves. This solution of copper by the host plant may or may not be advantageous in protecting it from attack, as spores may not be present at the point where the solution has taken place. To this factor, however, must be attributed much of the injury frequently observed on such plants as peach, Japanese plum, etc. The amount of injury done to a given species, provided always that carefully prepared Bordeaux mixture is used, will depend on the specific susceptibility of the protoplasm of the plant to poisoning by copper, the solvent properties of the cell sap on copper hydroxid, the permeability of the epidermis or cuticle, and the weather conditions following spraying, particularly the conditions of moisture.

ENTOMOLOGY.

Some insects of the year 1899-1900, C. FOWLER (*California Sta. Rpt. 1899-1901*, pt. 1, pp. 73-85, figs. 10).—Biological and economic notes are given on a number of scale insects, including San José scale, black scale, red scale, purple scale, greedy scale, cottony cushion scale, etc. The report also contains brief accounts of injuries from peach-tree borer (*Sannina pacifica*), peach-twigg borer, cucumber beetle, squash bug, harlequin cabbage bug, pear slug, and plum-tree aphid.

Phorbia lupini is reported as boring in the stems of white lupines and causing the destruction of these plants. The eggs are laid in the growing top of the plant, or sometimes in the axil of the leaf. The larva then penetrates into the pith of the stem for a short distance. Other species of lupines are attacked as well as the white species. The Lawson cypress is said to have been considerably injured by the bark beetle (*Phloeosinus punctatus*). Affected trees first show an unhealthy appearance, and later turn brown and die. The galleries of the beetle are found under the bark. A species of *Andricus* was found injuring the English oak. The wasp did not produce galls like most related species, but when the larva was full grown it gnawed its way through the twigs and escaped. In combating this species, severe pruning and cutting back are recommended.

Notes are given on the woolly aphid, which injures not only the roots and trunks of apple trees, but is reported as penetrating into the apples, in the case of Newtown pippins. When the species appears above ground it may be readily destroyed with kerosene emulsion.

Brief notes are also presented on nematode worms, Paris green, kerosene emulsion, resin, soap, and lime-sulphur-and-salt wash.

Some insects of the year 1901, R. H. PERRY (*Michigan Sta. Bul. 200*, pp. 179-212, figs. 21).—*Lecanium armeniacum* is reported as injurious to apricot, plum, and grape. The greatest damage was done in the northern part of the State. Scale insects closely resembling this species were also observed on maple, elm, and hackberry. The natural enemies of the species include parasitic insects, and a fungus

disease (*Cordyceps clavulata*). For combating the scale insects the author recommends spraying with kerosene emulsion and whale-oil soap. *Lecanium nigrofasciatum* caused considerable injury to peaches. The species is said to be easily controlled by the use of winter washings. For destroying the young, applications of kerosene emulsion in June and the early part of July are recommended. A larger species of *Lecanium* is reported as injuring peaches and is described in detail. It is parasitized by *Blustothrix longipennis*, and may be controlled by winter applications of kerosene emulsion. English-walnut scale is said to have been quite injurious to peach and maple. It may be controlled by the remedies which are usually applied against San José scale.

Dactylopius trifolii was found in considerable numbers on sugar beets. The beets which were most infected with the insect were stunted, but it was not clear whether this effect was due to the insects or to other causes. Serious attacks of green aphids are reported as having occurred throughout the State. In some localities the species was greatly checked by the attacks of a parasite (*Aphidius granariaphis*), and syrphus flies. Kerosene emulsion will destroy the aphids, but the feasibility of this method in grain fields is much doubted. The destructive pea louse caused considerable damage in various parts of the State. In some places it attacks sweet peas. Spraying with kerosene emulsion or a mixture of kerosene, and the brush and cultivator method are recommended for controlling this species. Notes are given on experiments in combating spring and fall cankerworms. All of the caterpillars were apparently destroyed by two applications of Paris green. Good results were also obtained from the use of bands.

Basswood trees were attacked by *Hibernia tiliaaria* and *Phyllocolpa strigataria*. These insects may be controlled by the same remedies as were recommended for cankerworms. Great damage was caused to onions in a few localities by *Chortopsis uuen*. The maggots of this species pass the winter inside of the onions. The species appears to be many brooded. The author recommends the destruction of all of the infested onions in the fall, and the use of deterrents, such as carbolic-acid emulsion, kerosene and sand, and tobacco dust. Notes are given on the plum gonger, and in combating this insect the following remedies are recommended: Jarring the trees, destruction of fallen and infested fruits, and repeated spraying with Paris green.

An attack of *Epicauta vittata* was reported upon potatoes. Spraying with Paris green is recommended, or while the insect is present in large numbers it is believed that they may be driven away by brushing.

Insect record for 1901, C. M. WEED (*New Hampshire Sta. Bul. 90, pp. 29-44, figs. 12*).—Brief notes are given on the occurrence of injuries from the following insects: *Bibio albipennis*, squash bug, squash-vine borer, striped cucumber beetle, apple-leaf hopper, cankerworm, bean weevil, elm-leaf aphid, birch-leaf skeletonizer, fall webworm, white-marked tussock moth, imported elm-leaf beetle, oyster-shell bark-louse, brown tail moth, and gypsy moth. The imported elm-leaf beetle is said to have established itself in the northern part of the State. The brown tail moth was once found in the southeastern part of the State, but it is believed to have been temporarily exterminated.

Report of the entomologist, E. D. SANDERSON (*Delaware Sta. Rpt. 1901, pp. 127-199, pls. 6, figs. 16*).—The author presents an elaborate account of the plant lice which affect apple trees. An analytical key is given for the identification of each species, and detailed notes are given on the life history, habits, and means of combating the different species. These include *Aphis pomi*, *A. fitchii*, *A. sorbi*, and *A. brevis* (the last-named species being described as new). Tables are presented showing the measurements of various parts of the body of the different species, and bibliographical references are given in connection with the discussion of each species. A number of experiments were tried in the use of insecticides for destroying apple plant lice. Crude petroleum was found to be much more effective than kerosene and gave satis-

factory results in a 15 per cent solution, while kerosene had to be used in a 20 per cent solution. The most effective spray, however, was Rose Leaf tobacco extract, which was found quite satisfactory when diluted in a proportion of 1 to 40 in water. It proved to be impossible to destroy all the plant lice on a tree by one application of any insecticide.

Experiments in combating strawberry root louse showed that 0.2 gm. of cyanid of potash per cubic foot was not sufficient to destroy the lice in a period of 20 minutes. It was found that plants could be fumigated with this strength of gas for 45 minutes, or less, without injury. Whale-oil soap and Rose Leaf insecticide seriously injured the plants in some experiments, but weaker solutions proved harmless.

Notes are given on *Euzophera semijuneralis*. The species is reported as injurious to plums, apples, pears, and other fruit trees. A description is given, together with notes on its life history. It appears that there are two, or perhaps three, broods in Delaware. Notes on the destructive pea louse include an account of spraying and brushing, and the effectiveness and cost of these methods. The species was quite abundant in Delaware during the year and opportunity was had for experiments with the Brakeley sprayer, and other devices. The author believes that so long as the vines are still upright, any machine which will spray 2 or 4 rows at a time will be found satisfactory.

A number of experiments were made in testing remedies for combating the codling moth. During these experiments it appeared that the codling moth had 1 brood and only a partial second in central Delaware. Spraying experiments in combating the codling moth included the use of arsenid of lime, Paris green, and Disparene. These experiments were supplemented by banding tests. Arsenid of lime did not give very satisfactory results. With Paris green 61 per cent of benefit was observed, while with Disparene the benefit amounted to 87 per cent. On account of the dangers and practical difficulties of manufacturing arsenate of lead on the ordinary farm estate, it is recommended that the insecticide be bought in a prepared form. The results of experiments in the use of bands indicated that about 15 per cent of the codling moths were captured by this device. A combination of Bordeaux mixture with an arsenite and kerosene was successfully used for a number of purposes. A combined insecticide and fungicide was used against codling moth and plant louse with good success. Crude petroleum was tested in mechanical mixtures with water in strengths of 15, 20, and 25 per cent. All San José scales were killed by the 25 per cent solution, while some remained alive after spraying with weaker solution. Fumigation of low growing plants, such as melons, with hydrocyanic-acid gas proved possible and practicable. The author tested the use of paper covers and iron frame covers in these experiments. The results obtained indicate that the effectiveness of the gas depends upon its thorough diffusion, and that treatment can not be effective if not properly diffused.

The resisting power of insects, C. STERNE (*Prometheus*, 12 (1901), No. 610, pp. 602-605, figs. 4).—Notes on the resisting power of different species of insects to cold, heat, hunger, poisons, and submergence in water.

The principal insects injurious to tobacco in the Island of Réunion, E. BORDAGE (*Rev. Agr. Réunion*, 8 (1902), No. 3, pp. 103-112).—In this article the author gives biological and economic notes on a number of insects which attack tobacco in the island of Réunion. The more important species are *Gelechia solanella*, bollworm, suck fly, and cigarette beetle.

The sugar-cane borer, H. MAXWELL-LEFROY (*West Indian Bul.*, 3 (1902), No. 1, pp. 88-90).—The life history of *Sphenophorus sericeus* is summarized as follows: The eggs are laid singly in the tissue of sugar cane, and the grub, after hatching, burrows in the cane, destroying almost the whole interior. The remedies which are recommended for controlling this insect include the destruction of all rotten or infested cane, the covering of all ratoon stumps with mold as soon as the canes are cut in

order to prevent the deposition of eggs in such locations, and the destruction of ratoon stumps which are not intended to be grown.

The natural enemy of the sugar-cane beetle in Queensland. W. W. FROGGATT (*Agr. Gaz. New South Wales*, 13 (1902), No. 1, pp. 63-68, pl. 1).—Notes are given on the habits and life history of a parasitic wasp, *Scolia formosa*, which was found to be a valuable parasite for holding in check the cane beetle in Queensland. The notes are based largely on the report of Mr. J. T. Clarke, who worked out a part of the life history of the parasite in the laboratory of a sugar refining company. The author also gives notes on the habits and life history of *Lepidoderma albolirum* and *Xylotrupes australicus*, both of which are injurious to sugar cane in New South Wales.

A parasite of sugar-cane beetle grubs. H. TRYON (*Queensland Agr. Jour.*, 10 (1902), No. 2, pp. 133-140, pl. 1).—A hymenopterous parasite (*Diebis formosus*) is reported as being quite effective in checking the numbers of the sugar-cane borer. Notes are given on the distribution of the species, and the insect is described in detail in all its stages. In the discussion of the habits and life history of the insect it is stated that the eggs are probably deposited upon the larva of the cane borer when the latter has nearly reached its full size. It is suggested that the parasite in question may be artificially reared in such numbers as to permit its shipment to the United States and other countries where the cane borer is injurious.

The chinch bug. J. M. STEDMAN (*Missouri Sta. Bul.* 51, pp. 115-142, figs. 4).—In this bulletin a general popular account is given of the habits, life history, food plants, migrations, and means of combating the chinch bug. The different stages of the insect are described, and notes are given on its habits of hibernation, and natural enemies. The birds mentioned as most beneficial in destroying chinch bugs are quail, prairie chicken, meadow lark, red-wing blackbird, catbird, and thrushes. It is believed by the author that little help can be expected from parasitic fungi in destroying the chinch bug. His experience in Missouri indicates that the disease occurs naturally in most badly infested localities, and that the small amount of fungus which can be distributed by any one farmer has little effect on the general result.

The squash bug. C. M. WEED and A. F. CONRAD (*New Hampshire Sta. Bul.* 89, pp. 13-28, figs. 2).—The authors give a popular account of the habits, life history, and methods of attack of this insect. The most important parasitic enemy of the squash bug noted in New Hampshire during the past season was *Trichopoda pennipes*. It is believed that toads seldom feed upon the squash bug for the reason that the odor of the insect has been found to be fatal to toads as well as to a species of salamander. A number of squash bugs were found which apparently had died of an unidentified fungus disease. The remedies recommended by the authors include the use of netting covers when the plants are young, sowing an excessive quantity of seed, clean culture, hand picking, and spraying with a mechanical mixture of kerosene in water. The beetles may be collected from the vines and upon the ground in the spring, as well as from board traps and trap squash plants. In summer similar remedies may be applied, and also spraying with a mechanical mixture of kerosene and water weak enough to be harmless to the squash plants. In the autumn the squash plants may be sprayed with a stronger mixture of kerosene immediately after the first frost.

Experiments with insecticides for the San José scale. S. A. FORBES (*Illinois Sta. Buls.* 71 and 72, pp. 241-268).—In the fall of 1901 the author secured an appropriation of \$15,000 for insecticide work on the San José scale. It was decided to make experiments to determine the value of the lime, salt, and sulphur wash and also the lime, sulphur, and blue vitriol wash which is much used in Oregon. It was found that both of these washes had the effect of loosening the scales so that they were easily rubbed off and washed away by rain. The chief purpose of the experiments was to determine the effect of rains which might occur soon after spraying

with these washes. The experiments included the artificial application of water to a part of the trees after they had been treated with the wash. As a general result of the experiments it was found that a single application of the lime, salt, and sulphur wash caused the destruction of 90.6 per cent of the scales when no water was applied to the trees within 5 days after spraying and 86 per cent when water was used. The effectiveness of the lime, sulphur, and blue vitriol wash was 93 per cent and 92.2 per cent, respectively. During these experiments 43 trees were treated, 25 being apple and 18 peach trees.

Detailed descriptive and tabulated notes are given showing the time of treatment of the trees and the effect of the treatment upon the scales found on each tree. At the time of year when the experiments were made rain storms naturally occurred. One experiment was made under a tent, the artificial application of water being strictly controlled by placing a tent over the tree at night and at the approach of rain storms. Two trees were treated in this manner, one being sprayed with the lime, salt, and sulphur wash and the other with the Oregon wash containing blue vitriol. In this experiment no important differences were noted in the action of the insecticides, the general effect being the destruction of about 95 per cent of the scales. The results of the experiments, as observed on March 25 or 20 and 22 days after the application of the wash, indicated that the Oregon wash of lime, sulphur, and blue vitriol is a valuable insecticide for use in Illinois for the destruction of San José scale. It appears from these experiments that frequent short rains do not noticeably diminish or delay its action, even when they occur within a period of five days after the application of the wash. Both of the insecticides are harmless to trees, but should be used in winter. At the date mentioned it appeared that the California wash of lime, salt, and sulphur was somewhat less effective than the Oregon wash.

When the trees were examined on May 12, however, a careful count of the scales found upon the trees showed that there were very few living scales. Of 9,000 scales carefully examined only 35 were found living. One-half of the trees on which these statistics were based were sprayed with the California wash and the other half with the Oregon wash. It appears, therefore, that the two insecticides are about equally effective. The action of the washes is apparently prolonged to a period of 3 weeks or more. The chief differences between the two washes are considered to be in the rapidity of action rather than in the ultimate effect on the scales.

A scale insect infesting the fig tree, and its enemies, TRABUT (*Bul. Agr. Algérie et Tunisie*, 8 (1902), No. 7, pp. 161-167, figs. 9).—An account is given of the habits and life history of *Ceroplastes rusci*. This bark louse may, under certain conditions, almost completely cover the branches, fruits and leaves of the fig tree. Ordinarily, however, it is held in check by its numerous enemies, among which special mention is made of several species of ladybirds and parasitic insects.

The grapevine and *Cœpophagus echinopus*, S. JOURDAIN (*Compt. Rend. Acad. Sci. Paris*, 134 (1902), No. 5, p. 316).—The author believes that the disease of grapevines attributed to this mite is not thus produced. The mite was frequently found on tubercles, roots, and bulbs which had commenced to decompose; it was not believed, however, to have made the original attack upon these tissues. It is stated that this mite does not attack healthy vines, but only such as are more or less injured by unfavorable conditions in the environment.

The destruction of grapevines by the mite *Cœpophagus echinopus*, L. MANGIN and P. VIALA (*Compt. Rend. Acad. Sci. Paris*, 134 (1902), No. 4, pp. 251-253; *Bul. Agr. Algérie et Tunisie*, 8 (1902), No. 4, pp. 107-109).—The observations of the authors, extending over several years, indicate that grapevines are not usually attacked by this mite while they are in perfect health. When, however, the soil is only slightly permeable, compact, and moist, and the root system poorly developed, the mites attack the plants, causing disease or death of the vines. A considerable variation in

the resisting power of different varieties to the attacks of the mites was noted. Submersion of infested areas had no good effect; on the other hand, it appeared to aggravate the trouble. Sulphocarbonate of potash proved to be ineffective. The only good remedy found was carbon bisulphid applied at the rate of 300 kg. per hectare in a single treatment, or better, in two treatments of 200 kg. each. The parasite was completely eradicated by this method.

Trap lanterns, or "moth-catchers," M. V. SLINGERLAND (*New York Cornell Sta. Bul.* 202, pp. 197-225, figs. 2).—In a general discussion of the utility of trap lanterns it is argued that more importance should be ascribed to the kind of insects caught by such traps than to the numbers. It is well known that many beneficial insects are attracted to the light and killed along with the injurious ones. Two series of experiments were conducted at the station for the purpose of testing the value of lantern traps. One series of experiments was made with these lantern traps in 1889, and the other with one such trap, in 1892. The lantern traps in both series consisted of an ordinary lantern set on a brick in a tin pan, the whole being fastened to a platform on the top of a stake. In the series of experiments in 1889 the trap lanterns were set under various surroundings, such as the edge of a small hop field, under a tree, at the edge of an oat field, in a wheat plat, and in the center of an experimental garden containing bush fruits and some larger trees. It was necessary to visit the traps twice a day, and the six lanterns in the season of 1889 were kept in order every night from May 1 to October 15. The single trap utilized in 1892 was run from May 20 to October 1. Detailed notes are given in a tabular form concerning the number and species of insects captured during these experiments. In 1892 about 13,000 insects were taken, representing 350 species. Of this number 77 per cent were neutral with regard to their effect upon agriculture, while 10½ per cent were decidedly beneficial, and 12½ per cent were insects which are sometimes pests. No codling moths were captured. Among the serious insect pests represented, a much larger percentage of males was captured than females, the percentage of males in different species varying from 79 to 93. This indicates that lantern traps are of little value, in so far as largely male insects are attracted to the light, while females are still left to deposit their eggs. The majority of the insects were taken in June and August. In case of several species, sharply defined periods of flight were observed, during which large numbers of insects were captured. At other times these species might be almost entirely missing in the captures of the night.

The results obtained in various other stations in experiments with moth-catchers and trap lanterns are briefly discussed. Since only about 1 per cent of the insects caught by the author could be considered as common orchard pests, it is urged that the lantern traps have little to recommend them to the ordinary fruit growers. In case of a few insects, like the moths of tent caterpillars, which fly for a few nights only and then in large numbers, it may be possible to use lantern traps to advantage. So many beneficial insects, however, are captured by the traps that the very slight benefits to be derived do not pay for the trouble of maintaining the lantern traps.

Suggestions for insect control in the West Indies, H. MAXWELL-LEFROY (*West Indian Bul.*, 2 (1902), No. 4, pp. 318-344).—This article contains a general account of the problems of economic entomology, the local condition of the West Indies with reference to injurious insects, and a general classification of methods for controlling injurious species of insects. These methods include legislative measures for preventing introduction of new pests, the adoption of other methods of prevention, remedial measures, encouragement of useful birds and other enemies of insects, and the introduction of new insectivorous birds and predaceous insects.

Circular to nurserymen relating to shipment of nursery stock, W. B. ALWOOD (*Virginia Sta. Spec. Bul.*, May, 1902, pp. 6).—This circular contains information for nurserymen and other persons concerning the requirements in a certificate

of inspection and the regulations according to which the crop-pest law will be enforced.

The salt-marsh mosquito (*Culex sollicitans*), J. B. SMITH (*New Jersey Stat. Spec. Bul. T*, pp. 10, figs. 2).—The author gives brief notes on the habits and life history of this species of mosquito, which is considered one of the worst pests along the coast line. This species breeds in salt or brackish water, or occasionally in fresh water fields on salt marshes. The author never observed the species breeding in inland fresh water. The life history of this species of mosquito is not well understood. It probably passes the winter in the egg stage. The remedies which are suggested for mitigating the mosquito plague include the drainage of pools of stagnant water, and application of kerosene to small areas where this method would be more convenient than drainage. One peculiarity of the salt-marsh mosquito is noted, and consists in its habit of drifting with the wind to great distances from its breeding grounds. It may at times, therefore, cause annoyance in localities where no stagnant ponds are found.

The maggot fly, C. FULLER (*Agr. Jour. Cape Good Hope*, 20 (1902), No. 2, pp. 102-105).—This is a brief account reprinted from the *Natal Agricultural Journal* concerning the attacks of *Auchmeromyia depressa* upon dogs and man. Notes are given on the appearance of the insect in its different stages and upon its life history and habits. It is somewhat common in various parts of South Africa.

The distance apart at which apiaries should be placed, DE SOIGNIE (*Jour. Soc. Cent. Agr., Belg.*, 49 (1902), No. 3, pp. 267, 268).—The author discusses the various legal regulations which have been made for determining the localities for placing apiaries, the distance from public dwellings and thoroughfares, and various other devices which are to be adopted in preventing apiaries from causing annoyance to the public.

The relationship of honey to wax, C. P. DADANT (*Rev. Internat. Apicult.*, 24 (1902), No. 4, pp. 68-71).—A general discussion is presented on the question of the expensiveness of the manufacture of wax by bees. The author believes that the production of wax from honey by the bees is too expensive and should not be permitted to occur. Foundations of greater or less size will prevent to a large extent the use of honey for the manufacture of wax.

Do bees injure fruit? (*Queensland Agr. Jour.*, 10 (1902), No. 2, pp. 107, 108).—A brief discussion of possible injury to grapes by honeybees. It is urged that the mouth parts of bees are well adapted to biting fruits, but that according to common experience they rarely cause any damage of this sort.

Sericulture, J. BOLLE (*Ztschr. Landw. Versuchs. Oesterr.*, 5 (1902), No. 3, pp. 475-480).—Experiments were made in crossing different races of silkworms for the purpose of determining whether larger cocoons, with silk more easily reeled, could be produced. For a considerable length of time the results in crossing races were unsatisfactory; many undesirable characters which belonged to the different races reappeared from time to time in the crosses. Even when the desired characters were produced, they seemed to be obtained at the expense of the vitality of the silkworms. After a long series of experiments some results were obtained which indicate the possibility of improving the character of the silk and the size of the cocoon without losing the vigor of the worms at the same time. It is recommended that until improved races shall show themselves as being constant in character it would be best to continue with the old well-known races.

The author made some experiments with micro-organisms which were found in the alimentary tract of silkworms infected with flaccidity. It was found possible to inoculate healthy silkworms with organisms which were obtained from infected worms, but it is not considered that the causal connection of these organisms with the disease has been definitely proved. In localities where jaundice of silkworms

appears in an endemic form it was found possible to disinfect the premises by fumigation or by spraying with formalin. The treatment was very effective and not expensive.

Experiments were made to determine the feeding value of *Scorzonera hispanica* for silkworms. The results were unfavorable to this plant. Many of the worms became sick, and it is recommended that no attempt be made to use the plant for feeding silkworms.

Sericulture in Tunis, F. VERRY (*Bul. Agr. Algérie et Tunisie*, 8 (1902), No. 6, pp. 140-150).—The author gives an account of the local conditions in Tunis which are favorable to the raising of silkworms and the production of silk. A large number of mulberry trees are already planted and it is believed that silk mills will be established as soon as the production of cocoons is sufficiently great to warrant it.

FOODS—NUTRITION.

Human food investigations, H. SNYDER (*Minnesota Sta. Bul.* 74, pp. 109-174, figs. 21).—The investigations reported include studies of the digestibility and nutritive value of beans, oleomargarine, butter, cheese, oatmeal, bread made from different grades of flour, and toast, as well as studies of the digestive power of enzymes of milk. The natural digestion experiments were made with healthy men; the artificial digestion experiments were made by the usual laboratory methods. On an average, baked beans eaten with a simple mixed diet had the following coefficient of digestibility: Dry matter, 90.91; protein, 80.22; fat, 79.82, and carbohydrates, 96.19 per cent. It was found that the greatest degree of digestibility was secured when the beans were consumed in a mixed ration. The digestibility of beans with the skins removed by parboiling and the use of soda, beans parboiled with soda and the skins not removed, beans baked without parboiling and without the use of soda, was studied with pepsin-pancreatin solutions.

"When the skins of the beans were removed the beans were more readily acted upon by digestive solvents, as pepsin, diastase, and pancreatin. In 12 hours 25 per cent more of the protein nutrient was digested when the skins of the beans were removed than when the beans were baked in a similar way without the removal of the skins."

In connection with the above tests, the effect of adding soda to the water in which beans were parboiled, the removal of the skins, and related topics were studied. The bean skins were found to have the following percentage composition: Protein, 10.67; fat, 2.10; crude fiber, 39.55; nitrogen free extract, 40.95; ash, 6.73. A number of the author's conclusions were in effect, as follows:

When soda was used in the preparation of the beans it was found that 84 per cent of the soda remained in chemical combination with the proteid material, and 16 per cent remained in the water in which the beans were parboiled. Less than 0.66 of 1 per cent of the total nitrogen of beans was lost in the water used in parboiling, while 99.33 per cent of the total protein remained in the beans.

"When the skins of beans were removed by parboiling in water containing a little soda about 6.5 per cent of the total dry matter of the beans was removed in the skins. The skins contained a large amount of crude fiber and a relatively small amount of protein; about 3 per cent of the total protein in the beans was removed in the skins.

"When the skins of beans were removed there was less tendency for the formation of gas in the intestines during digestion. A small amount of germ adhered to and was removed with the skins; the germ and skin are the parts of the beans which

are the most fermentable and produce sulphuretted gaseous products during digestion. . . .

"The nutrients in beans are different in character from the same class of nutrients in cereal foods. The protein in beans is mainly in the form of legumin, while that in the cereals is in the form of glutens. Bean-starch granules are larger in size and differ in microscopic structure from the cereal-starch granules. Beans contain only a small amount of ether extract, a portion of which is in the form of lecithin and free fatty acids. The ether extract from beans, however, has about the same caloric or heat-producing power [which was on an average found to be 9.4 calories per gram] as the ether extract from other foods.

"In these experiments, over a pound of baked beans was consumed per day by men engaged, part of the time, in active outdoor work. It is believed, however, that not more than 4 oz. of uncooked beans or 6 oz. of baked beans should be consumed in the daily ration. While beans are slow of digestion, they can not be considered as indigestible when the availability or total amount of nutrients actually utilized by the body is considered. In these experiments, over 90 per cent of the dry matter in the beans was digested and utilized by the body."

In a study of the comparative digestibility of oleomargarine and butter as part of an otherwise uniform ration, it was found that the average digestibility of the latter ration was protein, 89.66; fat, 95.54; and carbohydrates, 96.97 per cent; available energy, 92.06 per cent. The digestibility of the ration with oleomargarine was protein, 87.90; fat, 94.20; and carbohydrates, 97.01 per cent; available energy, 91.30 per cent.

Several experiments were undertaken in which a considerable amount of cheese was eaten. Only one of these was satisfactorily completed. It was found in this case that cheese consumed with a bread and milk ration had the following coefficient of digestibility: Protein, 93.36; fat, 94.5, while the available energy was 92.59 per cent. When samples of Minnesota, Wisconsin, and New York cheese were subjected to the pepsin and pancreatin digestion processes it was found that from 47.4 to 52.9 per cent of the total protein, namely, casein, was digested and rendered soluble by the action of the peptic ferments (in acid solution), and that from 44 to 49.2 per cent of the remaining protein was dissolved in the alkaline pancreatin solution.

"The digestion with pepsin and pancreatin solutions show that a large part of the work is carried on by the pancreatin solution. If the peptones present in the cheese were deducted it would be found that the larger part of the work of digestion takes place in the alkaline pancreatin solution. These artificial digestion trials emphasize the fact that the main portion of the work of digestion of cheese is carried on in the intestines rather than in the stomach. This is probably the reason why cheese is characterized as a 'hearty food' and frequently causes digestion troubles when eaten. In such cases the amount of cheese consumed should be reduced to correspond with the digestive capacity of the individual. Cheese should be consumed in small amounts, and by so doing the digestive powers of an individual can be strengthened and not impaired."

Two experiments on the comparative digestibility of bread and toast are reported. On an average, 87.1 per cent protein and 97.5 per cent carbohydrates of the bread were digested, as compared with 84.7 per cent protein and 97.3 per cent carbohydrates of toast. The comparative digestibility of bread and toast was also studied with diastase ferments. When 10 gm. of sterilized dry toast was treated for 45 minutes with a dilute solution of malt, 14.68 per cent of starch was rendered digestible. Under the same circumstances 21.38 per cent of the starch of toast was rendered digestible. According to the author, the experiments show that toast is more readily acted upon by a diastase ferment than bread, and that by toasting a food is produced which is more readily though not quite as completely digested as bread. This, in

the author's opinion, does not detract from the value of toast as a food for invalids and others requiring a sterilized food product, but indicates that, as far as the digestibility of nutrients is concerned, bread is preferable to toast.

"Toast is a sterile food while some breads contain various ferment bodies which have not been destroyed in baking, as the interior of the loaf is not heated above the boiling point of water. The ferment and fungus bodies present in unclean flour undergo incubation during the process of digestion, particularly if the digestion is in any way impaired. In the case of normal digestion, however, these bodies do not develop to any appreciable extent because the digestive tract disinfects itself. Microscopic examination of the feces, particularly of those when the diet consisted of graham or entire wheat breads, showed that these fungus bodies had undergone the incubation process during digestion. The patent grades of flour produced by the roller process of milling contain less of these ferment bodies than either graham or entire-wheat flour. This is because the bran and germ parts of wheat which are included in the graham and entire wheat flours are the parts which contain the ferment bodies. . . .

"In case it is necessary to use a sterilized food, as toast, in the dietary it is more economical to prepare it at home from flour of good quality than it is to purchase it in the form of so-called health foods. . . .

"It would appear that the prolonged action of heat in the preparation of foods lessens the digestibility of the protein but not of the carbohydrates. The two classes of nutrients in foods, proteids and carbohydrates, are evidently affected in a different way, as far as the total digestibility is concerned, the carbohydrates being made more easy to digest and the proteids less completely digestible by the prolonged action of heat. Since in many of our foods, particularly the grains, the carbohydrates are by far the most abundant class of nutrients, the action of heat in their preparation has a favorable influence in making food more easy of digestion rather than affecting the completeness of the process.

"A study of the results of two series of digestion experiments with man showed that when milk formed a part of the ration the nutrients, especially protein, are more completely digested than when no milk is consumed. According to the author:

"When milk was used in a ration, with bread, butter, beans, eggs, and potatoes, all of the protein of the milk was digested, and in addition 4.91 per cent more of the protein of the other foods with which it was combined was digested than when the milk was omitted."

This suggested that the enzymes present in milk might assist in the digestion of other foods, therefore the author studied the digestive power of milk by treating samples of toast weighing 10 gm. with 10 cc. of milk and 90 cc. of water for 2 hours at a temperature of 98.5°. It was found that on an average 12.25 per cent of the total protein of the bread present was digested. When pasteurized milk was used, 7.6 per cent of the protein was digested. On account of the coagulation of the albumen, the author states that experiments could not be made with sterilized milk. "The soluble ferments of milk evidently exert a material influence as digestive agents, and fresh milk is a digestive fluid, as well as a food of high nutritive value."

The experiments on the digestibility of oatmeal and the comparative digestibility of bread made from flour from different grades have been noted from another publication (E. S. R., 13, p. 370).

Report on a standard emergency ration, M. E. JAFFA (*California Sta. Rpt. 1899-1901, pt. 1, pp. 54-56*).—A healthy young man (one of the California University students) lived for 5 days on an emergency ration which is marketed in the form of tablets. He lost weight, and in other ways, according to the author, showed a condition of lowered vitality. The conclusion is drawn that the ration did not supply sufficient nourishment. The composition of the ration is reported. In the author's

opinion, protein and nitrogen-free nutrients were not present in the proper proportion, while the total nutrients furnished were lower than the commonly accepted dietary standard calls for.

The diet of native laborers, J. M. ORPEN (*Salisbury, Rhodesia: Argus Printing and Publishing Company, Ltd., 1902, pp. 12*).—In this paper, presented before the Salisbury branch of the Rhodesia Scientific Association, the author discusses food and diet with especial reference to native laborers. He calls particular attention to the extended use of fermented foods and beverages by them, and believes that such materials serve a useful purpose.

Hygiene of food and digestion, H. STAEDTLER (*Hygiene der Nahrungsmittel und der Verdauung. Leipzig: F. Leineweber, 1902, pp. 103*).—Diseases of the digestive system due to errors in diet are discussed, as well as food as a remedial agent in such diseases, and related topics.

The effect of fineness of division and of cooking food upon its digestibility, K. B. LEHMANN, F. MEYER and M. GÖRTZ (*Arch. Hyg., 43 (1902), No. 2, pp. 123-133, figs. 2*).—The comparative digestibility of coarsely and finely divided cooked egg white, meat and cheese, and of coarsely and finely divided vegetable foods, including coarse bread, peas, vegetables, macaroni, etc., was tested by methods of artificial digestion. In some cases the vegetable foods were raw and in others they were cooked. Generally speaking, the digestibility increased with the fineness of division, and the authors believe that the importance of thorough mastication has been generally underestimated rather than overestimated. The increased digestibility due to cooking the vegetable foods was also very marked. Coarse food, such as graham bread, which is not finely divided by chewing, the authors believe from their experiments would remain a long time in the stomach and would be digested slowly. This would account for the feeling of satiety observed for a considerable time after such food is consumed, and on account of which the nutritive value of coarse food has been often overestimated.

Testing the baking quality of flour, G. BARTH (*Ztschr. Untersuch. Nahr. u. Genussmit., 5 (1902), No. 10, pp. 449-457, fig. 1*).—The value of a special apparatus (which is described) for determining the baking quality of flour was tested, and different sorts of flour were compared. The apparatus was not regarded as sufficiently accurate. The author points out that estimating the amount of gluten and the amount of water which it will absorb furnishes a means of judging the quality of flour. The glassy appearance of wheat is also an indication of the baking quality, the two things being directly proportional.

A study of the banana and its future possibilities, G. C. NUTTALL (*Longman's Mag., 1902, No. 232, pp. 320-325*).—The author discusses the food value of bananas and banana flour, and calls attention to the fact that green bananas, banana shoots, and the starchy pith of the stalk are used as vegetables. The article contains the erroneous statements so frequently made regarding the high food value of the banana, which are evidently based on a comparison of the composition of the dry matter of the banana and the fresh material of flour and potatoes.

Concerning the toxic and injurious properties of certain coal-tar colors, G. W. CHLOPIN (*Ztschr. Untersuch. Nahr. u. Genussmit., 5 (1902), No. 6, pp. 242-245*).—The author was the subject of some of the tests reported; others were made with a dog. The conclusion was drawn that metanil yellow, in doses of 0.2 gm. in the case of a man, and from 2 to 3 gm. daily in the case of a dog, was not poisonous, and therefore may perhaps be regarded as a harmless coloring matter. Mandarin (orange II), according to the experiments, must be regarded as poisonous.

Inspection and analyses of foods, M. A. SCOVELL and R. M. ALLEN (*Kentucky Sta. Bul. 100, pp. 83-147*).—The State pure-food law is quoted, as well as the

improved form of food guaranty, and details are given of the samples analyzed under the State pure-food law during the year. The following table, which summarizes the work, shows that the percentage of adulteration was high:

Summary of analysis under pure-food law.

	Not found adulterated.	Adulterated.	Total.
Baking powder.....	5	36	41
Canned goods.....	12	12
Butter.....	116	5	121
Jellies, preserves, etc.....	8	7	15
Milks (sweet and butter).....	300	30	330
Minced meats.....	2	9	11
Oleomargarine.....	82	82
Olive oil and lard.....	13	1	14
Tomato catsup, sauces.....	3	50	53
Syrups, sugar, honey.....	15	15
Soda-fountain drinks.....	43	26	69
Feeding stuffs.....	4	1	5
Total number found adulterated.....	227
Total number not found adulterated.....	521
Total number of samples analyzed.....	748

The use of the serum diagnosis in the examination of foods, G. VON RIGLER (*Oesterr. Chem. Ztg.*, 5 (1902), No. 5, pp. 97-100).—Taking advantage of the fact that after inoculation for a time with the blood of a given species of animal, the blood of the inoculated animal gives a characteristic reaction with the blood used for inoculation, the author studied the possibility of identifying by these means different sorts of flesh foods and different kinds of sugar. The results obtained are not regarded as definite. The author believes, however, that the method is worthy of the attention of physiological chemists.

Serum agglutination and its value for the examination of meat, MIESSNER and HERBST (*Arch. Wiss. u. Prakt. Thierh.*, 1902, No. 3-4; *abs. in Ztschr. Fleisch u. Milchhyg.*, 12 (1902), No. 8, pp. 241, 242).—The authors concluded from their investigations that the serum agglutination method furnishes a simple and accurate means of detecting mixtures of beef with horse or dog flesh.

A new method of preserving eggs (*Bul. Soc. Vaudo. Agr. et Vit. [Lausanne]*, 1902, No. 151, pp. 28, 29).—The method described consists in immersing the eggs for a quarter of an hour in water of 35° C., then immersing them in boiling water for 5 seconds, and storing in wood ashes, chaff, bran, or sawdust.

ANIMAL PRODUCTION.

Preliminary report on steamed silage, J. WITHERCOMBE and A. L. KNISELY (*Oregon Sta. Bul.* 72, pp. 187-201, figs. 2).—Silos were filled with corn fodder in the usual way and immediately treated with steam for some time. The steamed silage kept well. Its chemical composition was studied, as well as that of silage treated with salt, with and without the addition of water, and silage which had received no special treatment. Since the work is regarded as of a preliminary nature, no definite conclusions are drawn, but the authors regard the practice of steaming silage as promising.

Concerning the keeping qualities and properties of peat-molasses feeds, A. HERZFELD, O. SCHREFELD, and K. STIEPEL (*Ztschr. Ver. Deut. Zuckerind.*, 1902, No. 554, II, pp. 207-217).—From experiments which are reported in detail, the following conclusions are drawn. A water content of over 25 per cent does not lower the keeping qualities of peat-molasses mixtures. Long-continued heating at a high tem-

perature causes an increase in the invert sugar content, but does not lower the keeping qualities. The invert sugar is formed only in acid peat molasses, and may be best prevented by using alkaline molasses. The peat possesses some antiseptic properties since peat-molasses mixtures ferment more slowly than molasses solutions. Owing to the fact that peat absorbs materials other than sugar, peat-molasses mixtures have a higher purity quotient and a better flavor than molasses itself.

Experiments on the changes induced by micro-organisms in feeding stuffs and food. I. The changes induced by molds in feeding stuffs rich in fat, A. SPIECKERMANN and W. BREMER (*Landw. Jahrb.*, 31 (1902), No. 1, pp. 81-128, pls. 2).—Noted from another publication (E. S. R., 13, p. 581).

Concerning the changes which micro-organisms induce in feeding stuffs and foods on storing, J. KÖNIG (*Landw. Vers. Stat.*, 57 (1902), No. 1-2, pp. 71-85).—Noted from another publication (E. S. R., 13, p. 581).

The rôle of sugar in nutrition, L. GRANDEAU (*Jour. Agr. Prat.*, n. ser., 4 (1902), No. 28, pp. 37, 38).—A discussion of the value of sugar as part of the ration of farm animals.

Food value of pie melons, M. E. JAFFA (*California Sta. Rpt. 1899-1901*, pt. 1, pp. 52-54).—Analyses are reported of the flesh and rind, and seeds of the pie melon. The feeding value of the pie melon is briefly discussed and compared with that of other succulent feeds.

Foods, feeding stuffs, and fertilizers, M. E. JAFFA (*California Sta. Rpt. 1899-1901*, pt. 1, p. 51).—Brief statements concerning the analyses made at the station of foods and food materials, dairy products, and fertilizers.

Analyses of concentrated commercial feeding stuffs made in connection with the State inspection, H. J. WHEELER and A. W. BOSWORTH (*Rhode Island Sta. Bul.* 84, pp. 168-176).—The materials analyzed include cotton-seed meal, gluten meal of different brands, linseed meal (old and new process), gluten feed, cereal breakfast food by-products, hominy, hominy meal, hominy chop, mixed commercial feeds, barley sprouts, middlings, beef scrap, and animal meal.

Licensed concentrated feeding stuffs, F. W. WOLL and A. VIVIAN (*Wisconsin Sta. Bul.* 92, pp. 12-20).—The State feeding stuff law is quoted, and data showing the amount of protein and fat guaranteed by the manufacturers in a number of feeding stuffs on sale in the State are given.

Experiments in wintering and fattening steers, H. J. WATERS (*Bul. Missouri State Bd. Agr.*, 1 (1901), No. 6, pp. 14-26).—Tests on the comparative merits for winter feeding of steers of different sorts of coarse fodder, the value of balanced rations, and feeding in barns, sheds, and open lots are briefly reported. In the first trial on the comparative merits of different sorts of coarse fodder, timothy hay, cowpea hay, and corn fodder and clover hay in nearly equal amounts, were compared with 3 lots of 4 steers each, in a test beginning in December and covering 119 days. In every case corn was fed with the coarse fodders. The average daily gain per steer on timothy hay ration was 1.69 lbs.; on the cowpea hay ration, 2.64 lbs.; and on the clover hay and corn fodder ration 1.94, the grain required per pound of gain being 11.51, 8.31, and 11.29 lbs., respectively.

In the second test timothy hay, clover hay, cowpea hay, clover and corn fodder, and clover and wheat straw were compared with 5 lots of 4 steers each, in a test beginning in January and covering 105 days, corn being fed with the coarse fodder as before. The average daily gain per steer in the 5 lots was 1.97, 2.84, 2.84, 2.85, and 2.68 lbs., respectively, the corresponding amount of grain eaten per pound of gain being 11.19, 8.69, 8.65, 8.30, and 9.21 lbs., respectively.

The author notes that the addition of clover hay or cowpea hay to the ration induced better and cheaper gains. He says in effect that the steers consuming these hays have always carried to market far more finish, a much better coat, a finer bloom, and would readily have outsold any other lot in these experiments. Even

when the coarse fodder was a mixture of corn fodder or wheat straw, with either clover or cowpea hay, the effect on the appearance of the steers was quite as marked as upon gain in weight.

The value of a properly balanced ration was studied with 4 lots of 4 steers each, in a test beginning in December and covering 104 days. Lots 1, 2, and 3 were fed 6 lbs. per head daily of corn with timothy hay, clover hay and corn fodder, and cowpea hay, respectively, in addition. Lot 4 was fed cowpea hay only. On these rations there was an average daily gain of 0.64, 0.88, 1.54, and 0.56 lb., respectively. In a second test covering 80 days, made under similar circumstances, the coarse fodders compared were timothy hay, clover hay, millet hay, sorghum hay, and clover and corn fodder, 6 lbs. of corn per head daily being consumed in each case in addition to coarse fodder. The average daily gain per steer in the 5 lots was 1.00, 2.00, 0.37, 0.52, and 1.35 lbs., respectively. The author calls attention to the fact that the use of leguminous hay to balance the ration was very satisfactory.

Four tests on the effect of shelter on the gains made by steers fed heavy rations in winter are reported. In every case the lots compared were fed similar rations of corn and hay. In the first test the average daily gain of steers fed in barns was 1.47; of those fed in sheds, 1.72 lbs. In the second trial corresponding gains were 1.85 and 2.3, while similar gains made by steers fed in an open lot were 2.29 lbs. In the third test steers in barns gained on an average 1.67 per head daily; those fed in open sheds 1.69; and those fed in open lots 1.78. In the fourth test the corresponding values were 1.83, 1.97, and 2.09 lbs. The author calls attention to the fact that better gains were made by the steers fed in sheds and open lots than by those fed in barns, a result which was not expected. Inquiries bearing upon the subject were sent to a large number of feeders; over half of those who replied favored feeding in open sheds, some 18 per cent favored feeding in barns, and some 23 per cent feeding in open lots. As will be seen, the experience of practical feeders, as shown by these figures, was in accord with the results of the tests.

Feeding problem this winter, H. J. WATERS (*Bul. Missouri State Bd. Agr., 1 (1901), No. 7, pp. 16-34, figs. 3*).—Winter feeding and the comparative value of different feeding stuffs are discussed and a number of feeding tests with cattle are quoted. On the basis of the data the author suggests rations which he believes will prove satisfactory. Tests on the comparative value of timothy hay, corn fodder (whole, shredded, and ensiled) are also reported, which covered in every case about 3 months and were made with steers weighing about 900 lbs. each. In no case was grain fed with the coarse fodder. The data reported include the results of one test with shredded corn fodder fed with clover hay, two with shredded corn fodder and with ensiled corn fodder, and three with timothy hay and whole corn fodder.

On an average 20.2 lbs. of timothy hay was eaten per head daily, the total gain being 30.7 lbs. The average amount of whole corn fodder eaten was 25.8, and on an average there was no gain or loss. On an average 20.6 lbs. of shredded corn fodder per head daily was eaten, and there was an average loss of 11.6 lbs. On ensiled corn fodder the average amount eaten was 58.4 lbs., the average gain 44 lbs. Similar values for the shredded corn fodder and clover hay ration were 25.2 lbs. and 58.4 lbs. The author notes that satisfactory results were obtained with ensiled corn fodder and with the shredded corn fodder and clover hay ration. A number of his other conclusions follow:

"It is clearly shown that yearling steers may be carried through the winter with practically no loss in weight and in some cases with a little gain on nothing but whole corn fodder. With good timothy hay such cattle will make a small gain. . . . From these trials it is perhaps safe to estimate that timothy hay is worth fully twice as much as whole corn fodder pound for pound for wintering young cattle. . . .

"When whole fodder and shredded fodder are compared the difference is surpris-

ingly small, and instead of the shredding process having increased the feeding value it seems to have diminished it. . . .

"Shredding fodder undoubtedly relieves the farmer of some very disagreeable work in hauling the coarse stalks in bad weather, overcomes the necessity of digging the material out of the snow in winter, and makes it possible to feed the material in the barn and use the portion refused by the stock for bedding. The manure may be handled much more conveniently, and in short the greatest drudgery of winter feeding is removed.

"On the other hand the farmer with the regular force he would probably keep in any case can handle the fodder crop without additional cost or outlay if it be fed whole, whereas if it be shredded or siloed the work is concentrated into a few days and much extra labor must be hired for the purpose. This is the chief argument against shredding, especially since the results of the experiments already quoted fail to show an increased feeding value due to the process. . . .

"Unquestionably the siloing process increases the palatability of the material, [and] greatly reduces the waste by inducing the stock to eat practically all of the stalk. Herein lies the chief advantage of silage, for experiments have clearly shown that the material is not more fully digested after it has been made into silage than if well cured and fed dry.

"Finally it seems safe to say that corn fodder is too cheap in the ordinary year and likely to be too cheap in the great corn belt for many years to come to warrant the expenditure of much money in increasing its feeding value. The investment of this extra money in cutting more fodder will likely pay better than putting it on the amount that is now ordinarily cut."

Steer feeding, H. T. FRENCH (*Idaho Sta. Bul. 32, pp. 71-76*).—To learn something of the possibility of feeding steers economically in stalls, a test covering 56 days was made with three lots of 2 animals each. During the first four weeks of the test, lots 1 and 2 were fed chopped wheat, and lot 3 wheat and bran, 2:1. During the following two weeks all the lots were fed bran, chopped rye, and chopped wheat in different proportions. During the last two weeks of the test lot 1 was fed barley and shorts 1:1; lot 2 barley and wheat 1:1; and lot 3 barley and shorts 1:1. In addition to the grain, the steers were fed hay and silage. The average results of the test follow.

Results of steer feeding test.

	Weight at beginning of test.	Average daily gain per head.	Feed eaten per pound of gain.			Cost of feed per pound of gain.
			Grain.	Hay.	Silage.	
	Pounds.	Pounds.	Pounds.	Pounds.	Pounds.	Cents.
Lot 1	2,170	2.10	4.05	2.51	13.72	4.39
Lot 2	1,830	1.78	3.66	3.71	9.69	4.39
Lot 3	2,000	1.38	6.51	3.26	23.61	7.05

According to the author there was on an average a net profit of \$15.13 per steer. "The barley shorts and the barley chopped wheat combinations constitute an excellent grain ration for steers. The chopped rye was not especially well relished by the steers. Chopped wheat alone is a good grain ration when combined with corn silage and hay. The conditions in this locality, so far as affected by climate and food supply, are favorable for stall feeding cattle."

Sheep-feeding experiments, W. J. KENNEDY and F. R. MARSHALL (*Iowa Sta. Bul. 63, pp. 178-185*).—The possibility of profitably fattening sheep under local conditions was studied, two feeding tests being reported. The first had to do with the problem of finishing Western lambs on grass and grains for the early summer market

and was carried on with 4 lots of 15 sheep each, and 1 lot of 101. The sheep cost, including freight, 4.25 cts. per pound. All the lots were fed on blue grass pasture. Lot 2 was fed corn, lot 3 oats, lot 4 barley, and lot 5 corn and oats in addition to the pasture. In the case of the latter lot, the oats were fed only for 30 days of the 60 days during which this lot was studied. The other lots were fed for 63 days.

The sheep in lots 1 to 4, inclusive, weighed a little under 81 lbs. each at the beginning of the trial; those in lot 5 some 75 lbs. each. The average daily gain of the 5 lots was 0.41, 0.46, 0.42, 0.39, and 0.44 lb. The grain consumed per pound of gain in lots 2 to 5 was 1.7, 1.86, 1.99, and 2.05 lbs. The cost of feed per pound of gain in the 5 lots was 1.05, 1.95, 2.36, 2.75, and 2.26 cts., respectively. According to the authors, the test indicates that sheep will make practically as large gains on grass alone as on grain and grass. "Corn at 33 cts. per bushel is a more economical grain to feed sheep on grass than oats at 23 cts. or barley at 40 cts."

"Mutton can be produced much more economically during the summer months on grass alone or grain and grass than it can be produced by feeding grain and hay during the fall and winter months. The feeder can oftentimes purchase half-fat lambs during the latter part of April or the first part of May, and by grazing them for from 40 to 60 days realize a good profit, due to the advance in market prices during the latter part of June and the first of July over those ruling in April and the first part of May."

In the second test the problem of finishing Western wethers for early winter market was studied with 7 lots, special attention being paid to the feeding value of emmer (commonly called speltz). Lots 1 to 4 contained 10 sheep each. There were 15 in lots 5 and 7, and 30 in lot 6. Lots 1 to 4 were fed clover hay, lot 5 grass and rape, and lots 6 and 7 grass. In addition lot 1 was fed emmer, lot 2 soy beans, lot 3 corn and gluten feed 2:1, and lots 4, 5, and 6 corn. All these lots also received a little bran during the first few days of the test. The animals receiving grain were given about $\frac{1}{4}$ of a pound per head daily at the beginning of the test, which covered 56 days, the amount being increased as the test progressed. The average weight of the sheep in the different lots was not far from 110 lbs. The average daily gain was 0.46, 0.41, 0.45, 0.45, 0.45, 0.41, and 0.28. The grain eaten per pound of gain in lots 1 to 6 was 3.26, 2.29, 3.0, 3.02, 2.41, and 3.01 lbs., respectively, in addition to a little bran. The clover hay eaten by lots 1 to 4 was a little over 4 lbs. per pound of gain. According to the author, the data obtained indicated that for sheep-feeding purposes when corn is worth 40 cts., emmer is worth 26 $\frac{1}{2}$ cts. per bushel of 35 lbs. When corn is worth 40 cts., soy beans, if they compose the sole grain ration, are worth but 45 cts. per bushel. Corn alone when fed in conjunction with clover hay produced larger and more economical gains than the ration of corn, gluten feed, and clover hay. Sheep can be fattened more economically on grass and corn or on grass alone than on emmer and clover hay or the other rations tested. "Soy beans on account of their high protein content should not form the sole grain ration in conjunction with clover hay. Pound for pound corn is more valuable than emmer. Mutton can be produced economically on grass alone during the summer months."

Feeding lambs, H. T. FRENCH (*Idaho Sta. Bul. 32, pp. 77-86, pls. 4*).—Three feeding tests with lambs are briefly reported. In the first 20 selected grade lambs, averaging 75 lbs. each in weight, were fed 36 days to fit them for the Christmas market. They were kept in a box stall and given 1 $\frac{1}{2}$ lbs. per head daily of whole wheat and oats, in addition to coarse fodder ad libitum. There was an average daily gain of 0.15 lb., and a calculated profit of 87 cts. per head, not deducting the cost of the coarse fodder. In the second test 59 grade lambs, weighing somewhat less than those used in the first trial, were fed for 103 days a ration of pea hay and clover hay, with some corn silage and roots, in addition to a grain ration of 1.1 lbs. of oats and wheat, 1:2. They were kept in box stalls, but were allowed to run in the yard once a day when they were watered. The average daily gain was 0.2 lb. per head, the

grain eaten per pound of gain being 5.36 lbs. The lambs were sold for \$21.35 more than they originally cost, plus the cost of the grain eaten.

The comparative merits of grade Shropshire and Oxford down lambs were tested in the third trial with two lots, one containing 10 lambs of the former breed and the other 10 of the latter. All the lambs were kept in pens and feed for 16 weeks a grain ration consisting of whole oats and wheat, 2:1, in addition to clover hay, a mixture of pea hay and wild oats, and mangel-wurzels and carrots mixed. During the last 4 weeks they were also given some corn silage. At the beginning of the trial the average weights of the lambs in the two lots were 75 and 70 lbs., respectively. During the test the average daily gains were 0.24 and 0.20 lb., respectively. Considering the test as a whole, the cost of a pound of gain was 6.1 cts. It was calculated that there was a total profit of \$1.08. Five lambs in each lot were slaughtered; the dressed weight being on an average 52.3 per cent of the live weight.

"There was no profit in feeding the lambs under the conditions prevailing in this experiment, except such as would result from feeding the coarse products of the farm instead of selling them off the farm. We believe it is better to feed lambs than to sell them for mutton in the fall, where more favorable conditions for feeding can be obtained. If lambs are fed in winter in this section, they should have an open, dry shed in which to run a portion of the time. An open yard with no roof will not do for sheep here on account of the mud. It will pay, where more exercise can be given, to feed a heavier grain ration, and make the feeding period shorter.

"While the results in this experiment are somewhat negative, yet they will serve as a guide for further work, and we shall repeat the work under other conditions and at other seasons of the year."

The author also reports analysis of chopped rye, shorts, barley, millet seed, corn silage, and pea hay.

The food value of sugar beet, A. D. HALL (*Jour. Southeast. Agr. Col., Wye, 1902, No. 11, pp. 100-103*).—Using two lots of 13 sheep each, the comparative value of mangel-wurzels and sugar beets was tested for 8 weeks. In addition to the roots, each sheep received per head per day a pound of a mixture of oats, maize, and linseed cake. All the animals were folded on grass land and frequently shifted to secure satisfactory pasturage. The average weight of the sheep fed mangel-wurzels at the beginning of the trial was 123 lbs.; of those fed sugar beets 122 lbs. The average increase of the two lots was 30 and 22 lbs., respectively. According to the author the wool of the sheep fed mangel-wurzels was superior to that of the other lot. The conclusion is drawn that sugar beets can not profitably replace mangel-wurzels as a fodder crop for sheep.

A comparison of feeds for pigs, D. W. MAY (*Kentucky Sta. Bul. 101, pp. 152-164*).—The comparative merits of feeding corn alone and combined with other materials were tested with five lots, each containing 4 Berkshire grade pigs. Lot 1 was fed shelled corn alone; lot 2, shelled corn and corn and soy bean silage; lot 3, shelled corn and shelled soy beans, 2:1; lot 4, shelled corn and dried distillery grains, 1:1, and lot 5, shelled corn and dried distillery grains, 2:1. The pigs weighed on an average about 140 lbs. each at the beginning of the trial. In the ten weeks of the test the average daily gain in the different lots was 0.70, 0.87, 1.16, 1, and 0.63 lbs., respectively. At the conclusion of the test proper the feeding was continued for a supplementary period of 3 weeks. During the first week all the pigs were fed shelled corn and skim milk, those in lots 1 and 4 receiving $\frac{1}{2}$ lb. of cotton-seed meal per head daily in addition. During the second week all the pigs were fed hominy meal and tankage, those in lots 2 and 3 receiving $\frac{1}{4}$ lb. and those in lot 5 $\frac{1}{2}$ lb. of cotton-seed meal per head daily. During the third week the basal ration again consisted of shelled corn and tankage, the pigs in lot 1 receiving in addition $\frac{1}{4}$ lb. and those in lot 4 $\frac{1}{2}$ lb. of cotton-seed meal per head daily. The average daily gain without cotton-seed meal was 1.4 lbs. and with cotton-seed meal, 1.62 lbs. On

the former ration 3.95 lbs. of feed and on the latter 3.47 lbs. was required per pound of gain. The author's conclusions follow:

"The results of these experiments, like those of several previously made, indicate that in feeding pigs corn should be combined with other feeds to get the best returns. Experiments indicate that silage can not be profitably substituted for a part of the grain ration with pigs. In this experiment it was fed in addition with some profit, giving quicker gains and keeping the animals in better condition.

"Soy beans made an excellent pig feed mixed with corn in the proportion of 1:2. Being rich in protein it is recommended as an especially efficient addition to the ration when corn composes the larger part. Dried distillery grains proved to be a poor pig feed except in small proportions. When fed as $\frac{1}{3}$ or $\frac{1}{4}$ of the ration with corn it was unprofitable. Where it composed $\frac{1}{3}$ of the ration very good returns were obtained. Cotton-seed meal may be profitably used to finish hogs for market. In such cases it may be safely fed in quantities of $\frac{1}{2}$ lb. per pig daily and then omitted during periods of alternate weeks.

Analyses are reported of the shelled corn, dried distillery grains, soy beans, corn and soy bean silage, and hominy meal used in the above test.

Growing swine of various breeds and crosses, T. SHAW (*Minnesota Sta. Bul.* 73, pp. 73-108, figs. 21).—In the first of two tests of the comparative gains made by different breeds and crosses of pigs, the following were represented: Pure-bred Poland Chinas, Poland Chinas (corn-fed), pure-bred Tamworths, large improved Yorkshires, cross-bred Tamworth-Poland Chinas, large improved Yorkshire-Poland Chinas, second cross large improved Yorkshire-Berkshires, third cross large improved Yorkshire-Berkshires, 3 pigs of each breed constituting a lot in every case except the cross-bred Tamworth-Poland Chinas, when only two were used. Beginning when they were 10 weeks old the pigs were fed for 28 weeks skimmed milk, ground grain, and during the season some green feed (rape, corn, and mangel-wurzels). The grain consisted of shorts and corn 3:1, shorts, corn, and barley 2:1:1, and corn and barley 1:1, on an average 3.43 lbs. of grain being consumed per head daily. Considering the ration as a whole, meal constituted a little over 70, skimmed milk a little over 9.5, and green feed a little less than 20.5 per cent. At the beginning of the test the pigs weighed on an average 44.12 lbs., and the average daily gain was 0.89 lb. per head. The greatest gains (131 and 128 lbs. respectively) were made by the second cross Yorkshire-Berkshires and the Yorkshire-Poland Chinas, and the least gain (84 lbs. and 88 lbs. respectively) by the corn-fed Poland Chinas and the Poland Chinas fed the same ration as the majority of the lots. Gain was most economically made by the Tamworths and the large improved Yorkshires, costing, respectively, 2.01 and 2.02 cts. per pound; the most expensive gains, costing 2.52 cts. per pound, were made by the pure-bred Poland Chinas.

The second test was made under the same conditions as the first. The breeds and crosses represented were as follows: Pure-bred Tamworths, large improved Yorkshires and Poland Chinas, cross-bred, large improved Yorkshire-Berkshires, large improved Yorkshire-Poland Chinas, large improved Yorkshire-Poland Chinas (Minnesota bred dam), Tamworth-Poland Chinas, and third cross large improved Yorkshire-Berkshires. At the beginning of the test the weight was 48.38 lbs. each on an average. The average gain was 1.11 lbs. per head daily. The greatest gain (166 lbs.) was made by the Yorkshire-Poland Chinas, and the least gain (119 lbs.) by the pure-bred Tamworths. The range in the cost of a pound of gain was from 2.11 cts. in the case of the Yorkshires to 2.48 cts. in the case of the pure-bred Poland Chinas. Some of the conclusions drawn from the tests as a whole follow:

"These experiments do not sustain the view that the results will be less satisfactory from each succeeding cross of Yorkshire on Berkshire. Swine of the lard-producing types are not more cheaply grown up to the age of 196 days than swine of the bacon-producing types. Pork can be made more cheaply from swine of the

large improved Yorkshire and Tamworth breeds than from the Poland Chinas or what may be termed the lard types. The cross of the large improved Yorkshire and Tamworth breeds upon the Poland China sows of the corn-reared types produces animals at once vigorous, shapely, 'growthy,' and relatively more profitable than pigs from the aforementioned sows. During the two years covered by the experiment pork was produced with six lots of pigs with various blood lines subsequent to the weaning period at an average cost for food 2.24 cents per pound."

Molasses as a food for army horses, G. E. GRIFFIN (*Twentieth Century Farmer*, 1902, No. 69, p. 2).—The feeding value of molasses was tested with 8 army horses in Porto Rico, this material being fed with chopped grass, in accordance with the local custom. The molasses ration was gradually substituted for the usual ration of oats and hay until the animals were fed on an average 35 lbs. of grass and 14 lbs. of molasses per head daily. "The molasses was diluted with 25 per cent of water and mixed with the chopped grass as far as possible; where all could not be mixed it was dissolved in water and offered as a drink, which was partaken of during the night out of the bucket left in each manger." The molasses ration was continued for some 5 months. At first all the horses lost weight, but after a time gained in weight from 35 to 68 lbs. The average cost of the grass and molasses ration was 15 cts. per day, and that of the hay and oat ration 27 cts. Favorable results were also observed when molasses and grass were fed instead of the ordinary ration to several horses which were out of condition.

From his tests, the author concludes that 35 lbs. of grass and 13 to 15 lbs. of molasses daily per 1,000 lbs. live weight is sufficient to maintain a horse in good working condition in a climate like that of Porto Rico. Upon this ration the animals tested did more work than on the usual ration, while their condition and coat improved; there was less tendency to perspiration, the wind decidedly improved, the urine increased slightly. A tendency to constipation was observed but was readily overcome by feeding bran. Sudden changes from the dry ration to the molasses ration did not prove injurious, nor did they cause digestive derangement. A change from the molasses ration to ordinary dry ration should be made gradually. The disadvantages noted were as follows: "Molasses attracts insects, notably flies and ants; it sticks to the animal's coat, smears his face and breast, halter and halter strap, soils the clothing and equipment of the men, and causes some trouble and delay in mixing it with the grass, which must be cut fine."

Poultry feeding, H. J. WHEELER (*Rhode Island Sta. Bul.* 84, pp. 155-167).—The principles of poultry feeding are discussed.

Plump v. shrunken wheat as food for laying hens, M. E. JAFFA (*California Sta. Rpt.* 1899-1901, pt. 1, pp. 56, 57).—Analyses are reported of shrunken and plump wheat. On account of its high protein content the author believes the shrunken would prove satisfactory as a food for laying hens.

DAIRY FARMING—DAIRYING.

Soiling crop experiments, C. B. LANE (*New Jersey Stat. Bul.* 158, pp. 18, pls. 4).—This bulletin summarizes the results of experiments during 6 years in regard to providing a uniform supply of succulent food for dairy cows from May 1 to November 1. Data obtained each year have been published from time to time in the reports of the station. The value of different crops for this purpose is discussed and methods of culture are given. Alfalfa is considered the most promising crop. During 5 years the herd averaged 21 cows and was fed soiling crops for 6 months and silage for 6 months each year. On soiling crops the average production per cow was 3,423 lbs. of milk and 172.7 lbs. of butter, and on silage 3,050 lbs. of milk and 157.4 lbs. of butter.

Cost of raising heifers, A. T. NEALE (*Delaware Sta. Rpt. 1901, pp. 28-30*).—The results of tests indicate that under Delaware conditions \$40 to \$45 barely covers the cost of raising heifers to the age of 25 to 30 months. A special study is to be made of this subject.

A new method of milking, J. J. HEGELUND (*Ber. Landökon. Konsulentverk., 1900, pp. 31-39*).—The method of milking originated by the author and described by him in this report in outline, has created great interest of late in Scandinavian dairy circles. The main point of the method consists in following up the regular milking by a system of manipulations of the udder which will remove all the milk remaining in the cavities and ducts of the udder at the time of the milking. The ordinary method of stripping fails to remove this portion, which is doubly valuable on account of its high fat content. The author does not give any data in this report as to the increase in yield of milk obtained by the new method, but others have stated it to be from about 1 to 3 lbs. a day per head. The following synopsis of the method of milking recommended by the author will explain its essential features:

The milking is done with dry hands and with the whole hand, the two fore teats being milked first. The milking is begun by lifting the hands alternately with a pressure against the udder, the teats being held loosely with the hands. When considerable milk has come down, each hand is lowered until the teat has its natural length, without being stretched. As the hand is lowered the teat is pressed from above downward with a gradually increasing pressure, and a continuous stream of milk is thus pressed out of the teat. At first the milking is done slowly, taking care that the teat is not stretched; stretching will cause the cow to hold up her milk. When the milk flows readily, the milking is proceeded with as rapidly as the milker can possibly do it, until but very little milk is obtained. Interrupting the milking from the time the milk flows freely until the udder is emptied must be guarded against. As soon as a good flow of milk comes, the pressure against the udder mentioned above may be omitted. When only a thin stream of milk is obtained by this manipulation, the hand is again opened above, and while the lower fingers loosely hold the teats, thus remaining at the place most convenient for pressing the milk out of the teats, the hand is pressed against the udder, or its lower part is grasped so as to more easily secure a full stream of milk. When the fore teats do not give more milk, the hind teats are handled in the same way, but without beginning with the pressure against the udder.

The hind teats being emptied, the "clean milking" is begun. The fore teats are again grasped and the hands lifted to around the lower part of the fore quarters, taking hold of this, thumb on one side and the other fingers on the other. The milk is pressed into the milk cistern by means of a light pressure, and from there out of the teat, emptying the fore quarters. In milking the hind quarters the hand grasps with each grip well up around the hind part of the quarters.

An "after-milking" now takes place, which is conducted in three different manipulations in the following manner: *First manipulation*: The right quarters are pressed against each other (if the udder is very large only one-quarter is taken at a time), with the left hand on the hind quarter and the right hand in front on the fore quarter. The hands are now pressed toward each other, while the milker at the same time lifts them toward the body of the cow. This pressing and lifting is repeated three times, the milk collected in the milk cistern is then milked out, and the manipulation repeated until no more milk is obtained, when the left glands are treated in the same way. *Second manipulation*: The glands are pressed together from the outside. The fore quarters are milked, each by itself, by placing a hand, with fingers spread, on each side of the quarter; the hands are pressed against each other and the teats then milked. When no more milk is obtained by this manipulation the hind quarters are milked by placing a hand on the outside of each quarter, likewise with

fingers spread and turned upward, but with the thumb just in front of the hind quarter. The hands are lifted and grasp into the gland from behind and from the side, after which they are lowered to draw the milk. The manipulation is repeated until no more milk is obtained. *Third manipulation:* The fore teats are grasped with partly closed hands and are lifted with a push up toward the body of the cow, both at the same time, by which method the glands are pressed between the hands and the body. The milk is drawn after each three pushes. When the fore teats are emptied the hind teats are milked in the same manner. The milking is then finished.—F. W. WOLL.

The new method of milking, C. SÖNDERGAARD (*Den ny malkemetode. Odense, Denmark, 1901, pp. 63, figs. 13*).—The book describes the new method of milking cows introduced in Denmark within the last two years by two Danish agricultural teachers, Hegelund and the author. The methods advocated by the two men differ somewhat, but are based upon the same principle, namely, to secure the most thorough milking by means of careful stripping, preceded by certain manipulations of the udder which will bring down the last traces of milk secreted at the time of milking. According to the author, the extra manipulations of the udder will bring an increase in the quantity of milk drawn of 1 lb. per head per day, or about 300 lbs. per cow annually. Reports in the Scandinavian agricultural and dairy press are on the whole very enthusiastic as to the value of the new method of milking and generally more than bear out the claims for increased yields brought about by its introduction in dairy herds.^a The book contains a popular description of the udder, the process of milk secretion, and the new method of milking, with half-tone reproductions of photographs showing the various steps in the manipulation of the udder. Discussions of udder and milk diseases, drying off before calving, milking two or three times a day, and brief suggestions as to the general care of dairy cows are also given in the book, making it a complete treatise on the subject of milk production.—F. W. WOLL.

The Hegelund method of milking, J. O. AASHAMAR (*Norsk Landmandsbl.*, 20 (1901), No. 43, pp. 529-531).

Report on the churnability of cream, trials carried out at the society's show at Croydon, May, 1901, E. MATHEWS (*Jour. Bath and West and Southern Counties Soc. [England]*, 4. ser., 12 (1901-1902), pp. 107-119).—The milk used in the trials here reported was obtained from Shorthorn, Jersey, Guernsey, and Kerry cows and separated under identical conditions. Sweet cream from morning's milk and ripened cream from evening's milk were churned at 54, 58, and 62° F. and also at 54° with the addition of water at 75° when the butter was on the point of coming. Of the estimated amount of butter in the milk the percentages obtained from unripened cream for the different breeds were as follows: Shorthorn 40.9, Jersey 55.7, Guernsey 47, and Kerry 57.1. The corresponding percentages obtained from ripened cream were 82.9, 96.5, 88.5, and 83.9. The results show a much greater loss from churning sweet cream as compared with cream ripened for 36 hours. The yield of butter was increased by the lower temperatures but not by the addition of hot water. With both ripened and unripened cream the Shorthorns showed the greatest loss of butter and the Jerseys the least. The author draws the conclusion that the fat content of milk as shown by chemical analysis is not a reliable guide as to the weight of butter to be obtained.

Payment for milk according to analysis as practiced in Belgium, G. E. LLOYD-BAKER (*Jour. Bath and West and Southern Counties Soc. [England]*, 4. ser., 12 (1901-1902), pp. 120-125).—A brief description is given of the method of payment

^a See Norsk Landmandsblad, 1901, pp. 366, 529, 563; Tidsskr. Norske Landbr., 1901, pp. 33, 247; Tidsskr. Landökon., 1901, pp. 88, 219; Ugeskr. Landm., 1900, p. 465.

for milk at factories suggested by Baron Peers, in which account is taken not only of the fat content of the milk as determined by the Gerber method, but of the quality of the fat as shown by centrifugal separation with an Alexandra tester. The results of tests of this method by Henseval are also summarized.

A note on the fat globules in milk, F. J. LLOYD (*Jour. Bath and West and Southern Counties Soc. [England], 4. ser., 12 (1901-1902), pp. 125-130*).—Measurements of the fat globules in several samples of Jersey milk showed a marked uniformity in size, the vast majority being from 8 to 12 μ in diameter, while very few were less than 4 μ . The majority of the fat globules in Shorthorn milk measured from 6 to 8 μ in diameter, while those measuring 1 to 2 μ were very numerous. The observations tended to show that the presence of exceptionally large fat globules in milk is rare and that the majority of fat globules are uniform in size. Other observations indicated no upward movement of fat globules smaller than 4 μ in diameter in milk which had been allowed to stand for 12 hours. The fat globules in all the samples examined appeared to be distinct, which militates against the theory that the larger globules carry up the smaller ones. The author was unable to detect a covering to fat globules which had taken on a granular form, which led to the conclusion that no such envelop exists.

Stagnant water germs in milk, E. F. PERNOT (*Oregon Sta. Bul. 71, pp. 177-184*).—Experiments were conducted to determine if the bacteria commonly found in stagnant water can gain access to the milk supply through the cow. Pure cultures of *Bacillus fluorescens liquefaciens*, *B. anthracis*, and *B. pasteurii* were in turn added to the drinking water and given to a cow every morning for periods of 10 days each. In no case were the bacilli added found on plate cultures made from the milk each morning and evening. *B. pasteurii* was administered in cultures containing spores in abundance and was not found in either the milk or excreta. The same cow was then given each morning for 10 days 10 cc. of a bouillon culture of the typhoid bacillus, and for the 5 days following 20 cc. of the culture without apparently affecting the health of the cow. In only 2 cases did typhoid colonies develop on plate cultures made each morning and evening from the milk, urine, and feces, and these were considered accidental inoculations. To determine if the typhoid bacillus can enter the udder through the milk ducts, the teats were immersed in a pure culture directly after milking and allowed to dry spontaneously. Twelve hours later the teats were disinfected, and plate cultures were made from the milk drawn under aseptic precautions. The experiment was repeated for 5 days, the cultures in no instance during the experiments or for a number of days after showing typhoid colonies.

The milk supply of London, R. W. WOOSNAM (*Dairy, 14 (1902), No. 166, p. 310*).—Until recently the author analyzed over 10,000 samples of milk annually and found that about 25 per cent of the milk sent to London contained less than 3.5 per cent of fat, the average annual composition being 3.6 per cent of fat and 8.8 per cent of solids-not-fat.

Testing milk and cream, F. L. KENT (*Oregon Sta. Bul. 70, pp. 161-176, pl. 1, fig. 1*).—The author makes a number of suggestions in regard to testing milk and cream and reports several experiments. A comparison was made of the small dipper and the Scoville sampling tube in sampling milk. Composite samples of the milk of 52 patrons, varying in amount from 15 to 450 lbs. daily, were taken by the two methods and the results compared with daily tests for the same period, which lasted 15 days. The average of the daily tests for the whole number of patrons was 4.01 per cent. The average of the composite samples taken by the sampling tube was 4 per cent and by the dipper 3.95 per cent.

In sampling cream by the dipper and by the milk thief, the two methods gave the same results in 58 trials, the milk thief higher results in 3 trials, and the dipper higher results in 39 trials. The methods of weighing and measuring cream for the

Babcock test were compared and the adaptability of the composite sample to the testing of cream was investigated with results summarized as follows:

"For all practical purposes, a pipette holding 18 cc. can be used in measuring test samples of sweet cream containing between 18 and 25 per cent fat. If the cream is sour or contains more than 25 per cent fat, the test sample should be weighed.

"Considerable variation will be found in the tests of daily deliveries during a composite test period. A variation of 9 per cent or more may be expected.

"The composite sample can be applied to the testing of cream quite as successfully as in milk testing. Fifty comparisons of composite tests with 'tests from total fat' showed an average difference of but 0.03 of 1 per cent.

"Composite test periods for cream should not exceed 10 days in hot weather. At other seasons of the year semimonthly periods will prove satisfactory."

Testing skim milk by the Babcock test, F. W. WOLL (*Country Genl.*, 67 (1902), No. 2569, p. 357).—The limit of accuracy of the Babcock test for separator skim milk is discussed, the author considering that tests of less than 0.05 per cent are suspicious and may be taken as pretty conclusive evidence that the tests were not properly made. Tests made by using about 20 cc. of acid and whirling for 5 minutes in turbine testers or 7 minutes in hand testers show generally 0.10 per cent of fat. "It is a safe rule to go by, to increase readings of separator skim milk tests made by the Babcock test by 0.03 per cent, if these are conducted under the most favorable conditions for the separation of the fat, and by 0.05 per cent in other cases, when too little acid was used or the whirling not continued long enough."

The spontaneous decomposition of milk at 40-44° C. and the micro-organisms concerned, M. FERGUSON (*Inaug. Diss., Göttingen, 1902, pp. 46*).—In this study, carried on under the direction of W. Fleischmann, 50 samples of milk from two dairies (taken each month from May to November) were allowed to sour spontaneously at 40, 42, and 44° C., and then examined bacteriologically. Four forms were noted—two bacteria, a bacillus, and a micrococcus. These were studied at length, and the effect of their growth in milk noted. *Bacterium I* resembled *Bacillus lactis aerogenes*, but did not agree entirely with the description of any forms of the latter. *Bacillus II* agreed almost entirely with the hay bacilli; and *Bacterium III* showed many similarities with the hay bacillus and the tyrothrix species, but did not correspond in all respects with any of them. *Micrococcus IV* showed great similarity to the *Micrococcus acidil paralactici liquefaciens* of Kozai, and is thought to be closely related to it.

The first three forms, I, II, and III, were more numerous and constant. All produced volatile acids principally and only traces of lactic acid. The micrococcus produced somewhat more lactic acid, in association with volatile acids, but was present in smaller numbers and absent in some samples. This leads the author to suggest tentatively that in the spontaneous souring of milk at 40 to 44°, more volatile acids than lactic acid are formed as a rule. The work of others is reviewed.

On the increased resistance of bacteria in milk pasteurized in contact with the air, H. L. RUSSELL and E. G. HASTINGS (*Centbl. Bact. u. Par.*, 2. Abt., 8 (1902), No. 15-16, pp. 462-469).—This is a reprint of the author's latest paper on this subject in the Annual Report of the Wisconsin Station (E. S. R., 13, p. 986).

Studies on the causes of rancidity of butter, O. JENSEN (*Centbl. Bact. u. Par.*, 2. Abt., 8 (1902), Nos. 1, pp. 11-16; 2, pp. 42-46; 3, pp. 74-80; 4, pp. 107-114; 5, pp. 140-144; 6, pp. 171-174; 7, pp. 211-216; 8, pp. 248-252; 9, pp. 278-281; 10, pp. 309-312; 11, pp. 342-346; 12, pp. 367-369; 13, pp. 406-409).—This is an extensive investigation of this subject, including a review of the important literature relating to it. According to our present knowledge, the decomposition of fat is of two general kinds, namely, oxidation processes and hydrolytic processes. By the oxidation process the unsaturated fatty acids (i. e., in butter the oleic acid) and in part the glycerids are attacked, as Duclaux and others have shown. The decrease in the iodine absorption

number is a convenient means of measuring the progress of this process. By the hydrolytic processes the fats are split up into glycerin and free fatty acids, and accordingly the progress of the process is measured by the amount of free fatty acids, expressed in acid number. It has been shown by numerous investigators that the unpalatability of fat is not always in proportion to the content of free fatty acids, which appears to be due to the fact that only those fatty acids which are volatile or soluble affect the senses. Fats which contain no glycerids of volatile fatty acids can not, like butter, become rancid as the result of hydrolytic cleavage, but only as the result of oxidation.

The author enumerates four possible causes to which rancidity has been assigned, namely, the oxygen or the carbonic acid of the air, the enzymes originally present in the milk, and micro-organisms. These possibilities were each investigated, the action of a long list of micro-organisms being studied.

It is shown that several forms of micro-organisms commonly occurring in butter are capable of decomposing the butter, with the formation of volatile fatty acid and esters. This, the author believes, is sufficient proof that the rancidity of butter may be due to micro-organisms, and that the hypothesis of the action of a milk enzyme is very improbable. It is thought very possible, however, that the micro-organisms effect the cleavage of the fat by means of a ferment (steapsin) which they form. The author added to filtered and sterilized butter a quantity of an old milk culture of the organisms to be tested which had been passed through a Chamberland filter. Samples of butter were treated in this way with cultures of *Bacillus fluorescens liquefaciens* and of *Oidium lactis*. These experiments showed that the acid number increased, i. e., that the rancidity progressed, and the author concludes that this was due to enzymes (steapsin).

The author sums up the principal results of his investigations as follows:

The air plays a direct part in the spoiling of butter only when the latter is exposed to sunlight or to a high temperature. The butter is then oxidized and takes on a very disagreeable odor and taste, but is not rancid.

Butter becomes rancid only through the action of certain micro-organisms. As these are all aerobic, rancidity progresses from the surface inward. For the preservation of butter it is, therefore, advisable to seal it up hermetically, or at least to leave as little surface exposed as possible, i. e., to keep it in large pieces rather than in small.

The micro-organisms which under ordinary conditions cause rancidity are *Oidium lactis*, *Cladosporium butyri*, *Bacillus fluorescens liquefaciens*, and occasional *Bacillus prodigiosus* also. All of these cleave the butter fat.

The volatile fatty acids are formed at first by the bacteria and later by the two molds working together. By the latter action butyric acid ester is also formed. By means of salt the formation of volatile fatty acids can be reduced, and by means of milk sugar the ester formation checked. Whether or not rancidity can be entirely prevented by the combined action of these two substances has not been determined.

Bacillus fluorescens liquefaciens and *B. prodigiosus* are often introduced into the butter in the water used, the former the more frequently. The *Oidium lactis* and *Cladosporium butyri* are believed to come from the air. The former is always present in the air of creameries in large quantities. In order to make butter which keeps well, therefore, the milk, cream, and butter should come into contact as little as possible with water, and be excluded, so far as possible, from the air. Experiments have shown that the danger of infection through water is materially diminished by ripening the cream, provided actual pure cultures of lactic acid ferments are used, since with an impure starter there is much danger of infection with mold. Pasteurization of the cream at 85° C. destroys all of the micro-organisms injurious to the keeping quality of butter. If the cream is cooled, however, by allowing it to spread out in a thin layer over the cooler under the free access of air, and is then kept in

open vessels for a considerable time, it is exposed to infection from the air; and if the butter is washed with unboiled water there is danger of water infection. The whole object of pasteurization can, therefore, be defeated by improper subsequent treatment. Absolute safety requires that the pasteurized cream should be cooled in a closed apparatus with the aid of sterilized air, the cream vat kept well covered, and the butter washed only with boiled water.

Lactic acid ferments and the ripening of cheese, E. VON FREUDENREICH (*Centbl. Bakt. u. Par., 2. Abt., 8 (1902), Nos. 21, pp. 674-681; 22, pp. 705-711; 23, pp. 735-738; Landw. Jahrb. Schweiz, 16 (1902), No. 3, pp. 91-104; Rev. Gén. Lait, 1 (1902), Nos. 13, pp. 289-295; 14, pp. 313-319; 15, pp. 340-346*).—The author sought to obtain decisive proof of the causal relation of lactic acid bacteria to the ripening of cheese. The milk used in the experiments was drawn with thorough aseptic precautions and made into Emmenthaler cheese according to the usual methods. Notwithstanding the care taken the milk was found to contain a maximum of 680 and an average of 230 bacteria per cubic centimeter. At the same time milk drawn without aseptic precautions contained as high as 11,250 bacteria per cubic centimeter. Lactic acid bacteria were almost invariably absent in the freshly drawn milk. Experiments to ascertain the source of the lactic acid bacteria showed their absence in outdoor and laboratory air, spring water, soil, and fecal matter; and their presence in the air of the stable, dust and hair from the cows, and liquid manure. The bacteria regularly met with in the freshly drawn milk were mainly liquefying and nonliquefying micrococci.

In all 35 experimental cheeses were made, each from 14 liters of milk. Hansen's rennet tablets were used in all cases except for cheeses ripened with lactic acid bacteria, when natural rennet rich in lactic acid bacteria was employed. Six cheeses were made without the addition of cultures and were used as controls. The other cheeses were made with the addition of liquefying micrococci, lactic acid bacteria, and *Bacillus nobilis*, either in pure cultures or mixed. The cheeses were judged by a commission and subjected to bacteriological and chemical examination, the results of which are considered by the author as showing that lactic acid bacteria play the principal rôle in the ripening of cheese. The control cheeses did not undergo normal ripening especially as regards flavor. The favorable action of the lactic acid bacteria was most marked when they were added in the form of natural rennet. The liquefying micrococci in the absence of lactic acid bacteria gave the cheese a bitter flavor, but in the presence of lactic acid bacteria their development soon ceased. *B. nobilis* added in pure cultures did not develop in the presence of lactic acid bacteria, which was also the case when Tyroge alone was used. Pure cultures of *B. nobilis* in the absence of lactic acid bacteria gave the cheese a repulsive odor. Several other experiments are noted briefly, which likewise demonstrate, according to the author, that Tyroge does not exert the least influence in the ripening of soft cheese.

Investigations on the presence and development of Tyrothrix bacilli in Emmenthaler cheese, GERDA TROILI-PETERSSON (*Landw. Jahrb. Schweiz, 16 (1902), No. 1, pp. 26-32; Ann. Agr. Suisse, 3 (1902), No. 1, pp. 5-12*).—Bacteriological studies here reported led to the conclusion that the number of Tyrothrix bacilli in cheese is insignificant compared with the total number of bacteria or even with the number of other liquefying bacteria present, and that there is no increase in the number of Tyrothrix bacilli in cheese. On the contrary, when pure cultures of *Bacillus nobilis* were used in large quantities the bacilli diminished rapidly during the first two days.

Acid and rennet producing bacteria in milk, C. GORINI (*Landw. Jahrb. Schweiz, 16 (1902), No. 1, pp. 22-25; Centbl. Bakt. u. Par., 2. Abt., 8 (1902), No. 5, pp. 137-140; Ann. Agr. Suisse, 3 (1902), No. 1, pp. 1-4*).—The author's studies indicated the presence in milk of micrococci producing acid and rennet and capable of peptonizing casein in an acid medium.

The duration of the life of the bacillus of tuberculosis in cheese, F. C. HARRISON (*Landw. Jahrb. Schweiz*, 16 (1902), No. 4, pp. 138-140; *Ann. Agr. Suisse*, 3 (1902), No. 2, pp. 44-46).—Experiments with Cheddar cheese made in Canada were carried out in the same manner as those with Emmenthaler and Cheddar cheese made at Berne and previously reported (E. S. R., 12, p. 985). As determined by inoculation experiments with guinea pigs, the tubercle bacilli in the cheese retained their vitality for 62 to 70 days from the time of manufacture, although their virulence was much lessened during the last 20 days of this period. In the Cheddar cheese made at Berne the bacilli remained alive for 104 days. Reasons offered in explanation of this difference are the increased acidity, saltiness, and firmness of the Canadian cheese. The author concludes that there need be no fear of ingesting living tubercle bacilli with Cheddar cheese.

Dairying in Australia (Brisbane: The Brisbane Newspaper Company, Ltd., 1902, pp. 80, figs. 3).—A reprint of a series of articles on this subject.

Cheese, butter, and condensed milk, factory product, H. E. ALVORD (*Twelfth Census United States, Census Bul.* 189, pp. 29, figs. 2).—The statistics given are for the census year ended May 31, 1900, and embrace the operations of establishments engaged in the manufacture of cheese, butter, and condensed milk. From a summary of the statistics of the dairy industry of the United States as a whole the following figures are taken: Total number of cows kept for milk, 18,112,707; total gallons of milk produced, 7,728,583,350; total pounds of butter made, 1,492,699,143; total pounds of cheese made, 299,006,818; aggregate value dairy products of United States, \$590,827,154.

VETERINARY SCIENCE AND PRACTICE.

Experimental anæmia. The study of the hemolytic cytase in the plasma of normal animals, C. LEVADITI (*Ann. Inst. Pasteur*, 16 (1902), No. 4, pp. 233-256, pls. 2).—The author conducted an extensive series of experiments, chiefly on guinea pigs, for the purpose of determining as accurately as possible the effects of hemolytic cytases or sensibilizing substances in the organism of normal animals. It was found that the hemolytic sensibilizing substance when introduced into the peritoneum was rapidly absorbed. It was located chiefly in the organs in which the destruction of the red blood corpuscles normally takes place, especially in the spleen. Some of the substance was found in the kidney and liver but the largest quantities were found in the spleen. As a result of the accumulation of the cytases in the spleen this organ becomes the seat of an active and intense phagocytosis of the red blood corpuscles. The blood plasma is deprived of its hemoglobin and contains a quantity of the cytase. A portion of the red blood corpuscles which float in the plasma fix the cytase, but the larger part of it remains free. Immediately after introducing cytase into the peritoneal cavity it comes in contact with the leucocytes in the peritoneal lymph and the red blood corpuscles which are in this lymph or which are set free by the hemorrhage due to injection. A portion of the cytase is immediately fixed by the leucocytes and red blood corpuscles but the larger part remains free.

Concerning infection from the uninjured conjunctival sac, K. HIROTA (*Cynth. Bull. n. Par., 1. Abt.*, 31 (1902), No. 6, Orig., pp. 225-240).—A general discussion is given of the possibility of the penetration of the conjunctiva by micro-organisms. The author presents a review of the literature of the subject and a discussion of results obtained by numerous experiments on various experimental animals with different pathogenic organisms. The organisms were in each case placed in the conjunctival sac in a careful manner so as not to injure the conjunctiva in any way. In experiments with anthrax bacillus it was found that 9 out of 10 white mice showed no local alteration of the conjunctiva and only one became infected with anthrax. The same results were obtained with white rats. In guinea pigs and rabbits no

infection occurred, or even alteration of the conjunctiva. Anthrax spores were tested in the same manner on white mice, guinea pigs, and rabbits, with negative results in every case. The organisms of mouse septicaemia produced a conjunctivitis and death after 9½ days, in 4 out of 6 white mice upon which the experiments were made. In rabbits this organism caused conjunctivitis but no infection. The organism of fowl cholera produced infection and death in 5 out of 7 white mice upon which experiments were made. Experiments on white rats gave negative results, while 4 out of 7 rabbits became infected. Experiments with swine plague bacillus gave negative results in white mice, white rats, and guinea pigs. The organism of pneumonia caused the death of 4 out of 8 white mice, but did not affect rats, guinea pigs, or rabbits. The author concludes from these experiments that a general infection may be produced by bringing the organisms of mouse septicaemia, fowl cholera, or pneumonia into the uninjured conjunctiva sac, while such infection is quite doubtful in the case of anthrax bacillus. In further experiments, in which the lachrymal canal was closed or destroyed, no infection was produced with any of the organisms in any experimental animals. More or less serious conjunctivitis was produced in many cases, but the infection did not spread. It appears, therefore, that the entrance of the organism into the general system takes place through the lachrymal canal rather than through the conjunctiva.

The influence of the lowest temperatures obtainable with liquid air upon the virulence of pathogenic bacteria, C. M. BELL (*Centbl. Bakt. u. Par., 1. Abt., 31 (1902), No. 8, Orig., pp. 355-360*).—The author conducted experiments in subjecting various pathogenic bacteria to the influence of low temperatures secured by means of liquid air. The temperatures obtained by this means were as low as -200°C . It was found that a temperature of -200°C . for a period of 15 hours had no influence upon the virulence of the anthrax bacilli. Careful counts were made of cultures subjected to these low temperatures and it was found that a number of the less resistant bacteria in each culture were killed by the cold; inoculation experiments, however, showed that the cultures as a whole remained virulent.

Modifications in blood and serum preserved in an aseptic manner, M. DOYON and A. MOREL (*Compt. Rend. Acad. Sci. Paris, 134 (1902), No. 10, pp. 621-623*).—It was found by the authors that in the blood of normal dogs and horses selected and preserved in an aseptic manner at a temperature of 37°C . the ether extract and the combined fatty acids diminished in quantity. This diminution of the ethers in the blood is not accompanied with an increase in the acid of the blood; it takes place only in the presence of oxygen and is intimately connected with the red blood corpuscles.

Immunity and protective inoculation, A. T. KINSLEY (*Industrialist, 28 (1902), No. 28, pp. 411-422*).—A popular discussion of the general subject of immunity with special reference to the prevention of blackleg, anthrax, hog cholera, and swine plague.

Experiments in the transmission of leprosy to animals, Y. TASHIRO (*Centbl. Bakt. u. Par., 1. Abt., 31 (1902), No. 7, Orig., pp. 276-278*).—In the experiments undertaken by the author, rabbits and guinea pigs were used as experimental animals. The tissue from leprosy patients was used for making interperitoneal or hypodermic inoculations. It was found that the bacillus maintained itself for a considerable time in the tissue of the inoculated animals, but was ultimately disintegrated so that no permanent infection resulted. It is believed, therefore, that the transmission of leprosy to animals is absolutely impossible.

Morphology and experimental researches on the trypanosoma of nagana or tsetse-fly disease, A. LAVERAN and F. MESNIL (*Ann. Inst. Pasteur, 16 (1902), No. 1, pp. 1-55, figs. 9*).—A general historical account of this disease is given with numerous references to the literature on the subject. The disease affects a large

number of mammals belonging to different families, including the majority of domesticated animals. Man and birds are entirely immune to the disease. The habits and anatomy of the tsetse fly (*Glossina morsitans*) are described, with special reference to the manner of infection in which this insect acts as agent. The authors carried on numerous inoculation experiments with the trypanosoma of this disease on different experimental animals, including rats, mice, guinea pigs, rabbits, and dogs. It was found that when fresh blood containing trypanosoma was injected into the subcutaneous connected tissue, the organisms usually appeared in the blood in from 36 to 48 hours. Mice which were inoculated in the body cavity with virulent blood diluted in 5 times its volume of physiological salt solution showed signs of infection after 2 days and died at the end of 5 days. Virulent blood carefully collected and preserved in glass vessels in contact with the air retained its virulence for at least 3 days. In experiments to determine the influence of cold upon the trypanosoma it was found that this organism could not be preserved so long in a refrigerator as *T. lewisi*. The organism retained its virulence no longer in an ice chest than at the temperature of the room. When the organism was subjected for 3 hours to a temperature of 40° C., or for 1 hour and 20 minutes at a temperature of 42° C., the virulence was destroyed. Detailed notes are given on the morphology of *T. brucei*; its appearance in fresh blood and in stained preparations, the mode of multiplication, and its agglutination are discussed. The organism was differentiated from other closer related species of the same genus. This species became agglutinated in from $\frac{1}{2}$ to 1 hour in blood which was drawn directly from the heart. A detailed account is given of the course and symptoms of the tsetse-fly disease in the various species of mammals which are susceptible to this disease. The characteristics of other diseases caused by other species of trypanosoma are discussed for the purpose of distinguishing them from the tsetse-fly disease. The related diseases are surra, mal de caderas, and dourine.

The tsetse-fly disease, A. THEILER (*Schweiz. Arch. Tierh.*, 43 (1901), Nos. 3, pp. 97-112; 4, pp. 153-162).—The greater part of this article is occupied with a critical discussion of the literature relating to this subject. Attention is called to the difficulties of demonstrating the presence of the blood parasite in the blood of affected animals. The blood parasite outside of the animal body lives for periods of different lengths, depending on the medium in which it is cultivated. In defibrinated sterilized blood the organism was maintained in a living condition for 8 days. In some instances the blood parasite is present in such small numbers that the investigator may fail to find a single example, in making tests for this purpose. Where large quantities of blood are examined, however, a few parasites will be found in all cases of the disease. The period of incubation of the disease varies in different species of animals. In horses the minimum was 3 days and in one case the period was 12 days. The duration of the disease in horses varied in the author's experiments from 4 to 22 days. During the progress of tsetse-fly disease a progressive anemia is observed. The number of red blood corpuscles per cubic millimeter diminished in one case from 5,500,000 to 2,500,000. In sheep the course of the disease occupied from 26 to 48 days. The author was unable to demonstrate the presence of trypanosoma in the blood of infected sheep or goats. The blood parasite was most easily demonstrated in the dog. The parasites were readily seen on the second day after the appearance of the disease. The clinical symptoms are described and attention is especially called to those symptoms which differentiate the tsetse-fly disease from other similar diseases. No medicinal treatment has proved successful. The author tried experiments with quinin, by way of the mouth and subcutaneously, and with arsenic by way of the mouth, without good results.

The action of human serum on the trypanosoma of the tsetse-fly disease, A. LAVERAN (*Compt. Rend. Acad. Sci. Paris*, 134 (1902), No. 13, pp. 735-739).—During the author's researches on the subject of the treatment of tsetse-fly disease,

human serum was injected into diseased animals, with the result that the blood parasite always disappeared. This result was considered somewhat surprising from the fact that the serum of animals which enjoy a natural immunity against a given disease is not ordinarily effective in the treatment of this disease. The experiments were repeated many times on rats and mice, and the results were always the same. The trypanosoma of tsetse-fly disease when injected into these animals increases rapidly in numbers until the death of the animals takes place. A dose of 0.5 cc., however, of human blood was sufficient to cause the parasites to disappear and the disappearance was more rapid and certain if the dose was increased to 1 or 2 cc. While injections of human serum thus appeared to have a remarkable curative effect, its preventive action was not very striking.

Report on the surra disease of cattle and horses in the Protectorate of Togo, SCHILLING (*Centbl. Bakt. u. Par., 1. Abt., 31 (1902), No. 10, Orig., pp. 452-459*).—The author presents the results of his investigations on surra among horses and cattle. A considerable number of cases were observed and notes were made on the symptoms of the disease and on the pathological lesions. It was found that while the trypanosoma might be absent in many instances from the blood of the general circulation after death, the parasites were always present in large numbers in the red bone marrow. The author believes, therefore, that the anæmic condition which is a prominent symptom of this disease is not due so much to an attack of the parasite upon the fully developed red blood corpuscles, but to the destruction of the tissue in which the supply of red blood corpuscles is renewed.

Texas fever, CLAUDE and SOULÉ (*Bul. Agr. Algérie et Tunisie, 8 (1902), No. 3, pp. 65-73*).—An outbreak of this disease was reported as occurring in a dairy herd in Algeria, during which 10 out of the 35 cows died. The symptoms are described and an account is given of a number of post-mortem examinations which were conducted on the dead animals. A microscopic examination of the blood showed conclusively that the disease was Texas fever, and attention is called to the interesting fact of the comparatively large mortality during a cool season.

A second note on Texas fever, M. NICOLLE and ADIL-BEY (*Ann. Inst. Pasteur, 16 (1902), No. 4, pp. 291-293*).—The authors continued their observations on the pathogenic effects of the organism of Texas fever, giving special attention to the conditions found in the liver, kidneys, and spleen. Sections of these organs were studied under a microscope. The fixing and staining methods used during these studies are described in detail.

The Queensland redwater immune cattle for South Africa (*Agr. Jour. Cape Good Hope, 20 (1902), No. 3, pp. 184, 185*).—An experiment is being tried in Natal in the introduction from Australia of cattle immune to Texas fever. If the animals prove to be strictly immune to the disease, it is suggested that further extensive importations will probably be made from Australia and from North and South America.

The etiology of rinderpest, NICOLLE and ADIL-BEY (*Compt. Rend. Acad. Sci. Paris, 134 (1902), No. 5, pp. 321-324*).—The authors made numerous experiments for the purpose of determining the relative size of the micro-organisms of rinderpest. It was found possible to select a Berkefeld filter of a thickness which would allow the organisms of rinderpest to pass through and would not permit the passage of other micro-organisms. The organisms of rinderpest, as well as of other diseases, may frequently be contained in white blood corpuscles, and it is therefore suggested that in order to make the microscopic examination more accurate the material should be first triturated, so as to set free micro-organisms which may have been contained in the leucocytes, and thus make possible their identification.

Studies on rinderpest, M. NICOLLE and ADIL-BEY (*Ann. Inst. Pasteur, 16 (1902), No. 1, pp. 56-64*).—The authors conducted numerous experiments in the filtration of rinderpest virus under different conditions through different filters. The passage of

virulent organisms through filters depends on the diameter of the pores of the filter, the thickness of the walls, and the surface of the filter. In addition to the factors of the problem which belong to the filter, the size of the organism, the nutrient medium, the temperature, and pressure are to be considered. Experiments were made in filtering the virus of rinderpest through a thin Berkefeld, a normal Berkefeld, and a Chamberland filter. The filtrate which was obtained from a thin Berkefeld filter proved to be inactive, of vaccinating power or virulent according to the conditions under which the filtration was done. The filtrate from the normal Berkefeld filter was likewise inactive, of vaccinating power or infectious according to circumstances, but it was inactive in a much larger number of cases than the filtrate from the thin Berkefeld filter. The filtrate from the Chamberland filter was for the most part inactive, rarely it had vaccinating power or was virulent. From these experiments the authors conclude definitely that the organism of rinderpest may pass through filters, but that the extent to which this occurs depends on a number of conditions.

Modifications of the leucocytes in rinderpest, RÉFIK-BEY (*Ann. Inst. Pasteur*, 16 (1902), No. 2, pp. 163-168, figs. 6).—An increase in the total number of leucocytes is frequently observed during the early stages of the disease, but this is followed by a diminution in the number, and another increase subsequently. The first increase in numbers takes place on the second or third day, when there may be as many as 18,200 per cubic millimeter. The number begins to decrease on the fourth day, the minimum is reached on the fifth day, or occasionally on the fourth, or even on the sixth or seventh. The lowest number observed was 2,000 per cubic millimeter. The mononuclear leucocytes did not participate in the first increase in the total number of the leucocytes. In half of the cases observed the number remained lower than normal, while in the other half it was largely increased. The polynuclear leucocytes reached a maximum during the first increase in the total number of leucocytes. After vaccination with bile the fluctuation in the number of leucocytes, which is characteristic of infection, disappears to a large extent. In animals vaccinated with serum followed by virus a temporary hyperleucocytosis was observed. The fluctuation in the number of polynuclear leucocytes was much more irregular than in the mononuclear.

A contribution to the tuberculosis problem, K. MÜLLER (*Ztschr. Fleisch. u. Milchhyg.*, 12 (1902), No. 5, pp. 129-132).—The author described in detail two cases of tuberculosis in butchers who exhibited a good family history and robust health and who had apparently contracted the disease in cuts and scratches while working with tuberculous animals. The evidence in these two cases for the transmission of bovine tuberculosis to man is considered by the author as quite conclusive.

The prevention of bovine tuberculosis, H. RAQUET (*L'Ing. Agr. Gembloux*, 12 (1902), No. 8, pp. 380-388).—The author discusses in a general way the problems involved in the reduction of tuberculosis of cattle and especially of dairy cows. The means recommended for controlling this disease may be summarized as follows: The widest possible publication of the chief facts thus far established regarding the nature and spread of the disease; the subordination of indemnities paid for tuberculous animals to the strict enforcement of proper regulations for preventing contagion; the compulsory pasteurization of cream and other milk products in all cooperative creameries; the compulsory destruction of all the residues of centrifugal separation of cream, by means of strong chemical reagents; and frequent inspection of dairies by sanitary officers.

How to get rid of tuberculosis in cattle, W. C. EDWARDS (*Wallaces' Farmer*, 27 (1902), No. 19, p. 694).—A discussion is presented of the problem of the tuberculin test from a practical standpoint. It is argued that much opposition has been aroused against the extensive use of the tuberculin test, from the fact that certain veterinarians at first advocated the wholesale destruction of all animals which reacted to the test. Attention is again called to the fact that perfectly sound calves may be raised

from cows badly infected with tuberculosis, and it is contended that tuberculous cows may thus be profitably made use of, and should therefore not be destroyed in a whole-sale manner.

Remarks on the relations of human and bovine tuberculosis, C. H. CATTLE (*British Med. Jour.*, 1902, No. 2147, pp. 443-445).—The author gives a critical review of Koch's arguments against the liability of transmission of tuberculosis from animals to man, or vice versa, and also of the arguments opposed to Koch's contentions. The author calls attention to the fact that physicians and veterinarians appear to be coming gradually to the belief that, as a rule, tuberculosis arises from direct infection or from case-to-case.

Tuberculosis, LIEBNER (*Fühling's Landw. Ztg.*, 51 (1902), No. 1, pp. 1-5).—This article, like many others which have appeared since the publication of Koch's address at the British Congress on Tuberculosis, is occupied largely with presentation of arguments against Koch's position. It is urged that the possibility of transmission of tuberculosis from animals to man is still an open question, and that sanitary efforts to prevent the use of the meat and milk of tuberculous animals should be continued. Such products are considered harmful in addition to the possibility of their being infectious.

Tuberculosis in sheep, A. G. R. FOULERTON (*Public Health*, 14 (1902), No. 9, pp. 544, 545).—This account of the author's article is an abstract made from the article as read at the Pathological Society of London, April 15, 1902. On account of the rarity of tuberculosis in sheep it had been suggested that the blood of these animals might possibly contain an alexin which would tend to produce a partial immunity. Experiments in treating tuberculous guinea pigs with subcutaneous injections of extracts prepared from the spleen of sheep gave negative results, and it is believed, therefore, that sheep are not really immune, but owe their freedom to tuberculosis largely to circumstances of their environment.

Infection of swine with tuberculosis, S. STEWART (*Twentieth Century Farmer*, 1902, No. 74, pp. 1, 2).—The author discusses the pathological lesions caused by tuberculosis in hogs, and calls attention to the great danger of infection of these animals from eating the waste from slaughterhouses.

A case of tuberculosis of the lungs in Ursus malaiianus, K. GEISENBERG (*Centbl. Bakt. u. Par.*, 1. Abt., 31 (1902), No. 6, Orig., pp. 248-250).—A post-mortem examination was made on a female Malay bear which had died of a wasting disease. The various pathological conditions found in the different organs are described in detail. Typical miliary tubercles of tuberculosis and giant cells were found in various tissues. The tubercle bacillus was found in such pathologically altered tissues, but no experiments were made to determine which variety of the bacillus was present in the tissue.

Tuberculosis in cold-blooded organisms, H. HERZOG (*Centbl. Bakt. u. Par.*, 1. Abt., 31 (1902), No. 3, Orig., pp. 78-85, figs. 2).—The author undertook to determine the pathological changes which are produced in frogs by inoculation with the tuberculosis of fish, and the question as to whether the organism of mammalian tuberculosis would produce pathological changes in cold-blooded animals. Eight frogs were inoculated with the tuberculosis of fish and were kept in water at a temperature of 15 to 16° C. In another experiment 2 frogs were similarly inoculated and kept in water at a temperature of 22° C. In 6 of the experimental frogs no changes in the organs were visible to the naked eye when the animals were killed. In the other 4 quite extensive changes were apparent; tubercles of varying size appeared in various organs and ulcerous perforations of the skin were observed in a few cases. In another experiment 4 frogs were inoculated with the organism of mammalian tuberculosis and kept at the ordinary temperature of the laboratory. Three of the frogs were killed after 16, 17, and 24 days, respectively; the other frog died 60 days after inoculation. Of these 4 frogs, 2 exhibited no special pathological changes. The

other 2 gave evidences of infection. In 1 the lymph sac contained a reddish exudation and the spleen was swollen. In the other the liver was much enlarged and covered with numerous minute white spots. In the fourth experiment material was taken from one of the frogs in the last-mentioned experiment and was inoculated into 2 frogs and 1 guinea pig. The frogs were kept at the ordinary temperature of the room. Both frogs died, one 4 days and the other 15 days after infection. The guinea pig was killed about 8 weeks after the inoculation and a post-mortem examination showed that it had not become infected.

Observations and studies on a disease of the extremities observed in young cattle in South America, O. VOGES (*Centbl. Bakt. u. Par., 1. Abt., 31 (1902), No. 4, Orig., pp. 136-141*).—A report was made on a disease of cattle of quite wide distribution in South America. A most characteristic symptom is a striking lameness in one leg, the lameness being due to an inflammatory swelling, which later develops into a large suppurative abscess, involving a considerable portion of the extremity. The author attempted to isolate the pathogenic organism from the pus contained in such abscesses. A number of suspected organisms were cultivated and inoculation experiments were made, without success in demonstrating the causal relationship of any of them to the disease. No attempt was made to devise a serum treatment since it was found that a much less expensive remedy might be used. If the abscess is thoroughly opened and drained a prompt recovery takes place in all cases.

Carcinoma of the eye in cattle, O. VOGES (*Centbl. Bakt. u. Par., 1. Abt., 31 (1902), No. 4, Orig., pp. 142-145, fig. 1*).—Brief notes on the symptoms of this disease, together with a description of the appearance of the infection to the naked eye and the microscopic changes produced in the diseased tissues. The disease appears to be confined to pure-bred cattle, especially to the Hereford.

Study of sorghum poisoning in cattle, A. PETERS (*Nebraska Sta. Rpt. 1901, pp. 50-54*).—On account of the numerous complaints received from farmers whose stock had been poisoned by eating sorghum, the author made a special effort to ascertain the circumstances surrounding such cases and to observe the symptoms and study the disease more carefully. In one case 15 cattle accidentally broke into a field of sorghum, where they remained 20 minutes; 3 of these cattle became sick and died within a few hours. Other similar cases of poisoning from sorghum are related. An experiment was tried, during which 2 young cattle were turned into a sorghum field. Only 1 of the animals ate any appreciable quantity of sorghum, and this animal was so badly affected that it fell to the ground within 10 minutes after entering the field. While in a recumbent position peculiar twitchings of the muscles in various parts of the body were observed. There was a partial paralysis of the tongue and increased salivation. The animal was finally killed when it was apparent that it would soon die, and a post-mortem examination revealed the fact that it had eaten $1\frac{1}{2}$ lbs. of sorghum leaves. In this case, as well as in 11 other post-mortems, the author was not able to observe any evidence of sorghum leaves having become adherent upon the entrance of the trachea, so as to cause strangulation. In the cases thus far mentioned, poisoning was due to eating standing green sorghum. A few cases are reported of poisoning from eating sorghum several hours after it was cut. It is recommended that one animal be turned into the sorghum field first, and that others be allowed to enter if no symptoms of poisoning are observed in the first one. In this way serious cases of poisoning may be avoided to a great extent.

A study of the enzymes of green sorghum, H. B. SLADE (*Nebraska Sta. Rpt. 1901, pp. 55-62*).—The author worked in connection with A. T. Peters in an investigation of the cause of sorghum poisoning (see above). Analyses were made of stalks of sorghum about 2 ft. high, in a vigorous growing condition. Extracts were obtained from such material, both in water and in a solution of common salt, which exercised more or less action upon starch. The action thus produced varied to a considerable extent, according to the part of the plant from which the extract was obtained and

according to the method by which it was extracted. With guaiac and peroxid of hydrogen the extracts yielded a blue coloration. Analyses made by the author indicated the presence of a number of enzymes in green sorghum, among which mention is made of diastase, glucase, catalase, and oxydase. The enzymes thus far found do not appear to be the source of the poisonous product and the study is to be pursued further.

A poisonous plant—the common horsetail (*Equisetum arvense*), F. A. RICH and L. R. JONES (*Vermont Sta. Bul.* 95, pp. 185-192, figs. 2).—The poisoning of horses from eating common horsetail has been observed for several years in Vermont. Within the past five years 41 cases have been treated. The authors made a special investigation of the matter and conducted feeding experiments for the purpose of determining more accurately the symptoms and effective methods of treatment. A description of the plant is given. While the plant seems quite frequently to affect horses, no cases of poisoning from it are known in cattle; in fact, there appears to be evidence that dairy cows may eat it without harm. Two feeding experiments were carried out, involving 5 horses. The horses were old and not as susceptible as young horses to the poison contained in the plant. The symptoms appear gradually. At first, there is emaciation to be observed; in from 2 to 5 weeks the horse begins to lose control of its muscles and staggers, or may fall. Animals may eat after they have fallen and are unable to rise. The temperature is subnormal during the first stages of the disease, and the mucous membranes of the mouth, nose, and eyes become pale. Horses fed grain resist the action of the poison much longer than those which do not receive grain. No evidence was obtained that the green plant ever caused poisoning—apparently the plant causes trouble only when present in hay. The treatment recommended by the authors consists in the administration of Barbados aloes and ginger, followed by raw linseed oil and nux vomica, in the grain feed 3 times a day.

Experiments with malarial catarrhal fever of sheep, SPREULL (*Agr. Jour. Cape Good Hope*, 20 (1902), Nos. 8, pp. 469-477; 9, pp. 530-534).—Malarial catarrhal fever is a noncontagious but readily inoculable disease of sheep. The period of incubation is about 3 days and the beginning of the disease is marked by a condition of high fever. A blood parasite which affects the red blood corpuscles has been observed in cases of this disease. The mucous membrane of the mouth and lips turns blue and numerous sores appear in the mouth and on the tongue. The pure-bred Merino appears to be most susceptible, especially when young. The author undertook an extensive series of experiments in inoculation with the serum, bile, and pulp of the spleen of diseased animals. It was found that partial immunity might thus be produced and that it might be fortified by subsequent injections of virulent blood, beginning with small doses. Experiments with rabbits indicated that the symptoms of the disease might be produced in these animals by inoculation with virulent blood. Mild forms of the disease were also produced in goats, but they are apparently more resistant than sheep. In the inoculation experiments only 4 out of 80 sheep died of the disease. Similar experiments were made in the field with very good success.

Reindeer plague and the pathogenic bacillus of this disease, A. M. BERGMAN (*Ztschr. Thiermed.*, 5 (1901), Nos. 4, pp. 241-283; 5-6, pp. 326-337, pls. 3, figs. 8).—In the years 1896 and 1897 a serious outbreak of this disease occurred in Lapland. The outbreak was investigated by Prof. Lundgren and the pathological material obtained from this investigation was submitted to the author for further study. A detailed description is given of the pathogenic organism and notes presented on its growth and behavior on a large variety of nutrient media. The clinical symptoms and pathological anatomy of the disease are described. Reindeer plague resembles to some extent blackleg, malignant oedema, and braxy. The author gives the special characteristics of the reindeer plague by which it may be distinguished from the diseases which it resembles. An extended series of inoculation experiments were made on other animals, and the results of these experiments are discussed in considerable

detail. The reindeer is the only animal in which a natural infection of the disease is known to have occurred. By artificial inoculation, however, the disease may be readily transmitted to sheep, guinea pigs, white mice, pigeons, and sparrows. The disease can be produced by inoculation also in cattle, cats, and frogs. Rabbits, dogs, hogs, and chickens appear to be completely immune. It is considered that if sheep were allowed to range in the localities where outbreaks of the disease occur among reindeer they would also become infected. In sheep inoculated with the disease the author succeeded in bringing about a recovery by hypodermic injections of weak solution of lysol. A vaccine was obtained which had the power of rendering sheep immune, but no experiments were made to determine the effectiveness of vaccine in reindeers.

Normal serum in hog cholera, S. SALTUKOW (*Ann. Inst. Pasteur*, 16 (1902), No. 1, pp. 94-96).—Voges, as the result of his experiments, claimed that 0.1 cc. of the normal serum of guinea pig when injected subcutaneously in another guinea pig, protected the latter against infection from an injection at the same point of a dose 1,000 times the fatal size, from a culture of the hog cholera bacillus. The author tested these conclusions by means of experiments along the same line. The virulence of the culture obtained directly from hogs infected with hog cholera was augmented by passing through several guinea pigs. It was found that the fatal hypodermic injection was at least 200 times greater than the fatal peritoneal dose. The influence of normal serum of guinea pigs was found in the author's experiments to be practically nil. Experimental animals died as soon or sooner after injection than check animals.

The problem of the differential diagnosis of glanders, B. S. TROFIMOV (*Arch. Vet. Nauk. St. Petersburg*, 32 (1902), No. 2, pp. 134-152).—Experiments were made for the purpose of determining the relative accuracy of different methods recommended for diagnosing cases of glanders. For this purpose 6 glanderous horses were tested with mallein and the blood was used for making cultures and for direct inoculation of guinea pigs. As the result of these studies it was found that the glanders bacillus was not always present in the blood of horses affected with this disease. Even in cases where the lymphatic glands and various internal organs are extensively affected by glanders, it may be impossible to demonstrate the presence of the glanders bacillus in the blood, either by making inoculations of fresh blood in guinea pigs or by using the blood in cultures.

The diseases of the horse which are grouped together under influenza, DIECKERHOFF (*Ztschr. Veterinärk.*, 14 (1902), No. 1, pp. 1-8).—Of the various diseases which have been included under the name influenza, the author recognizes and gives a differential diagnosis for the following: Contagious pneumonia, distemper of horses, scald, acute infectious laryngeal catarrh, infectious inflammation of the pharynx, and epizootic cough.

Pneumonia of horses, IVERSEN (*Ztschr. Veterinärk.*, 14 (1902), No. 4, pp. 162-165).—The author attempted to answer the question whether a quarantine period of 6 weeks was sufficient in preventing the spread of this disease. It was found that in one instance an outbreak of the disease occurred among horses 4 months after bringing them into quarantine. Experiments indicated, however, that immediate isolation of the first case and scrupulous disinfection of the premises are effective in preventing the further spread of the disease.

Experiments in the artificial transmission of pneumonia of horses, C. TROESTER (*Ztschr. Veterinärk.*, 14 (1902), No. 4, pp. 159-162).—The author attempted to determine whether the organisms and virus of this disease were contained in the excretion from the kidneys. Experiments were instituted during which small quantities of the urine of diseased animals was fed to colts upon their other food. In all cases an elevation of temperature took place, but the animals recovered within a few days. It appears from these experiments that the virus of the disease may be excreted by the kidneys.

The present status of investigation concerning the South African horse

disease, KAESEWURM (*Ztschr. Veterinärk.*, 14 (1902), Nos. 1, pp. 8-18; 2, pp. 63-71).—This disease, which is also known as horse sickness and Paardenziekte, was described in 1881 as a peculiar outbreak of anthrax. Later investigations led to the discovery of a blood parasite similar to that of malarial and Texas fever of cattle. The author discusses in a critical manner the literature relating to the method of infection, clinical symptoms, diagnosis during life, the anatomical alterations, and prophylactic treatment by means of serum injections.

An epizootic of herpes, CHRISTIANI (*Ztschr. Veterinärk.*, 14 (1902), No. 3, pp. 101-108).—The author discusses an unusually severe outbreak of this disease which occurred in several localities during the season of 1900. In the majority of cases the disease was confined to isolated parts of the skin. In 7 horses, however, the eruption rapidly spread over the whole body. In treating these cases it was found that corrosive sublimate dissolved in water was not very satisfactory. Better results were obtained from the use of soapuds. It is recommended that in treating this disease care should be exercised not to apply too drastic remedies, which may render it difficult to determine by inspection when the cause of the disease has been removed.

Internal treatment of morbus maculosus with 10 per cent iodine-vasogen, STRAUBE (*Ztschr. Veterinärk.*, 14 (1902), No. 2, pp. 71-73).—In a serious case of this disease, which would probably have resulted fatally, the author decided to use the iodine preparation known as iodine-vasogen. A 10 per cent solution was employed and 15 gm. was administered along with oats each day for 4 days, making a total of 60 gm. The temperature of the animal fell and the petechial spots disappeared. It is believed by the author that this substance furnishes a valuable remedy for morbus maculosus.

Antistreptococcic serum for contagious coryza and morbus maculosus, MAIER (*Ztschr. Veterinärk.*, 14 (1902), No. 3, pp. 112-117).—An antistreptococcic serum having been prepared in the Pasteur laboratory in Stuttgart and placed upon the market, the author tested the action of this remedy in the treatment of contagious coryza and morbus maculosus. In treating the former disease it was found that the serum was not inactive, but the experiments showed that in severe cases it was not very effective. In treating morbus maculosus, however, the results were more satisfactory, and it is believed that as soon as the remedy can be manufactured more cheaply it will come into more general use.

Common parasites of domestic animals, L. L. LEWIS (*Oklahoma Sta. Bul.* 53, pp. 24, figs. 11).—This bulletin contains a popular account of the habits, appearance, and means of combating a number of animal parasites which commonly attack domesticated animals. The species upon which special notes are given include botfly, stomach worms of cattle and sheep, round worm of hogs, thorn-headed worm, short-nosed and long-nosed ox louse, biting louse of cattle, hog louse, cattle tick, screw worm, hen flea, horn fly, biting louse of horses and mules, sucking horse louse, ox botfly, and mange mites of sheep, cattle, and horses. The remedies usually applied in combating these parasites are recommended in the bulletin. In tests with creolin, zenoleum, and other coal-tar disinfectants, it was found that hog lice could not be killed with less than a 2½ per cent solution. In dipping experiments a 1 per cent solution of these coal-tar preparations was found to be of little or no avail. Kerosene emulsion, when made in the proportion of ½ lb. hard soap and 2 gal. kerosene to 1 gal. of water, proved to be a very effective remedy. In combating horn fly, good results are reported from the use of a mixture of creolin, fish oil, and kerosene, and from a mixture of pulverized resin, soap shavings, water, fish oil, oil of tar, and kerosene.

Intravenous injections of corrosive sublimate, A. SERAFINI (*Munich: J. Lehmann, 1902, pp. 16; reprinted from München. Med. Wchschr.*, 1902, No. 16).—The author discusses in a critical manner the experiments which have thus far been conducted in the use of corrosive sublimate by intravenous injections. Experiments were made on rabbits which had previously been infected with anthrax. It was found that

intravenous injections of corrosive sublimate had no effect on the development of the disease or the multiplication of the organisms in case of injections varying in size from 1 to 5 mg., and varying in proportion to the total weight of the blood from 1:150,000 to 1:130,000. It is believed, therefore, that this method of treatment can not be adopted with expectation of success in other animal or human diseases.

Farm management of germ diseases, J. J. REPP (*Breeders' Gaz.*, 41 (1902), Nos. 7, pp. 309, 310; 8, pp. 364, 365).—The author gives a popular discussion of the various methods by which the different infectious diseases may be transmitted from one locality to another, and outlines practical remedies which may be applied in preventing the transmission or in disinfecting premises after the occurrence of contagious diseases.

AGRICULTURAL ENGINEERING.

Sanitary engineering; a practical manual of town drainage and sewage and refuse disposal, F. WOOD (*London: Charles Griffin & Co., Ltd.; Philadelphia: J. B. Lippincott Co., 1902, pp. 304, figs. 181*).—In this book the attempt is made to deal with the principles of the subject "in a comprehensive, concise, and easily intelligible form," with a view to meeting the needs of "sanitary authorities, engineers, inspectors, architects, contractors, and students." In addition to a brief introduction, the book contains chapters on hydraulics; formulæ for velocity of water in pipes; earth pressure and retaining walls; power; house drainage; land drainage; sewers, separate system (for sewage and rainwater); sewage pumping; sewer ventilation; drainage areas; sewers, manholes, lampholes, etc.; trade refuse and river pollution; sewage disposal; bacteriolysis (bacteriological purification of sewage); sludge disposal; construction, materials, and cleansing of sewers; refuse disposal; and chimneys and foundations. The subjects of refuse destruction and refuse destroyers receive special attention. "Two chapters are specially devoted to the study of sewage disposal, and most of the well-known systems are briefly and sufficiently described to give a fair idea of the methods of working them. A chapter has been allotted to bacteriolysis, which is more fully and amply discussed owing to the special importance which has been attached to it in recent years, and to the large amount of data available."

Irrigation farming, L. M. WILCOX (*New York: Orange Judd Co., 1902, rev. and enl. ed., pp. 494, pl. 1, figs. 113*).—The first edition of this book appeared in 1895. The revision and enlargement in the present edition consists mainly of the addition of the following sections: Addition of silt, manure on irrigated soil, the Newsum system of water supply, the drop-head, silting of reservoirs, the arc stave flume, advantage of large heads, the Stokes measuring gate, a simple method of measuring water, importance of grading, the dammer, a caution against erosion, the depth of soaking, the contour system, wheat by subirrigation, rhubarb, roses, cultivation, the plowsole, nuts, foreign grapes, cranberries, Turkestan alfalfa, grain with alfalfa, alfalfa in rotation, the alfalfa sandwich, capacity of windmills and reservoirs, battle-ax windmills, the merry-go-round, the propeller pump, hot-air engines, pumping from quicksand, the Van Horn tap gate, simple grade levels, a ditch cleaner, a tandem hitcher, manure vat, the corrugated roller, and irrigation hardpan. New chapters are added on the following subjects: Seepage and drainage, electricity in irrigation, irrigation in humid climates, and winter irrigation. There has been no correction of the scientific inaccuracies so conspicuous in the earlier edition (E. S. R., 7, p. 431).

Irrigation in humid climates, C. S. PHELPS (*Massachusetts State Bd. Agr. Rpt. 1901, pp. 398-415*).—This article discusses the importance of irrigation to the New England farmer, gives instances of successful irrigation, makes suggestions regarding means of making water available (rams, windmills, steam power), and describes methods of applying water.

Irrigation (*Rpt. Registrar-Gen. on Agr. and Pastoral Statis. [Queensland], 1901, pp. 16-18*).—Statistics are given of the area irrigated, the source of the water supply and the means of utilizing it, and the crops grown under irrigation.

Reclaiming the arid Southwest, R. M. BARKER (*Forum*, 33 (1902), No. 3, pp. 343-371).—A general review of the more important physical characteristics of this region and of the progress made in its development under irrigation.

The prevention of the pollution of streams by modern methods of sewage treatment, L. P. KINNICUTT (*Science, n. ser.*, 16 (1902), No. 390, pp. 161-171).

Influence of height of wheel on the draft of farm wagons, T. I. MAIRS (*Missouri Sta. Bul.* 52, pp. 143-165, figs. 8).—This bulletin reports the results of a number of tests of the draft of wagons, equipped with wheels of different height, on macadam, gravel, and dirt roads in all conditions, and on meadows, pastures, cultivated fields, stubble land, etc. The draft was measured by means of a Giddings self-recording dynamometer, the net load in every case being the same, namely, 2,000 lbs. Three sets of wheels of different heights, all with 6 in. tires, were used as follows: Standard, front wheels 44 in., rear wheels 55 in.; medium, front wheels 36 in., rear wheels 40 in.; low, front wheels 24 in., rear wheels 28 in. The results obtained were in brief as follows:

"For the same load, wagons with wheels of standard height drew lighter than those with lower wheels.

"The difference in favor of the standard wheels was greater on road surfaces in bad condition than on good road surfaces.

"Low wheels cut deeper ruts than those of standard height.

"The vibration of the tongue is greater in wagons with low wheels.

"For most purposes wagons with low wheels are more convenient than those of standard height.

"Wagons with broad tires and wheels of standard height are cumbersome and require much room in turning.

"Diminishing the height of wheel to from 30 to 36 in. in front and 40 to 44 in. in the rear did not increase the draft in as great proportion as it increased the convenience of loading and unloading the ordinary farm freight.

"Diminishing the height of wheels below 30 in. front and 40 in. rear, increased the draft in greater proportion than it gained in convenience.

"On good roads, increasing the length of rear axle so that the front and rear wheels will run in different tracks to avoid cutting ruts, did not increase the draft.

"On sod, cultivated ground, and bad roads, wagons with the rear axle longer than the front one, drew heavier than one having both axles of the same length.

"Wagons with the rear axle longer than front one require wider gateways and more careful drivers, and are on the whole very inconvenient and not to be recommended for farm use.

"The best form of farm wagon is one with axles of equal length, broad tires, and wheels 30 to 36 in. high in front and 40 to 44 in. behind."

Agromotive, E. DELIGNY (*Jour. Agr. Prat., n. ser.*, 4 (1902), No. 32, pp. 180-182, fig. 1).—Under this name a form of farm traction engine is described.

Refrigerating machines, H. D'ANSHALD (*Jour. Agr. Prat., n. ser.*, 4 (1902), No. 36, pp. 316-318, figs. 5).—A number of machines are described.

The ventilation of stalls, R. PREUSS (*Deut. Landw. Presse*, 29 (1902), No. 72, p. 592, fig. 1).

MISCELLANEOUS.

Report of California Station, 1899-1901 (*California Sta. Rpt. 1899-1901, pt. 1, pp. 144*).—This includes the organization list of the station; financial statements for the fiscal years 1899-1901; a review of the work of the station during the three years by the director and of the substations by C. H. Shinn; a report on farmers' institutes

by E. J. Wickson, numerous articles noted elsewhere, brief abstracts of several bulletins of the station, and a reprint of Bulletin 130 on Preservation of Unfermented Grape Must (E. S. R., 12, p. 794).

Thirteenth Annual Report of Delaware Station, 1901 (*Delaware Sta. Rpt. 1901, pp. 213*).—This includes a financial statement for the fiscal year ended June 30, 1901, the organization list, and reports of the agriculturist, mycologist, chemist, horticulturist, entomologist, and meteorologist, noted elsewhere.

Biennial Report of Iowa Station, 1900-1901 (*Iowa State Col. Agr. Rpt. 1900-1901, pp. 14-20, 54-58, 84*).—An account of the work of the station during the year and financial statements for the fiscal years ended June 30, 1900 and 1901.

Ninth Annual Report of Minnesota Station, 1901 (*Minnesota Sta. Rpt. 1901, pp. XXII + 366*).—This contains the organization list of the station, a financial statement for the fiscal year ended June 30, 1901, a report of the director reviewing at some length the work of the different divisions of the station and of the experimental farms, and reprints of Bulletins 69-72 of the station on the following subjects: Bugs injurious to our cultivated plants (E. S. R., 13, p. 66), influence of wheat farming upon soil fertility (E. S. R., 13, p. 546), investigation in milk production (E. S. R., 13, p. 683), the forest garden (E. S. R., 13, p. 1053), and fruits and shrubs (E. S. R., 13, p. 1048).

Fifteenth Annual Report of Nebraska Station, 1901 (*Nebraska Sta. Rpt. 1901, pp. 62*).—This includes the organization list, a report of the director on the work of the station during the year, a financial statement for the fiscal year ended June 30, 1901, an article on Some Forage Plants for Summer Feed, already noted (E. S. R., 13, p. 176), and several articles abstracted elsewhere.

Agricultural experiment stations in foreign countries, A. C. TRUE and D. J. CROSBY (*U. S. Dept. Agr., Office of Experiment Stations Bul. 112, pp. 230*).—This is a list of the agricultural experiment stations and other institutions in foreign countries, in connection with which investigations relating to agriculture are conducted. The information regarding each is given under the following headings: Governing board, station staff, origin, equipment, income, and lines of work. A general review of the subject, constituting an introduction to the bulletin, is taken mainly from an editorial in this journal (E. S. R., 13, p. 605).

Our foreign trade in agricultural products, 1892-1901, F. H. HITCHCOCK (*U. S. Dept. Agr., Section of Foreign Markets, Bul. 27, pp. 67*).—The following table summarizes some of the statistics given in the bulletin:

Value of imports and exports of the United States, 1892-1902.

Year ended June 30—	Imports.			Domestic exports.			Excess of agricultural exports over agricultural imports.
	Total.	Agricultural.	Percentage agricultural.	Total.	Agricultural.	Percentage agricultural.	
	<i>Dollars.</i>	<i>Dollars.</i>		<i>Dollars.</i>	<i>Dollars.</i>		<i>Dollars.</i>
1892.....	827,402,462	436,697,057	52.8	1,015,732,011	803,122,045	79.1	366,424,988
1893.....	866,400,922	425,657,448	49.1	831,030,785	621,201,671	74.8	195,541,223
1894.....	654,994,622	365,160,319	55.8	869,204,987	636,633,747	73.2	271,473,428
1895.....	721,969,965	373,115,985	51.0	793,392,599	558,385,861	70.4	185,269,876
1896.....	779,724,674	391,029,407	50.1	863,200,487	574,398,264	66.5	183,368,857
Annual average, 1892-1896.....	772,098,529	398,332,043	51.6	874,512,164	638,748,318	73.0	240,416,275
1897.....	764,730,412	400,871,468	52.4	1,032,007,603	689,755,193	66.8	288,883,725
1898.....	616,049,654	314,291,796	51.0	1,210,291,913	859,018,946	71.0	544,727,150
1899.....	697,148,489	355,514,881	51.0	1,203,931,222	792,811,733	65.9	437,296,852
1900.....	849,941,184	420,139,288	49.4	1,370,763,571	844,616,530	61.6	424,477,242
1901.....	823,172,165	391,931,051	47.6	1,460,462,806	951,628,331	65.2	559,697,280
Annual average, 1897-1901.....	750,208,381	376,549,697	50.2	1,255,491,423	827,566,147	65.9	451,016,450

The leading agricultural imports during 1901, mentioned in the order of their importance, were sugar, coffee, hides and skins, silk, vegetable fibers, fruits and nuts, tobacco, wool, and tea, and the leading agricultural exports were cotton, wheat, corn, wheat flour, lard, cattle, bacon, fresh beef, leaf tobacco, ham, oil cake and oil-cake meal, and cotton-seed oil.

Agricultural imports of the United Kingdom, 1896-1900, F. H. HITCHCOCK (*U. S. Dept. Agr., Section of Foreign Markets Bul. 26, pp. 227*).—Statistical tables are given showing the kinds, values, and quantities of the agricultural imports from the different countries of supply for each of the 5 years 1896-1900. The total value of the agricultural imports in 1900 was \$1,578,000,000, or 62 per cent of the entire import trade of the United Kingdom. The United States supplied about 33 per cent of the agricultural produce.

Suggestions to pioneer farmers in Alaska, C. C. GEORGESON (*Alaska Sta. Bul. 1, pp. 15, pls. 7*).—This bulletin discusses clearing and draining land under Alaskan conditions, points out briefly the value of oxen as work animals, and gives directions for the construction of a log silo. The sterility of new ground in Alaska, to which attention has been called in former publications (*E. S. R.*, 13, p. 125), is again discussed, and methods of bringing these soils to a satisfactory state of fertility are recommended.

Agricultural monograph of the Polder region of Belgium (*Monographie agricole de la région des Polders. Brussels: Ministry of Agriculture, 1902, pp. 171+85*).—The region discussed in this monograph is a zone 10 to 15 kilometers wide, running parallel with the coast from Furnes to Knocke. As in previous monographs of this series (*E. S. R.*, 13, pp. 723, 799), the subjects discussed are climate and soil (see p. 230), agricultural operations (plant and animal production and agricultural manufacturing industries), permanent improvements, and the agricultural régime.

Teaching agriculture in Germany, II, J. VANDERVAEREN (*Bul. Agr. [Brussels], 18 (1902), No. 2, pp. 160-198*).—A brief summary of the different kinds of schools and methods of teaching agriculture in Germany.

Teaching agriculture in Austria, J. VANDERVAEREN (*Bul. Agr. [Brussels], 18 (1902), No. 2, pp. 199-213*).—A summary of methods and courses in agriculture in Austria.

Practical agriculture, C. C. JAMES (*New York: D. Appleton & Co., 1902, pp. 203, figs. 50*).—This book, the American edition of which is edited by John Craig, discusses the plant, the soil, the most common and important field and garden crops, the orchard, the vineyard, stock raising and dairying, and presents a chapter each on bees, birds, forestry, roads, and the rural home.

Practical manual for the farmer, L. BEURET and R. BRUNET (*Manuel pratique de l'agriculteur. Paris: L. Mulo, 1901, pp. 640+36, figs. 115*).—This book is divided into 3 parts, the first being devoted to meteorology, soils, fertilizers, drainage, irrigation, cultivation, and machinery; the second to cereals, industrial plants, viticulture, meadows, forage crops, horticulture, sylviculture, insects, and plant diseases, and the third to stock raising, wine, cider, beer, and resin making, silkworm culture, bee-keeping, and other industries.

NOTES.

COLORADO COLLEGE AND STATION.—E. D. Ball, assistant in zoology and entomology, has accepted the professorship of biology at the Utah College, and has entered upon his new work. Amos Jones, assistant professor of irrigation engineering, has accepted a position in the U. S. Geological Survey. The college and station are planning numerous improvements. A reservoir with an area of 50 acres and an inlet ditch for conducting storm water from an extensive watershed have been under construction during the year. A building for a central heating plant is in course of construction. This building will also be used for a department of electrical engineering. A building for the department of irrigation engineering and to contain the offices of the station is planned. This is to cost about \$60,000. An appropriation from the legislature will be asked for this purpose.

DELAWARE COLLEGE AND STATION.—C. O. Houghton, an assistant in the entomological department of Cornell University, has been elected zoologist and entomologist in the college and entomologist to the station, vice E. D. Sanderson, who, as previously noted, has gone to Texas.

MICHIGAN COLLEGE AND STATION.—Dr. R. C. Kedzie, who had been connected with the college for nearly forty years and with the station ever since its establishment, died November 7, after a short illness. A brief account of his services to agriculture will be given in the next number.

OREGON COLLEGE AND STATION.—The new Agricultural Hall was dedicated with appropriate ceremonies October 15. It is a handsome building of three and a half stories, costing something over \$40,000. It is 125 by 85 ft. and provides 35,000 square feet of floor space. On the first floor are the live-stock judging room, 40 ft. square, and the dairy department. The latter includes a main workroom 24 by 44 ft., provided with modern apparatus for the manufacture of butter and cheese, a testing laboratory 24 by 40 ft., which will also be equipped for pasteurizing in the near future, two commodious cheese-curing rooms, class room, office, boiler and engine room, etc. The second floor has a large hall to be used as an assembly room for conventions and for special lectures to students in agriculture. The office of the station director, fireproof vault for records, a spacious class room for general agriculture, and laboratories for soil physics and bacteriology are also located on this floor. A special bacteriological laboratory for station work is provided. The departments of horticulture, entomology, and botany are located on the third floor. Here provision is made for both the instruction and experimental work, there being a number of separate rooms for the station laboratories and collections. The entire south wing of the building, including the three stories, is devoted to chemistry. Here also special provision has been made for the station work, with separate storage rooms, laboratories, balance rooms, dark room, office of the station chemist, etc. The upper floor will be used as a general museum. The building will add greatly to the facilities of the institution for instruction in agriculture and for the work of the experiment station whose departments were previously somewhat scattered.

PENNSYLVANIA COLLEGE AND STATION.—C. A. Browne, jr., first assistant chemist, has resigned to accept a position at the Louisiana Sugar Station. It is expected that his time will be quite largely occupied in the chemical investigation of problems connected with the manufacture of sugar from cane. C. W. Norris, assistant chemist, has resigned to accept a position with a fertilizer firm in Philadelphia. The foundation has been completed for an assembly hall, the gift of Mr. and Mrs. Chas. M. Schwab. The original amount of the gift has been increased to \$140,000. The building will be a handsome structure of Roman brick with light terra-cotta trimmings, and will serve as a chapel and general assembly hall. Plans are being drawn for the new Carnegie library, for which \$100,000 was donated to the college last commencement. Some minor alterations are being made in the respiration calorimeter, which were suggested by the experience with the apparatus last winter. An electric motor will be substituted for the gasoline one for operating the pumps, the gasoline engine not having been found sufficiently regular and reliable in its work for such delicate experiments. It is planned to carry on a series of experiments with the respiration calorimeter the coming winter, using steers as subjects.

WISCONSIN COLLEGE STATION.—John C. Brown has been appointed instructor in agricultural chemistry in the college and assistant chemist of the station.

U. S. DEPARTMENT OF AGRICULTURE.—The total number of officers and employees of different grades in the Department has more than doubled in the last ten years. The number on July 1, 1893, was 1,870, and on July 1, 1902, 3,789, showing an increase of 1,919. The number of scientific workers and their assistants in the Department (including the Weather Bureau observers and meat inspectors) was 2,081 on July first last, and the number of executive officers and administrative assistants 1,708, making the total number of employees 3,789.

The Bureau of Plant Industry has constructed a barn at the Arlington Experimental Farm. The building is of brick, 40 by 100 ft. and two stories high, with a large attic or loft. It contains rooms for the storage of crops, seeds and machinery, a root cellar, stalls for a number of horses, a photographic laboratory, and office rooms. Such a structure has been much needed and will greatly facilitate the Department's work on this farm. The cost was about \$4,000.

A seed building 60 by 100 ft., and two stories high has just been completed which will provide offices and workrooms for the seed and plant introduction, storage for the special seeds, paint and carpenter shops for the Bureau of Plant Industry, etc. This building was provided for in the last appropriation act, which allowed the use of \$10,000 out of the fund for seeds for the erection of a warehouse for the seed handled by the Department.

Several new greenhouses and a large potting shed have been erected, and a new central heating plant for the greenhouses and offices in the vicinity has been installed. This plant will take the place of 13 separate heaters, which were put in from time to time as the greenhouses were extended.

MISCELLANEOUS.—The Seventh International Congress of Agriculture will convene in Rome in the spring of 1903. The exact dates will be given out later with the programme. The congress will be divided into the following sections: Rural economy, agricultural education, agronomy, animal husbandry, agricultural engineering, special crops and their corresponding industries, vegetable pathology, forestry, pisciculture, and viticulture and enology. To become a member of the congress it is necessary to make application to the Commission of Organization, Via Poli 53, Rome, before January 31, 1903, and to remit a membership fee of 20 francs. It is also desired that applicants state what particular section of the congress they wish to attend. Persons desiring to present papers are requested to send them to the Commission of Organization before December 15, 1902. The languages to be used at the congress are

Doctor Kedzie's experimental work for agriculture was not distinguished by profound and exhaustive investigation, but was largely of the practical pioneer sort which has been so useful in improving agricultural conditions and practice, and so important in preparing the way for succeeding work. Upon going to the college he took up the study of the muck lands and the value of composts of muck with animal manures and night soil for grass lands, corn, and potatoes. In 1866 some experiments were made on the relation of the volatile constituents of animal manures to vegetable growth; and these were followed by extended experiments to determine the value of such mineral fertilizers as wood ashes, lime, land plaster, salt, etc., for farm crops. Later the soils of the State were analyzed and their agricultural values studied. He early perceived the dangers of soil exhaustion under the profligate system of farming which was being practiced, and sounded the note of warning to conserve its fertility by rotation and by returning the manure to the soil. As early as 1863 he began an elaborate system of meteorological observations at the college, which have been continued without interruption to the present time.

He won the confidence of the farmers by his earnest work in their behalf, the practical character of it, and the zeal with which he championed their cause. He considered his work outside the class room as belonging to the public that supported the institution, and never felt better than when exposing with caustic denunciation the impositions and frauds foisted upon the public by unscrupulous dealers. He scented the battle afar off, and went into it with vim and vigor and an incorruptible honesty that overwhelmed opposition. Two notable instances of this were his crusade against unprincipled lightning-rod agents, and against the producers of low-test and dangerous illuminating oils. The latter campaign resulted in the passage of a State law establishing the flash-light test, and the employment of "Michigan test" as a trade-mark for high quality.

The Michigan State law relative to the control of the sale of commercial fertilizers was instigated by Doctor Kedzie, as were also laws for the protection of the public from the dangers of arsenical poisons in wall paper, dress goods, and the like. Through his investigation of the chemical composition, baking quality, and vesiculating power of Clawson wheat, which the millers of the State persisted in grading below its proper quality, he fought and won a battle for the farmers of the State which resulted in adding thousands of dollars to Michigan agriculture.

The development of the sugar-beet industry in Michigan must be credited largely to Doctor Kedzie. He imported the first seed, grew and analyzed the first beets, was directly instrumental in the building of the first Michigan factory, and was one of the strongest champions of the industry.

Farmers' institutes in Michigan also owe their origin to the initiative of Doctor Kedzie. In 1875 he offered a resolution to the faculty calling for the appointment of a committee to make arrangements for holding agricultural meetings with farmers, in which members of the faculty, the State board, successful farmers, and local talent should participate. He was made chairman of this committee, and for twenty years was one of the most popular, forceful, and convincing speakers at these meetings.

The change in Doctor Kedzie's career from medicine to agricultural chemistry is rather remarkable in two ways. At that period it was not customary to require very advanced chemical instruction in a medical school, and Doctor Kedzie must have been unusually proficient in that science to be called to a chair of chemistry after thirteen years of practice as a physician and surgeon. It is still more remarkable that having entered upon his chemical work with such an absorbing zeal, he retained his position in the medical profession. This is probably due to his connection with the State board of health, of which he was president for two terms. This position brought him prominently before the people of the State as an advocate of various sanitary reforms, and he did not relinquish his efforts in that direction when he voluntarily withdrew from the board in 1881. He was honored alike by the medical and chemical professions by election to the highest offices in their State and National associations. This shows the breadth and genius of the man, and the broad field through which his influence and strong personality were felt. In his death agriculture and science have lost an effective teacher, and his college one of its wisest counselors.

The initial number of a yearbook of the Russian experiment stations and similar institutions has recently been received. This is to be the organ for summarizing the work of the various institutions for the benefit of agriculture in Russia, and thus bringing together the heretofore scattered reports of their progress. It is a government publication, issued by the Ministry of Agriculture and Imperial Domains—Department of Agriculture, and will hereafter appear annually. The volume contains over six hundred pages, with numerous illustrations. The plan is not to publish detailed papers, but rather summaries of all the work, classified by subjects and also on a geographical basis. It will not, therefore, replace the present special reports issued by the stations, or any other form of publication, but will better enable investigators and others to follow the work of the Russian stations as a whole. The widely divergent conditions in different parts of the Empire as to climate, soil, biological aspects, and economic status are thought to make a geographical arrangement the more useful. For example, the work at the institutions in the northern nonchernozem region of Russia

is brought together in two chapters, that in Western and Southern Russia is discussed in two others, and a fifth chapter is devoted to the work of the stations located on the southern boundary of European Russia.

An introductory chapter gives a general historical review of agricultural experimentation in Russia, an account of its present scope, and the condition of the experimental institutions, which represent a variety of grades. According to this, the first experiment station in Russia, established in 1864, was in the nature of a control station, connected with the Polytechnic Institute at Riga. The second was a station for seed selection, connected with the Imperial Botanical Garden in St. Petersburg, and established in 1877; and the third was an experimental field on the crown lands at Petergrof, near Riga. Of recent years the number of stations has multiplied quite fast, and the support of the stations given by the government has been liberally increased. Three new crown stations were established last year, at Shatil, Batischevo, and Valuiki. The list of stations given in the volume includes 13 imperial stations, 23 subsidized institutions, and a large number of special stations engaged in work on some particular crop or animal. The work at many of the institutions is quite specialized. Some, for instance, are studying irrigation primarily, others viticulture, flax culture, tobacco culture, plant breeding, and agricultural bacteriology, and a number are devoted to fish culture and to sericulture.

The yearbook emphasizes the necessity of more extensive study of some of the leading problems connected with agricultural practice in different parts of the Empire. The results already obtained lead the authors to regard this class of institutions as of very great importance to the national prosperity, and to hold a very optimistic view of the future prospects for the work.

CONVENTION OF ASSOCIATION OF AMERICAN AGRICULTURAL COLLEGES AND EXPERIMENT STATIONS.

D. J. CROSBY,

Office of Experiment Stations.

The Association of American Agricultural Colleges and Experiment Stations held its sixteenth annual convention in Atlanta, Georgia, October 7 to 9, 1902. There was an enrollment of 135 delegates and visitors, including representatives from all but 7 of the States and Territories. Addresses of welcome were delivered by Hon. Livingston Mims, mayor of Atlanta, and ex-Governor W. J. Northen, and a response on behalf of the association was made by G. W. Atherton. The citizens of Atlanta were very cordial in their welcome to the delegates and visitors, and arranged for them two delightful entertainments on the afternoon and evening of the second day of the convention. The afternoon entertainment consisted of a trolley ride to the Georgia School of Technology and other points of interest in the city, ending with a luncheon served at the Piedmont Driving Club. In the evening the members of the association were given an informal reception and luncheon at the Carnegie Library by Miss Anne Wallace, librarian. On the following day the association adjourned at noon in order that the delegates might visit the Georgia Experiment Station, near Griffin. Following the final adjournment of the association, many of the delegates took advantage of excursions that had been arranged for them to Tuskegee, Chattanooga, Asheville, and other points.

The second annual meeting of the American Horticultural Inspectors was held in Atlanta beginning October 6, and several sessions of the meeting were held in conjunction with the section on entomology of the association.

GENERAL SESSIONS.

The day sessions of the association were held in the State Capitol, the evening sessions in the ballroom of the Kimball House. The general sessions were presided over by Pres. W. M. Liggett, of the University of Minnesota, who delivered the annual presidential address on the first evening of the convention. The subject of the address, Agricultural Education, gave opportunity for discussing briefly all the important agencies for the promotion of instruction and research in agriculture. While recognizing the varying needs of different sec-

tions of the country as to ways and means for accomplishing the best results, the speaker emphasized the fact that in discussions of this kind geographical lines must be wiped out and a free interchange of ideas be encouraged. Efficiency and ability to do were set as the goal to be attained in any system of education, and these are attained quite generally in agricultural education. A review was given of the progress made in various lines of industrial education, including that of the agricultural colleges and experiment stations, agricultural high schools, short courses, farmers' institutes, and the Graduate School of Agriculture at Columbus. The speaker also emphasized the importance of giving attention to elementary instruction in agriculture in the rural schools. The need of adjusting the relation of instruction to research was pointed out, and two institutions were mentioned as important agencies in this connection—the Graduate School of Agriculture, to train teachers and investigators; and the Carnegie Institution, to provide for and aid research, to furnish conditions necessary for the development of science.

An address on Education at Tuskegee was presented in a general session by G. W. Carver, director of the agricultural department of the Tuskegee Normal and Industrial Institute. He reviewed the work of the institution, gave a general idea of its extent and equipment, and pointed out in an interesting way the different lines of instruction open to the children of the colored race, and the lines of demonstration in agriculture undertaken for the instruction of farmers who visit the institution. The association extended a vote of thanks to Professor Carver for his address.

Dr. Daniel Morris, Commissioner of Agriculture, Imperial Department of Agriculture of the British West Indies, and William Fawcett, Director of the Department of Public Gardens and Plantations, Kingston, Jamaica, attended the sessions of the convention; and upon invitation from the association, Dr. Morris made a short address, in which he thanked the association for courtesies shown him and his colleague and expressed a desire on the part of the Imperial Department of Agriculture of the British West Indies to cooperate with the United States Department of Agriculture in promoting agricultural education and research in the West Indian possessions of the United States.

The report of the executive committee was presented by H. H. Goodell, chairman. The committee recommended (1) renewed efforts for the establishment of colleges of mining; (2) revision of Circular No. 34 of the Office of Experiment Stations, Rules and Apparatus for Seed Testing, by the committee that prepared the circular, with such additions as may be necessary to fill vacancies; (3) that the association instruct its executive committee, or appoint a special committee, to communicate with the War Department and request some modifica-

tion of its recent order increasing the amount of military instruction in the land-grant colleges; and (4) that the Graduate School of Agriculture be continued, the association to assume the necessary expense of maintenance, less such amount as may be voluntarily contributed by the institution at which the school is from time to time held, this expense to be met by assessments upon the colleges and universities represented in the association in proportion to the income of these institutions, provided that assessments may take the form of scholarships to be maintained in the name of the contributing institution. The report was adopted, and E. Brown and A. D. Shamel were appointed members of the committee to revise Bulletin No. 34 of this Office, in place of G. H. Hicks and Gerald McCarthy, deceased.

The report of the treasurer, E. B. Voorhees, showed cash on hand \$78.40, bills payable \$271.04, deficit \$192.64.

The report of the bibliographer, A. C. True, noted especially the marked increase in the number of publications reviewing literature along general lines, such as chemistry, plant protection, and veterinary medicine, and called attention to the number (over 100) of partial bibliographies and reference lists along lines related to agriculture. Mention was also made of the preparation of an international catalogue of scientific literature in 17 branches of science, work upon which was undertaken in 1901.

The report of the section on horticulture and botany was presented by the chairman, John Craig. It included the report of a somewhat extensive inquiry regarding the trend of efforts on the part of teachers and investigators in horticulture and botany. It showed the tendency in horticultural teaching to be toward an increase of laboratory and field work; in horticultural investigation, toward an increase of cooperative work. Teachers of botany, he found, were making progress toward more clearly differentiating the different branches of the study. The majority of them considered physiological botany of greater relative importance than systematic botany. Investigators in botany are of the opinion that cooperation between botanists is feasible, but are doubtful whether the same is true between botanists and farmers.

A report on the Graduate School of Agriculture at Columbus was given by A. C. True, dean of the school. The school opened July 7 and continued four weeks, closing August 1. The faculty included 35 men, drawn from agricultural colleges, this Department, and the New York State Station. Seventy-five students were in attendance. These were drawn from 28 States and Territories, from Canada, and from Argentina. Twenty-seven of the students are professors or assistant professors of agriculture in agricultural colleges, 31 are assistants in the agricultural colleges and experiment stations, 9 are recent college graduates, and 8 are engaged in farming. The expense

of the school was \$3,945.12. The income from fees was \$450, leaving a net cost of \$3,495.12, which was borne by the Ohio State University.

The report of the committee on indexing agricultural literature, presented by A. C. True, chairman of the committee, included a statement regarding the work along this line accomplished by the Department of Agriculture during the year, including the card index of experiment station literature, published by this Office, and card indexes of Department publications prepared by the Librarian of the Department. Attention was called to the increasing amount of indexing necessary to keep up with Department publications and to the lack of sufficient funds for accomplishing this work. It was stated that the Librarian of Congress would cooperate to the extent of printing index cards from this Department as a part of the index issued by the Library of Congress. In order to prepare the copy for these cards, additional help is needed in the Department Library, and the committee recommended that the executive committee of the association make an effort to secure from Congress an appropriation of \$2,500 to carry on the work.

A lively discussion was precipitated by the reports of the two committees appointed to consider the matter of making exhibits from the land-grant colleges at the St. Louis Exposition. Both the committee on collective college and station exhibit and the committee on cooperative college exhibit (mechanic arts) favored making exhibits at St. Louis, but the latter committee reported in favor of a combined effort to project a comprehensive exhibit of the entire work of the colleges and stations. After considerable discussion the matter was referred to the two committees, who later reported in favor of a unified exhibit of the distinctive features of college and station work, to be in charge of one committee consisting of the members of the two committees already appointed, and asked the executive committee to make an effort to secure from Congress an appropriation of \$60,000 for installing and maintaining the exhibit. This report was adopted and H. W. Tyler, of Massachusetts, was appointed a member of the committee in place of J. H. Washburn.

The report of the committee on graduate study at Washington was presented by A. C. True. Progress in this work has been very limited, owing to the complications arising from the establishment of the Carnegie Institution. No effort has been made to secure opportunities for graduate study in any of the Departments except the Department of Agriculture, which, however, has considerably broadened its work and made more general use than formerly of the register for scientific aids.

H. J. Wheeler presented the report of the committee on uniform fertilizer laws, which included a statement of the work done during the year in the way of distributing circulars for the purpose of securing greater uniformity. It was recommended that persistent and con-

tinued efforts be continued along these lines, and that the functions of the committee be enlarged so as to include feeding stuffs. The report was adopted.

The report of the committee on methods of teaching agriculture was presented by A. C. True. The report included a brief account of the Graduate School of Agriculture, at Columbus, a statement that a report on facilities for teaching agronomy would soon be published, and an account of work undertaken by the committee for the promotion of secondary agricultural education. The demand for secondary agricultural education and the inability of existing institutions to fully meet that demand were pointed out. The committee therefore undertook to show how, with very little rearrangement, courses of study in the public high schools could be adapted to the needs of the pupils desiring instruction in agriculture. This report has been prepared for publication and will be issued at once as a circular of this Office.

The report of the committee on pure-food legislation was presented by the chairman, W. A. Withers, who stated that there was a growing sentiment in favor of pure-food legislation, but a lack of agreement regarding the machinery for the enforcement of regulations. He recommended continued efforts for the promotion of pure-food legislation.

No report was presented by the committee on cooperation between the stations and U. S. Department of Agriculture, but W. J. Spillman spoke briefly in this connection regarding the cooperative work with which the Bureau of Plant Industry is concerned.

W. M. Hays, chairman of the committee on animal and plant breeding, reported progress. The committee met at Columbus in July and recommended the organization of the Plant and Animal Breeders' Association. The report recommended that the committee be continued and authorized to call a conference at the next meeting of this association to organize a plant and animal breeders' association to meet for the first time in 1904.

For the committee on designation of substations and trial stations, W. M. Hays reported progress and recommended that the committee be continued in order that it might confer with the Department of Agriculture regarding the nomenclature of such institutions.

A resolution introduced by E. Davenport, and adopted by the association, indorsed the plans of the Secretary of Agriculture for the promotion of farmer's institutes throughout the country, and pledged the active cooperation of the association in efforts to secure adequate financial support for this enterprise. A resolution calling on the executive committee to use its influence with Congress to secure the regular and prompt publication of the Annual Report of the Office of Experiment Stations was introduced by H. J. Wheeler and adopted by the association.

W. H. Jordan introduced a resolution urging upon the trustees of Carnegie Institution the importance of agricultural science to the national welfare, and expressing the hope that the magnificent gift of Hon. Andrew Carnegie may be used in some measure to promote investigation touching the relations of the sciences to agriculture. The resolution was adopted, and on motion of H. H. Goodell a special committee, consisting of W. H. Jordan, H. C. White, and T. F. Hunt, was appointed to present the matter to the trustees of Carnegie Institution.

A committee consisting of H. E. Alvord, J. L. Snyder, W. A. Henry, C. F. Curtiss, and W. M. Hays, reported brief resolutions on the death of President William Le Roy Broun, of the Alabama Polytechnic Institute, and President W. M. Beardshear, of the Iowa State College of Agriculture and the Mechanic Arts, and recommended that the committee be continued, with authority to invite suitable persons to deliver brief addresses at the next convention of the association, commemorative of the deceased presidents.

A resolution, introduced by E. Davenport and adopted by the association, provided that the executive committee urge upon Congress that it increase the appropriation for each agricultural experiment station by the sum of \$15,000 annually if in the opinion of the committee such action would be expedient.

In accordance with a resolution introduced by A. R. Whitson and adopted by the association, the following committee on agricultural engineering in land-grant colleges was appointed: W. E. Stone, A. R. Whitson, C. S. Murkland, S. Fortier, and Elwood Mead.

On motion of the secretary of the association the assessment for each institution represented in the association was fixed at \$15 for the ensuing year.

Amendments to the constitution, introduced by W. A. Henry, provide for doing away with the present sections of the association and dividing it into two sections—one on college work and administration, the other on experiment station work. The amendments further provide that no action on public and administrative questions shall be final without the assent of the section on college work and administration.

The following officers were elected for the ensuing year:

President, J. K. Patterson, of Kentucky; vice-presidents, R. H. Jesse of Missouri, W. E. Stone of Indiana, T. H. Taliaferro of Florida, C. C. Thach of Alabama, and J. W. Heston of South Dakota; secretary and treasurer, E. B. Voorhees, of New Jersey; bibliographer, A. C. True, of Washington, D. C.; executive committee, H. C. White of Georgia, W. O. Thompson of Ohio, W. H. Jordan of New York, and C. F. Curtiss of Iowa.

Section on agriculture and chemistry.—Chairman, C. G. Hopkins, of Illinois; secretary, J. F. Duggar, of Alabama.

Section on horticulture and botany.—Chairman, H. L. Bolley, of North Dakota; secretary, H. H. Hume, of Florida.

Section on entomology.—Chairman, A. L. Quaintance, of Maryland; secretary, V. H. Lowe, of New York.

Section on mechanic arts.—Chairman, F. P. Anderson, of Kentucky; secretary, W. M. Riggs, of South Carolina.

Section on college work.—Chairman, E. R. Nichols, of Kansas; secretary, J. W. Heston, of South Dakota.

MEETINGS OF SECTIONS.

SECTION ON AGRICULTURE AND CHEMISTRY.

In this section the investigation of feeding problems was discussed from two points of view. H. P. Armsby discussed the practical value of respiration calorimeter experiments, and C. F. Curtiss the scientific value of large-scale feeding experiments. The former took the position that the question as to the practical value of experimental work is a pertinent one and that the experiments should show indication of ultimate practical bearing. In this broad sense he considered experiments with the respiration calorimeter practical. In his opinion every experiment should be scientific in methods and practical in aim. Some of the things that he considered possible to determine with the respiration calorimeter were (1) what relation does extra energy (over maintenance ration) bear to energy stored up, (2) proportion of available energy in different classes of feeding stuffs, (3) influence of age and condition of animals, and (4) influence of varying the amount of food given to a dairy cow. He thought there was urgent need of collecting data on the available energy in different feeds, and emphasized the general importance of more scientific station work—of getting at principles. C. F. Curtiss agreed with the former speaker that it is important to arrive at scientific principles first, but contended that these principles should then be applied. In the application of these principles he had found that some difficulties attending experiments with the respiration calorimeter, such as individual variation, could be overcome by means of experiments on a large scale. He noted a dangerous tendency on the part of the public to accept the results of experiments too readily—before they had been verified. His experience had taught him that the theories of stock feeders are not all reliable when applied to farm practice, and he emphasized the importance of experimenting with large numbers and verifying first results by repetition of the experiment if necessary.

Some of the beef problems of the South and what the stations can do toward solving them was discussed by A. M. Soule, C. W. Burkett, D. W. May, and J. C. Robert. All of the speakers agreed that beef production in the South can be made both feasible and profitable; some

even went so far as to say that beef could be produced in the South more cheaply than in any other section of the country. There was also a general agreement on the proposition that animal husbandry will be the most efficient means for restoring fertility to Southern soils, and that it should become in the near future one of the important industries of that section. The principal drawbacks to successful beef production in the South were said to be the prevalence of Texas fever and the lack of permanent pastures, of well-bred cattle and of knowledge among the farmers regarding the rudiments of stock raising.

J. C. Robert gave interesting data regarding Texas fever and outlined a method for eradicating it by ridding the entire country of the cow tick. This could be done, he said, by concerted effort on the part of stock raisers along the quarantine line to rid every animal of ticks and, by practicing a rotation of pastures, to keep cattle off infested pastures until the ticks have disappeared, which would require from 8 to 12 months. In this way the quarantine line could be gradually moved southward until the whole country was freed of ticks. The speaker also emphasized the importance of developing a better market for beef cattle and of establishing slaughterhouses in the South.

A. M. Soule gave figures showing the number of cattle in the Southern States and the value of the same. He also showed that many of these cattle leave the South as stockers and feeders and are fed in the North. He contended that they should be fed in the South, that the cotton-seed meal should be utilized as a cattle feed, and that sufficient roughage to go with the cotton-seed meal could be cheaply produced. He quoted figures to show that at the Tennessee Station roughage, including silage, has been produced at a cost of \$1.23 per ton.

D. W. May gave emphasis to the statement that the South has the advantage of a larger variety of forage crops, a longer grazing season, and less need of providing shelter than any other section of the country. He also emphasized the importance of stamping out Texas fever and of improving the herd by the introduction of more well-bred sires. Recent investigations had led him to believe that the influence of good bulls could be greatly extended by practicing artificial impregnation which has proven successful in practice among horse breeders. He had found that one drawback to this practice, the death of spermatozoa due to the fermentation of semen, can be avoided by the use of a little glycerin. In this way he kept spermatozoa alive and active 10 hours in a room at a temperature of 67° F. and 30 hours in a temperature of 90° F. He also found that the semen could be diluted and the spermatozoa kept alive several hours.

C. W. Burkett had found the cotton crop to be the great hindrance to the introduction of animal husbandry. The people must be shown, he said, that animal husbandry is profitable to cotton production. He considered Bermuda grass one of the best grasses for the establishment

of permanent pastures. He also considered it important to secure better bred cattle by the use of pure-bred bulls on native stock and to educate and train stockmen.

C. G. Hopkins discussed the possibilities in plant breeding and selection, considering chiefly the question of breeding and selecting corn for different purposes, that is, for high or low protein content, high or low starch content, and high or low oil content. He showed that a small change in any one of these constituents, if fixed by breeding and selection, would have a great influence on the market price of corn. J. T. Willard emphasized the importance of basing investigations on the real needs of the section of the country in which they are undertaken, and called attention to the fact that a variety bred up to meet a certain demand in one section of the country is quite apt to prove a failure from the same point of view in another section. He considered it important that stations encourage local effort in this connection, and that they devote themselves to problems of economic importance rather than to fanciful features. The papers were discussed with a great deal of interest by Dr. D. Morris, E. Davenport, W. J. Spillman, and others.

The Source of Carbohydrates for the South for the Production of Meat was the subject of papers by W. J. Spillman, J. F. Duggar, and R. J. Redding. The latter paper was read only by title. The two speakers were in practical agreement in nearly every point of their discussion. They brought out the fact that in the South carbohydrates are more expensive than in the North, and that the production of them to supplement nitrogenous feeds is an important problem. Among the things suggested for introduction and test were cowpeas, corn, sorghum, Kafir corn, millo maize, teosinte, cassava, sweet potatoes, peanuts, Bermuda grass, crab grass, and the by-products of rice.

SECTION ON COLLEGE WORK.

A. C. True, of this Office, presented a paper on The Graduate School of Agriculture as a Means of Improving the Pedagogical Form of Courses in Agriculture, in which he showed the existence of one of the elements which are considered necessary to pedagogical form, namely, a body of knowledge regarding the subject under consideration. Some of the other elements, such as the arrangement in progressive order of the topics selected to be taught, appropriate apparatus, illustrative material, text-books, and works of reference, he found to be inadequate. He showed, however, how the Graduate School of Agriculture might be expected to result in greatly improving these conditions, how it might result in better agreement among educators regarding topics to be taught and the order of treatment, how the excellent apparatus found at Columbus had furnished many suggestions for improving the apparatus in other institutions, and how already a

movement has been started to put in printed form some of the lectures there delivered. He noted as an encouraging indication the organization of agricultural faculties with special teachers for different divisions of the subject of agriculture, instead of, as formerly, a number of teachers presenting the sciences related to agriculture. As a result of these changes there has been great stimulation of a proper sense of the dignity of the profession of agriculture and agricultural teaching. The paper was discussed by T. F. Hunt, who summarized his views in the statement that the men engaged in agricultural work are able executives, many are able in research, but there are not so many who employ the best pedagogical methods. He considered it as important to prepare for the profession of teaching in agriculture as to prepare for executive duties or research work. J. F. Duggar had found the Graduate School of Agriculture valuable to the teacher in the suggestions it gave for methods of instruction and for making apparatus. The school, he said, was also valuable in that it reduced differences and misunderstandings among educators.

A paper on Agricultural Education in the South was presented by J. C. Hardy, who first reviewed agricultural conditions in the South from the earliest times to the present and showed what influences had been detrimental to the development of educational institutions in that section. The South, he said, has taken advantage of the provisions for land-grant colleges and experiment stations, but as yet there are few agricultural books and papers and comparatively few who would read them. The work of college and station men in farmers' institutes during the last few years he has found one of the most potent factors in arousing greater interest in educational institutions and in securing more funds. He quoted figures to show how quite recently the people in different Southern States have provided liberal appropriations to supplement Government funds for the support of agricultural institutions. In discussing this paper, C. C. Thach stated that the agricultural and mechanical colleges have been one of the strongest agencies in eradicating the prejudice against manual labor, and quoted figures from the report of the Bureau of Education to show that at the present time there is a larger percentage of students taking agriculture in the land-grant colleges of the South than in the land-grant colleges of the North. He also emphasized the importance of the work being done by the experiment stations and of farmers' institute work.

A carefully prepared paper on Military Instruction in Land-grant Colleges was presented by J. W. Heston, who pointed out the fact that heretofore military instruction has suffered from lack of definiteness in the instructions sent out from the War Department. An investigation of the conditions of military instruction in different land-grant colleges showed great diversity in the extent and quality of

instruction required. He thought it desirable to strengthen military courses somewhat, and emphasized the importance of target practice and camp life in a system of military instruction. He would have military instruction required for 5 hours a week during 2 years of the collegiate course. Speaking of the recent order from the War Department, he pointed out that in his judgment it is utterly impracticable to meet the requirements of that order, and in this position he was supported by C. W. Dabney, G. W. Atherton, H. E. Alvord, and others who discussed the question. Some means of bringing the matter to the attention of the War Department was sought and finally, by vote of the section, it was decided to refer it to the standing committee of the association on military instruction in land-grant colleges, with the request that the committee confer with the Secretary of War and immediately thereafter report the results of the conference.

SECTION ON ENTOMOLOGY.

In this section three subjects of general interest were discussed. The discussion on excellencies and defects of existing legislation for the control of insects and fungus pests was opened by S. A. Forbes, who reviewed and compared the requirements of inspection laws in different States and gave special attention to the California law. In the discussion which followed quite a number of the members of the American Horticultural Inspectors' Association participated, explaining the requirements under which they were operating in different States. In this connection it is interesting to note that the horticultural inspectors appointed a committee of three to attempt to harmonize these laws—that is, to draw up a uniform law that could be recommended for all the States.

J. B. Smith discussed recent observations and experiments with insecticides for the San José scale, reviewing in a general way recent experiments along that line. In this discussion and in that by other members of the section the consensus of opinion seemed to be that crude petroleum, kerosene, and lime, salt and sulphur constitute the standard remedies for San José scale. The latter remedy has not been tried with success in the East until quite recently.

Cooperation in making insecticide tests was the subject of a discussion opened by H. T. Fernald, in which it was generally agreed that cooperation is desirable and that cooperators should agree on certain investigations along well-determined lines.

SECTION ON HORTICULTURE AND BOTANY.

Owing to the small attendance in this section only three of the papers on the programme were read. A paper by A. D. Selby on *The Need of Better Courses of Preparation for Work in Applied Botany* was read by the secretary. The writer regretted the fact that there

is no provision in the curricula of agricultural colleges for teaching vegetable pathology and that little attention is given to vegetable physiology. The paper read by E. M. Wilcox on Plant Pathology and Physiology in College Curricula was along the same general lines. He gave statistics showing the lack of courses in these subjects in about 120 educational institutions in this country. The papers were discussed by F. W. Rane, H. L. Bolley, and others. On motion of F. W. Rane a committee was appointed to formulate desiderata for courses in botany for students in agricultural colleges, including supplementary chemistry, etc., and to report at this section next year. The chair appointed as members of this committee A. F. Woods of the United States Department of Agriculture, F. A. Waugh, and A. D. Selby.

A paper by L. H. Bailey on The Editing of Experiment Station Publications was read by the secretary. The writer urged that an editor is needed for experiment station literature, because no matter how accurately an investigation is conducted, it "fails of its purpose when it does not reach the popular audience for whom it is intended, and it reaches this audience more because of its literary and typographical form than because of its scientific contents." Among the faults commonly found in station publications, the writer mentioned lack of coordination, too much preamble, long and involved sentences, and attempts at fine writing. He urged that the papers should be progressive and cumulative and that all secondary and incidental details be sacrificed for the sake of brevity.

The papers in the hands of the secretary, which were read only by title, were as follows: Lines of Experimentation Invitingly Open to Station Botanists, L. H. Pammel; Plant Breeding to Secure Resistant Forms, E. M. Wilcox; Some Peculiar Needs in New States, (a) Home Adornment, (b) Home Production, A. Nelson; Variety Tests in Florida, H. H. Hume; Bulletin Illustration, F. A. Waugh; How Far Should the Experiment be Followed by Educational Effort on the Part of the Experimenter, H. L. Bolley.

SECTION ON MECHANIC ARTS.

The subjects discussed in this section were in the main closely related to problems of interest in the South. W. M. Riggs, in his paper on Methods of Conducting Engineering Laboratory Work, described the methods as they now exist and emphasized the importance of giving more time to laboratory work and of placing more responsibility on the student, with a view to making him more self-reliant.

The Power Question in the South was discussed by C. M. Strahan. The question discussed was whether the development of water power should be favorably considered as against steam power. The speaker

favoured water power on account of the high price of coal and cited statistics to show that water could be relied upon to manufacture the whole cotton crop of Georgia.

In a paper on Sugar Engineering, T. W. Atkinson described the course of study as it is arranged at the Louisiana State University and Agricultural and Mechanical College. He also described the processes involved in the manufacture of sugar.

RECENT WORK IN AGRICULTURAL SCIENCE.

CHEMISTRY.

The nucleic acid of the wheat embryo, T. B. OSBORNE and I. F. HARRIS (*Connecticut State Sta. Rpt. 1901, pt. 4, pp. 365-430*).—An extended study of the nucleic acid in the wheat embryo, the discovery of which was announced in the report of the station for 1899 (*E. S. R.*, 12, p. 512), is reported. The literature of nucleic acid is reviewed at length, and the methods used in the preparation and analysis of the nucleic acid studied, to which the name tritico-nucleic acid is given, are described in detail. The authors' conclusions are given below in full:

“(1) The embryo of wheat contains a relatively considerable quantity of nucleic acid, for which the name tritico-nucleic acid is proposed. About 3.5 per cent of the commercial embryo meal used in this investigation probably consisted of tritico-nucleic acid.

“(2) On keeping, the meal undergoes a change so that the unaltered nucleic acid is obtained from it in diminished quantity or not at all.

“(3) Tritico-nucleic acid has the properties of the true nucleic acids of animal origin, but is less soluble in water.

“(4) Its composition corresponds to the formula $C_{41}H_{61}N_{16}P_4O_{31}$. It forms acid salts with potassium, sodium, or ammonium, which are readily soluble in water with a strongly acid reaction to litmus. In consequence of this, it is impossible to make preparations of the acid wholly free from base. The lack of agreement between the analyses of nucleic acids, heretofore published, is largely due to this fact.

“(5) On hydrolysis with acids, tritico-nucleic acid yields 1 molecule of guanin, 1 of adenin, 2 of uracyl, and 3 of pentose for every 4 atoms of phosphorus, and also an unidentified basic body.

“(6) Silver tritico-nucleotinate contains 6 atoms of silver for every 4 of phosphorus, from which the free acid is supposed to contain 6 hydroxyl groups.

“(7) The constitution of tritico-nucleic acid may be represented by the union of four $P(OH)_5$ groups, in which the 4 atoms of phosphorus are united by 3 of oxygen, and all but 6 of the remaining 14 hydroxyls are substituted by the groups named, thus forming a complicated ester of pentahydroxyl phosphoric acid, an acid unknown in the free state, but which Stokes has shown forms stable esters.

“(8) By a brief hydrolysis with dilute acids, all the guanin and adenin are split off and, at the same time, about one-fourth of the phosphorus appears as orthophosphoric acid. By dilute alkalis, the purin bases are not easily split off, but orthophosphoric acid is rapidly and abundantly formed.

“(9) After a brief hydrolysis, in acid solution, a complicated phosphoric acid remains which contains no guanin or adenin and only 2 pentose groups for every 3 atoms of phosphorus. The composition of its barium salt indicates that it may be formed from the nucleic acid by splitting off 1 of the phosphorus atoms, to which are attached the guanin, adenin, and 1 pentose.

“(10) Tritico-nucleic acid resembles the nucleic acids of animal origin, in that it contains the purin, pyrimidin and carbohydrate groups, together with phosphorus. The purin groups are the same in the animal and vegetable acids, but in the former

the pyrimidin and carbohydrate groups are represented by thymine and hexose, in the latter by uracil and pentose.

"(11) Tritico-nucleic acid closely resembles, and may be identical with, the nucleic acid of yeast, since both contain uracil and a pentose and appear to have the same ultimate composition.

"(12) Tritico-nucleic acid resembles guanylic acid, in that both may be represented as complicated esters of a phosphoric acid formed by the union of four $P(OH)_3$ groups, but otherwise they present marked differences, which indicate different physiological relations.

"(13) The conception of tritico-nucleic acid as an ester of pentahydroxyl phosphoric acid suggests a chemical relation that may possibly exist between paranucleic acid and the true nucleic acids, for the organic part of the paranuclein of egg yolk, as one of us has previously shown, has nearly the same composition as that of the organic part of the paranucleo-proteid from which it originated, as is seen when the analyses are calculated PO_4 free. (Four $P(OH)_3$ groups united by 3 oxygen atoms contain $P:O::1:4\frac{1}{2}$).

"(14) The protein compounds of nucleic acid may be regarded as protein nucleates, those containing but little nucleic acid united with much protein forming the nucleoproteids, those with much nucleic acid and little protein forming the nucleins. The proportion in which the protein and nucleic acid unite is determined by the relative proportion of bases and acids present in the solution at any given time."

The ash constituents of plants, their estimation and their importance to agricultural chemistry and agriculture, B. TOLLENS (*Jour. Landw.*, 50 (1902), No. 3, pp. 231-275).—This is a revised reprint (in German) of an article published in the *Record* (13, pp. 207, 305).

On the determination of phosphoric acid in plants, G. SOKOLOV (*Zhur. Opušn. Agron.* [*Jour. Expt. Landw.*], 2 (1901), No. 6, pp. 770-779).—The investigations reported in this article relate especially to the determination of phosphoric acid in the ash of various kinds of wood. It was found that in case of woods ordinarily yielding an ash rich in lime simple incineration is the most satisfactory method of preparing material for the determination of phosphoric acid.

The chemical methods of determining the productiveness of soils as dependent upon phosphoric acid, K. K. GEDROIZ (*Zhur. Opušn. Agron.* [*Jour. Expt. Landw.*], 2 (1901), No. 6, pp. 745-769).—Comparison of results obtained by means of chemical methods with those furnished by pot experiments on a number of different plants indicate that plants vary so much in their power of taking up phosphoric acid from the same soil that no one solvent can be relied on to measure the availability of this constituent for all plants. The author, however, considers the use of 2 per cent citric acid preferable to 2 per cent acetic acid proposed by Bogdanov for determining available phosphoric acid in the soil.

On the amount of 1 per cent hydrochloric acid required for the digestion of soils for analysis, P. KOSSOVICH (*Zhur. Opušn. Agron.* [*Jour. Expt. Landw.*], 2 (1901), No. 5, pp. 639-642).—Tests of 5 very dissimilar soils using 10 gm. of the soil to 500 cc. and 1,000 cc. of 1 per cent hydrochloric acid, indicate that the smaller amount of acid is not sufficient in all cases, but that 100 times as much acid as soil should be used. The author recommends 50 gm. of soil and 5 liters of 1 per cent acid.

On the question of the determination of humus in soils, P. KOSSOVICH (*Zhur. Opušn. Agron.* [*Jour. Expt. Landw.*], 2 (1901), No. 5, pp. 643-646).—The author reports examinations of chernozem soils which show that such soils rarely contain carbonates in sufficient amounts to interfere with the determination of humus by combustion in oxygen.

The determination of lime and magnesia in water, A. GRITNER (*Zschr. Angew. Chem.*, 15 (1902), pp. 847-852; *abs. in Chem. Centbl.*, 1902, II, No. 11, p. 857).—

The author reports tests of the soap solution method for determining hardness and of the methods of Clark and Winkler. These methods are considered unreliable. Pfeiffer's modification ^a of Wartha's method is recommended.

The determination of nitric acid in water, R. Woy (*Ztschr. Oeffentl. Chem.*, 8 (1902), p. 301; *abs. in Chem. Ztg.*, 26 (1902), No. 76, *Repert.*, p. 251).—The author describes a modification of Devarda's method (*E. S. R.*, 9, p. 723), which, it is claimed, gives very accurate results.

The rapid estimation of boric acid in butter, H. D. RICHMOND and J. B. P. HARRISON (*Analyst*, 27 (1902), No. 315, pp. 179-182).—The method as used by the authors is as follows: To 25 gm. of butter in a beaker is added 25 cc. of a solution containing 6 per cent of milk sugar and 4 per cent of normal sulphuric acid. The butter is melted, stirred well, and the aqueous portion allowed to settle for a few minutes, when 20 cc. is drawn off, brought to a boil, and titrated with half-normal soda solution, phenolphthalein being used as an indicator. Twelve cubic centimeters of glycerol is then added and the titration continued until a pink color appears. The difference between the 2 titrations, less the amount of alkali required by the glycerol, multiplied by the factor 0.0368 gives the amount of boric acid in 20 cc.; and this multiplied by 100 plus the percentage of water in the butter and the product divided by 20 gives the percentage of boric acid.

Determination of lecithin in milk, F. BORDAS and S. DE RACZKOWSKI (*Compt. Rend. Acad. Sci. Paris*, 134 (1902), No. 26, pp. 1592-1594; *Ann. Chim. Analyt.*, 7 (1902), No. 9, pp. 331-333).—The determination of phosphoglyceric acid is recommended. The method is as follows: 100 cc. of milk is added to a mixture of 100 cc. of alcohol, 100 cc. of water, and 10 drops of acetic acid. The coagulum is separated by filtration and extracted with alcohol. The extract is evaporated to dryness and the residue taken up with ether-alcohol. After evaporation the residue is saponified with potassium or barium hydroxid and the soap decomposed with nitric acid. The filtrate from this is evaporated to dryness and the residue treated with concentrated nitric acid and potassium permanganate. The phosphate is then determined as magnesium pyrophosphate, which, multiplied by the factor 1.5495, gives the amount of phosphoglyceric acid in the original sample.

Department of chemistry, A. L. KNISELY (*Oregon Sta. Rpt. 1902*, pp. 53-59).—This is a report of the chemist on the work done during the year and contains incomplete analyses of 14 samples of soil, determinations of soil moisture in 4 plats at different dates, and analyses of 3 samples of "red albumen," 2 of Paris green, 1 of mineral water, and 2 of blackberries.

On a new acid indicator, L. J. SIMON (*Compt. Rend. Acad. Sci. Paris*, 135 (1902), No. 10, pp. 437-439).—The properties of a new product, isopyrotartaric acid ($C_7H_5O_8$), obtained by calcining tartaric acid with potassium bisulphate, are described.

A vacuum desiccator heated by regulated incandescent lights, A. SKITA (*Chem. Ztg.*, 26 (1902), No. 77, p. 898, fig. 1).

Agricultural chemistry in the nineteenth century, W. FREAR (*Pennsylvania Dept. Agr. Rpt. 1901*, pt. 1, pp. 664-669).—A popular discussion of this subject.

BOTANY.

The relation of nutrition to the health of plants, A. F. WOODS (*U. S. Dept. Agr. Yearbook 1901*, pp. 155-176, pls. 7).—An outline is given of some of the more important problems of nutrition in relation to the health of plants, and a discussion of the effects of soil conditions on plant growth, the functions of various chemical elements as constituents of plants, and the effect of overfeeding and overwatering on the general health of plants.

^a*Ztschr. Angew. Chem.*, 15 (1902), p. 193.

Investigations on the utilization of ternary compounds by plants, P. MAZÉ (*Ann. Inst. Pasteur*, 16 (1902), Nos. 3, pp. 195-232; 5, pp. 346-378).—As a result of an extended series of experiments with peas, beans, lupines, peanuts, and corn, the author claims that the carbohydrate or the oleaginous reserves of the plant are utilized by being passed through a number of transformations which always result in the formation of alcohol. The author believes that the combining of the ternary carbohydrate compounds with the nitrogenous elements is brought about by the oxidation of the alcohol and its transformation to ethyl alcohol, but the evidence of this is not deemed sufficient for publication as yet.

In the second paper the author states that peas, when deprived of oxygen, transform the fermentable sugar into alcohol and carbonic acid, but do not utilize it for the construction of living tissue. If placed in favorable conditions, however, the plant exercises the same action on sugar and can utilize the alcohol for plant growth. In carrying on subsequent experiments it was found that these conclusions did not fully apply to yeasts, but were fully borne out by the fungus *Eurotium gypsi*. This fungus not only ferments sugar with the same activity as yeast, but is able to develop in a mineral solution when alcohol or dextrose is added. These 2 methods of nutrition are, according to the investigations of the author, shown to be identical in principle. The assimilation of ternary carbon compounds derived from sugar is brought about through the utilization of aldehyde by the living plant. The alcohol which is formed by the plant is not used as such, but as aldehyde. The differences noted in the nutrition of the fungus are attributed to the presence of zymase, which is necessary for the assimilation of the carbon derived from sugar.

Cane sugar as a reserve material in phanerogams, E. BOURQUELOT (*Compt. Rend. Acad. Sci. Paris*, 134 (1902), No. 12, pp. 718-720).—Investigations were made of a number of plants representative of those whose reserve material consists of starch, inulin, mannane, galactan, oil, etc. The author claims that 18 out of 20 species examined showed the presence of cane sugar in the portion of the plant examined. Continuing his observations he claims to have found cane sugar in carob beans, honey locust, onion, holly, *Aucuba japonica*, phellandrium, caraway seed, coriander, etc., and to have isolated the cane sugar from the mature seed of the honey locust, holly, lily-of-the-valley, *Aucuba*, and from the root of peony.

The starch of evergreen leaves and its relation to photosynthesis during winter, K. MIYAKE (*Bot. Gaz.*, 33 (1902), No. 5, pp. 321-340).—An investigation was made of various evergreen trees and shrubs, in which it was determined that the starch content differs much according to the different species. Monocotyledons generally contain less starch than dicotyledons, gymnosperms, and pteridophytes, or in some species none at all was observed. The starch in evergreen leaves normally begins to decrease in November, reaching its minimum during January and the beginning of February, and begins to increase again at the end of February. The starch found in evergreen leaves in winter is generally limited in amount as compared with that observed at other times of the year, but in a few species of plants it was found quite abundant. Starch is formed by photosynthesis during winter in small amounts and is translocated during the same season. The majority of evergreen leaves in the northern part of Japan almost entirely lose the starch from the mesophyll and guard cells in winter. In the middle and southern part of Japan many evergreen leaves contain considerable starch in the mesophyll, although the amount varies with different species during the coldest part of the winter. The starch content of evergreen leaves is generally more abundant in spring than late in summer or early in autumn. The stomata of a number of evergreen leaves were found to be open during the winter. The entire absence of calcium oxalate crystals from the leaves during winter, as claimed by Lidforss, could not be verified.

Photosynthesis by green leaves in light rays of different wave lengths, A. RICHTER (*Rev. Gén. Bot.*, 14 (1902), Nos. 160, pp. 151-169; 161, pp. 211-218).—

A review is given of the effects of different colored light on photosynthesis, and the author describes experiments with bamboo leaves placed for a time under colored screens which admitted different portions of light, and whose wave length was measured. As a result of all the experiments, which are reported at length, it is shown that the effect of light rays on the leaf is in proportion to the absorptive energy of the leaf and entirely independent of the part of the spectrum or of the wave length of the light rays.

The transformation of oil in seed during their germination, P. MAZÉ (*Compt. Rend. Acad. Sci. Paris*, 134 (1902), No. 5, pp. 309-311).—Experiments are reported on the germination of the seed of castor bean and peanut, in which the transformation of the oil contained in the seed is shown. The experiments are believed to show that the increase in sugar and similar material which takes place during the germination of the seed is made at the expense of the oil.

The growth of alfalfa in noncalcareous soils, P. P. DEHÉRAIN and E. DEMOUSSY (*Compt. Rend. Acad. Sci. Paris*, 134 (1902), No. 2, pp. 75-80).—A report is given of experiments with alfalfa which was grown in soil which contained little or no lime. One sample of soil, which is designated as heath soil, contained a great amount of organic matter while the other soil was disintegrated gneiss. Each soil was free from carbonate of lime. The soils were placed in pots containing 3 kg. to which 3 gm. of potassium phosphate was added. In addition, different pots received varying amounts of carbonate of lime and some received an inoculation of garden soil. The results of the experiments show that the organisms which produce tubercles on the roots of the alfalfa were present in both soils. Their action was made more vigorous by the addition of lime. The inoculation with garden soil was followed with favorable results in the case of the growing of alfalfa, as also proved true for the growing of clover.

The comparative resistance to high temperatures of the spores and mycelium of certain fungi, ABIGAIL O'BRIEN (*Bul. Torrey Bot. Club*, 29 (1902), No. 3, pp. 170-172).—The well-known fact that the spores of bacteria are more resistant to heat than the vegetative cells has led to an investigation of the general belief that the spores of fungi are better able to resist high temperatures than is the mycelium. The author experimented with *Aspergillus flavus*, *Botrytis vulgaris*, *Rhizopus nigricans*, *Sterigmatocystis nigra*, and *Penicillium glaucum*. These were grown on beet cylinders in test tubes and the mycelium was taken from the culture tubes within 24 days after the fungus began to grow. The effect of temperatures of from 45 to 65° C. on the spores and mycelium of this fungus is shown. It was found that the mycelium of all the fungi, except *Botrytis*, gave vigorous fresh growth at 50° C. for exposures of 30 and 60 minutes. Both the spores and mycelium of *Penicillium* gave vigorous growth at 55° C. The germination of spores did not always vary as to the length of time of exposure. This is attributed to variation in the resistance of individual spores.

The digestion of mannane in the tubercles of orchids, H. HÉRISSEY (*Compt. Rend. Acad. Sci. Paris*, 134 (1902), No. 12, pp. 721-723).—Mannane, which exists in the pseudo-tubercles of many orchids, is said to be transformed into mannose under the influence of soluble ferments. This transformation may take place in the tubercle itself when the material is used for the development of the new plant. It is necessary to recognize, however, that the ferment is distinct from the reserve material upon which it acts.

The endophytic fungi of orchids, G. T. GRIGNAN (*Rev. Hort. [Paris]*, 74 (1902), No. 15, pp. 361-365).—A discussion is given of the relations existing between certain fungi and some orchids, it having been claimed that a form of symbiosis existed between them. The author is led to doubt the accuracy of this contention and shows that the presence of the parasite is not necessary to the germination and growth of the orchids.

FERMENTATION—BACTERIOLOGY.

Diagnosis of bacteria, T. MATZUSCHITA (*Bacteriologische Diagnostik*. Jena: Gustav Fischer, 1902, pp. 692, figs. 17).—In the present volume the author presents a system of classification of bacteria, with special reference to their more conspicuous biological characteristics. The number of species considered in the volume is 1,525. Only bacteria are considered, no parasitic fungi belonging to other orders being treated. The bacteria are classified from a biological standpoint into 5 general groups: (1) Those which liquefy meat gelatin; (2) those which do not liquefy meat gelatin; (3) those which do not grow on meat gelatin at a temperature lower than 20° C.; (4) bacteria which have not been accurately described in the literature of the subject; (5) bacteria which have not been cultivated on artificial media.

The bacteria included under these general heads are further subdivided into aerobic and facultative aerobic and anaerobic forms. A further subdivision under these classes is based on the presence or absence of locomotor organs, these classes being divided again into groups which form spores and those which do not, and these groups in turn being still further subdivided into forms which stain by the Gram method and those which do not. Under each bacterial species considered by the author the method of growth, behavior, and appearance on various nutrient media are mentioned for purposes of identification of the species. The bacteria are further classified in the second section of the volume on the basis of the material or location in which they are found. This classification is followed by a detailed key arranged for the purpose of assisting in the identification of species of bacteria.

Treatise of bacteriology, pure and applied to medicine and hygiene, P. MIQUEL and R. CAMBIER (*Traité de bactériologie, pure et appliquée à la médecine et à l'hygiène*. Paris: C. Naud, 1902, pp. XVI+1000, figs. 224).—In this volume the authors discuss the various subjects which relate to the morphology, biology, and cultivation of bacterial organisms. Pathogenic fungi and protozoa are excluded from this volume but will be discussed in a subsequent treatise. The work is divided into 4 parts, of which the first contains an account of the morphology and biology of bacteria, their resistance to physical and chemical changes, nutrient media, cultivation of bacteria under aerobic and anaerobic conditions, experimentation on animals, microscopic preparations, methods of staining bacteria in cultures, exudations and animal tissues, and optical apparatus necessary for studying bacteria. The second part contains a detailed discussion of the various pathogenic micrococci, bacilli, and spirilla, as well as an account of diseases due to unknown micro-organisms, and a consideration of the problems of virulence, immunity, and methods of immunization. In the third part of the volume the authors discuss zymogenic, chromogenic, and saprogenic bacteria. The fourth part is devoted to the application of bacteriology to hygiene and medicine, and contains a discussion of a bacteriological analysis of air, water, and soil, together with a general account of mechanical, physical, and chemical methods of disinfection. In connection with the discussion of pathogenic bacteria an account is presented of the virus and toxins of a number of diseases in which the micro-organism is not known. These diseases include influenza, aphthous fever, smallpox, cancer, pleuro-pneumonia, yellow fever, rabies, and syphilis.

The composition of the albuminoids and cell membranes of fungi and bacteria, K. S. IWANOFF (*Beitr. Chem. Physiol. u. Pathol. Ztschr. Biochem.*, 1 (1902), pp. 524-537; *abs. in Bot. Centbl.*, 89 (1902), No. 17, p. 491).—Studies are reported of *Aspergillus niger*, *Boletus edulis*, *Claviceps purpurea*, *Bacillus megatherium*, *B. anthracis*, and *Staphylococcus pyogenes aureus*, in which the albuminoids were found to contain 15 to 16 per cent of nitrogen and 0.75 to 2.25 per cent phosphorus. The large phosphorus content places the albuminoids of these plants among the nucleoproteids. The cell membranes showed a decided reaction of chitin, which agreed closely with

that substance as known in animals. The methods of determination are fully described.

Denitrification, H. WEISSENBERG (*Centbl. Bakt. u. Par.*, 2. Abt., 8 (1902), pp. 166-170; *abs. in Jour. Chem. Soc. [London]*, 82 (1902), No. 477, II, p. 470).—A brief account is given of observations on the behavior of denitrifying organisms under different culture conditions.

Department of bacteriology, E. F. PERNOT (*Oregon Sta. Rpt.* 1902, pp. 67-69).—A brief report is given of experiments with cultures of bacteria in the preparation of vinegar from waste prunes and other fruits. The bacterial fermentation of corn silage was also investigated, and a number of cases of supposed bacterial diseases of animals are reported.

Report of the Moscow Bacteriological Agricultural Station for 1901, S. SEVERIN (*Rev. in Izv. Min. Zem.*, 1 (1902), No. 23, pp. 478, 479).—An investigation was made of the bacterial preparation Alinit, and 2 organisms were isolated from it. These organisms were found to possess no property of increasing the yield of cereals. The experiments were carried out with the application of the dry cultures, as recommended by the distributors of Alinit. The station also made an extended study of the process of fermentation of the dough in the preparation of black bread. The stability of dry cultures and their resistance to winter temperature was also investigated. It was found that these cultures as prepared by the station do not retain their vitality longer than 4 months. They were not affected, however, by low temperatures, even when subjected to a temperature of -20°C . In addition to the above, the station reports investigations on the influence of micro-organisms on insects.—P. FIREMAN.

The relation between the so-called Alinit bacteria, *Bacillus ellenbachensis*, *B. megatherium*, and *B. subtilis*, B. HEINZE (*Centbl. Bakt. u. Par.*, 2. Abt., 8 (1902), Nos. 13, pp. 391-395; 14, pp. 417-425; 15-16, pp. 449-453; 17, pp. 513-519; 18-19, pp. 546-556; 20, pp. 609-626; 21, pp. 663-669).—Comparative studies are reported on the relation between the organisms which are mentioned above. Their identity has been often claimed, and the author conducted a long series of cultures and experiments to ascertain their true relationships. A tabular summary is given, in which the more important biological phenomena of each species is shown. Based upon his observations, the author claims that in no case should the so-called Alinit bacteria be confused with *B. megatherium*, although agreeing in some superficial characteristics. The resemblance to the hay bacillus, *B. subtilis*, is still more remote.

Nitrogen assimilating bacteria, GERLACH and VOGEL (*Centbl. Bakt. u. Par.*, 2. Abt., 8 (1902), No. 21, pp. 669-674).—Experiments are reported with a species of bacteria that is recognized as belonging to the group called *Azotobacter* by some authors. The species under investigation was isolated and cultivated for some time and culture media of known composition inoculated with the organism. After 20 to 25 days the nitrogen content of the medium was determined, and in every case where inoculation material was used there was a decided gain in nitrogen. Greater gains were obtained where grape sugar was added to the nutrient medium than where it was displaced by calcium propionate.

Notes and observations on nitrifying bacteria, R. HELMS (*Agr. Gaz. New South Wales*, 13 (1902), No. 2, pp. 215-222, pl. 1).—Notes are given on agricultural bacteriology and its progress, and the action of nitrifying bacteria is described. The results of inoculation experiments with nitrifying organisms, as shown by the growth of wheat in pots, are given. Field experiments were conducted with the same organisms, but no definite results were obtained.

The aerobic retting of flax, L. HAUMAN (*Ann. Inst. Pasteur*, 16 (1902), No. 5, pp. 379-385; *L'Ing. Agr. Gembloux*, 12 (1902), No. 11, pp. 513-516).—The retting of

textile plants is said to be the result of the action of micro-organisms which attack the pectic bodies constituting the middle lamella of the fibers, as well as the most of the parenchyma which surrounds the fibrovascular bundles. An examination of a number of samples of retted flax showed the presence of the following organisms: *Bacillus coli communis*, *B. mesentericus fuscus*, *B. fluorescens liquefaciens*, *B. mycoides*, *B. subtilis*, *B. termo*, *Streptothrix foersteri*, *Micrococcus roseus*, *Penicillium glaucum*, *Mucor mucedo*, and *Cladosporium herbarum*; together with the sterile mycelia of a number of fungi. Pure cultures were made of these different organisms and experiments conducted with them, together with other fungi, such as *Sclerotinia libertiana*, *Botrytis cinerea*, and *Aspergillus niger*. Of these the author found *Bacillus fluorescens* gave the best results, the *Streptothrix* attacked the fibers less rapidly, while *Micrococcus roseus* was the least efficient in retting the flax. His studies showed that these organisms act through the solution of the pectin in the flax, and in artificial solutions where pectate of lime was added the material was readily liquefied.

A variety of hog-cholera bacillus which closely resembles *Bacillus typhosus*, M. DORSER (*Abs. in Science*, n. ser., 15 (1902), No. 375, p. 370).—A variety of hog-cholera bacillus, which was isolated from a virulent outbreak of hog cholera in Page County, Iowa, is described. This variety corresponded in every way with the typical hog-cholera bacillus, except in its fermentation of glucose without the evolution of gas. In this respect it resembles *B. typhosus* more closely than the hog-cholera group of bacteria. Examination of several cultures has shown that structurally this variety of hog-cholera bacillus can not be distinguished from some specimens of *B. typhosus*; but the author concludes that when the source and pathogenic properties are considered the organism should be classed among the hog-cholera bacteria.

Oysters and sewage in Narragansett Bay, C. A. FULLER (*Abs. in Science*, n. ser., 15 (1902), No. 375, pp. 363, 364).—The sewage of the city of Providence, which amounts to about 14,000,000 gal. per day, is discharged into Narragansett Bay and is carried out by the tide, coming into more or less contact with some of the oyster beds. Samples of water and oysters were collected from different localities, and analyses made of the material while still quite fresh. The results showed that the water, oysters, mussels, and clams for a distance of a quarter of a mile from the sewer opening contained *Bacillus coli*, *B. cloacæ*, and *Bacterium lactis aerogenes*. The water and oysters from a bed 2 miles below the sewer contained the same organism. Thirty per cent of the oysters and about 60 per cent of the water samples from a bed situated in a strong tidal current 5 miles from the sewer contained *Bacillus coli*. Forty per cent of the oysters and 70 per cent of the water samples from a bed in sluggish water 5½ miles from the sewer contained the bacteria, and oysters from a bed 6 miles away were also infested. Oysters from a bed 6½ miles below the sewer contained no colon bacilli, and the water contained specimens only occasionally, and then only when taken on a falling tide. Beds still farther down the bay were entirely free from contamination.

Preliminary observations on *Bacillus coli communis* from certain species of animals, V. A. MOORE and F. R. WRIGHT (*Abs. in Science*, n. ser., 15 (1902), No. 375, pp. 372, 373).—A study has been made of *Bacillus coli communis* found in the large and small intestines of horses, cattle, sheep, swine, dogs, and chickens. The purpose of these examinations was to find the extent to which varieties of this bacillus exist normally in the intestines of different individuals of the same species, and of different species of animals. The object was to determine if the many varieties of the colon bacillus, which have been described from polluted water, soil, and from lesions of various kinds in man and animals, have their natural existence in the supposed normal habitat of this species of bacteria. The results showed no pronounced variation in the morphology or the cultural characters of these bacilli from different sources when grown on gelatin, agar, potato, and bouillon.

On the apparent identity of the cultural reactions of *Bacillus coli communis* and certain lactic bacteria, S. C. PRESCOTT (*Abs. in Science*, n. ser., 15 (1902), No. 375, p. 363).—While engaged in studying certain lactic bacteria the author noted the great similarity presented by some of the cultures to those of *B. coli communis*, and he has carried on investigations with a large number of lactic-acid-producing organisms, comparing their cultural reactions with those of the above species. Cultures were isolated from 47 different media. All of these were tested, and their growth and morphological characters noted. Of the 47 cultures examined, 25 gave typical colon reactions, 6 gave a weak response to tests, and the others failed. Regarding the source of these bacilli, the author suggests that they may be true colon bacilli from sources which can only be conjectured; or they may be lactic-acid organisms, not absolutely identical, yet almost impossible of differentiation from the colon bacilli. The latter view the author regards as the more probable. This work has a very practical sanitary bearing and seems to indicate that too much reliance can not be placed upon the so-called colon test of potable waters.

Toxicity of water toward pathogenic bacteria, H. L. RUSSELL (*Abs. in Science*, n. ser., 15 (1902), No. 375, p. 364).—A preliminary report is given on the action of natural water on the vitality of various organisms, particularly pathogenic organisms. When typhoid and colon organisms were inoculated in boiled waters (surface, deep well, and spring) growth generally occurred. This was more marked with the colon than with the typhoid organisms, and was most pronounced where the seeding was light. When the same cultures were exposed to the action of water filtered through a Chamberland or Berkefeld filter, or to etherized water in which the anæsthetic had been removed by aspiration, growth not only did not take place but the numerical content was greatly reduced, so that the cultures became sterile within 24 hours. Tests showed that if filtered water was heated to 60° C. for 10 minutes it lost its toxic power. The origin of the toxic substances is ascribed to the development of water bacteria. After incubation for 33 days, this water was again filtered and found toxic for typhoid and colon bacteria, and upon heating it again lost its toxicity. Some bacterial species develop in standing water, seeming to indicate their ability to tolerate the toxins.

Effect of low temperatures of liquid air on pathogenic organisms, C. M. BELLI (*Pub. Ist. Ig. Univ. Padova*, 2 (1902), XII, pp. 7; *extr. from Riforma Medica*, XVIII, No. 19).—An account is given of experiments with chicken-cholera bacilli and spore-bearing and nonspore-bearing forms of bacteria of carbuncle, which were subjected for 9 hours to the action of the temperature produced by liquid air. The results show that this temperature, which was about -190° C., not only checked the development of the bacteria but caused an actual diminution in the number of colonies present by destroying some of the least resistant.

On the germicidal action of the organic peroxids, F. G. NOVY and P. C. FREER (*Abs. in Science*, n. ser., 15 (1902), No. 375, pp. 365, 366).—The authors have conducted a series of experiments with a view of ascertaining the correct explanation of the action of certain metals and of sunlight on bacteria. It is known that certain substances exert a marked effect upon the formation of benzoyl acetyl peroxid, and this served as a basis for the view that metals act upon bacteria by giving rise to energetic peroxids. In order to substantiate that theory the authors have investigated the action of a number of known organic peroxids, some of which have proved wholly inert, while others exert pronounced and remarkable germicidal properties. With reference to diacetyl peroxids and benzoyl acetyl peroxid, it is shown that these bodies are chemically and bacterially inert, but on contact with water they undergo hydrolysis and give rise to the extremely energetic acetyl hydrogen and benzoyl hydrogen peroxids. A solution of 1:3,000 of these is capable of destroying all pathogenic bacteria, and even some very resistant spores, within one minute. The germs of cholera and typhoid fever added to tap water are promptly destroyed

by 1 part of peroxid to 100,000 of water. The powerful effects of the organic peroxids are believed to be due to the acetyl and benzoyl ions.

Tryptophane in proteolysis. S. H. VINES (*Ann. Bot.*, 16 (1902), No. 61, pp. 1-22).—The author claims that the proteolytic enzyme of *Nepenthes*, as well as those of the pineapple and the papaw, are essentially tryptic in their action. This is shown by the presence of a substance, known as tryptophane, among the products of digestion when tested by means of chlorin water. This substance is generally considered to be an indication of the disruption of the proteid molecules into nonproteid substances characteristic of tryptic digestion. In the present paper the author gives an extended account of his observations on the enzymes bromelin and papain, and describes experiments with the enzymes found in the fig, cocanut, germinating seeds of beans and barley, of yeast, and of the bacteria of putrefaction, as well as with animal pepsin. Under appropriate conditions the presence of tryptophane among the products of digestion of fibrin and Witte-peptone was demonstrated. The production of tryptophane in the experiments outlined is held to bear out the author's opinion that proteolytic enzymes of plants in general are essentially tryptic. Until the existence of a peptic enzyme is proved, the author claims that this statement will hold good. In respect to the action of the medium the vegetable enzymes may be taken to show affinity with pepsin on the one hand and trypsin on the other. In conclusion, the author adds a few words regarding the action of hydrocyanic acid in promoting proteolysis in plants. The general occurrence of this substance in plants has long been known, and it was once assumed to be present to afford protection to the plant, but recent experiments show that hydrocyanic acid is an early product in the nitrogen metabolism of the plant.

The symbiosis between *Amylomyces* and a species of *Micrococcus*. P. VUILLEMIN (*Compt. Rend. Acad. Sci. Paris*, 134 (1902), No. 6, pp. 366-368).—A brief description is given of *Mucor rouxianus*, which is the ferment employed in the manufacture of certain Chinese food products. When cultivated on cooked rice at a temperature of 15° C. this mucor takes on a fine orange-yellow coloration which is due to the accumulation in the filament of a refracting product. In the older filaments a crystallization of this pigment may be observed. When the cultures are made at a temperature of 28° or more, the color produced is much paler. The author has found associated with this mucor an undetermined species of *Micrococcus*, and it is believed that the association of these 2 organisms is symbiotic through the *Micrococcus* attacking the carbohydrates and consuming the maltose, making it possible for the fungus to grow luxuriantly and produce the orange-yellow pigment which characterizes it.

The action of tannin and coloring matter on the activity of yeasts. A. ROSENSTIEHL (*Compt. Rend. Acad. Sci. Paris*, 134 (1902), No. 2, pp. 119-122).—The action of tannin and coloring matter on the activity of yeasts used in wine making is described.

Notes on the enzymes of the Japanese sake-yeast. T. TAKAHASHI (*Bul. Col. Agr. Imp. Univ. Tokyo*, 4 (1902), No. 5, pp. 395-397).—Since the occurrence of certain enzymes is said to be characteristic of certain yeasts and as the sake-yeast differs in its physiological and morphological properties from the common beer and wine yeasts, the author has made a study to ascertain the kinds of enzymes present. The methods of procedure are described, and as a result of his investigations the author claims that sake-yeast contains sucrase, zymase, trypsin, catalase, and peroxidase.

A new form of incubator and thermoregulator for bacteriological work. H. E. WARD (*Illinois Sta. Circ.* 59, pp. 12, figs. 2).—A new form of incubator is described which is believed to be better adapted to use in the laboratory than those generally employed. The method of heating is by means of incandescent electric lamps, and a more constant temperature may be secured. Variations of less than a half degree in 24 hours have been reported for this form of apparatus.

ZOOLOGY.

A biological investigation of the Hudson Bay region, E. A. PREBLE (*U. S. Dept. Agr., Division of Biological Survey, North American Fauna No. 22, pp. 140, pls. 14*).—In this report the author gives an account of a trip by water from Lake Winnipeg to the western shore of Hudson Bay, and also along the shore to a considerable distance north of Ft. Churchill. The author describes the general features of the country along the course of the trip and presents notes on the life zones and boundaries of the region as well as on the new species of mammals which were discovered. Annotated lists of the mammals, birds, and batrachians collected on the trip are presented, together with an extensive bibliography of literature relating to the biology of this region.

The prairie dog of the Great Plains, C. HART MERRIAM (*U. S. Dept. Agr. Yearbook 1901, pp. 257-270, pls. 3, figs. 2*).—The prairie dog is distributed throughout the Great Plains region from Montana to Texas. The average number per acre in infested localities is about 25, although much larger numbers are found in some places. In the southern part of their range they are seen nearly every day even in winter, but in Montana and Wyoming they hibernate for periods of varying length during the winter. Prairie dogs are able to live without drinking and therefore inhabit grazing lands far from any source of water. The usual number of young for each pair appears to be 4. The burrow may be dug to a depth of 14 ft. or deeper below the surface and is provided with horizontal apartments. The chief enemies of the prairie dog are the coyote, badger, black-footed ferret, and rattlesnake. Hawks and owls also destroy the young prairie dogs. This animal is increasing in many parts of the Great Plains. The remedies recommended for combating prairie dogs include poisoning with strychnin or cyanid of potash, and fumigation with bisulphid of carbon.

Killing woodchucks with carbon bisulphid, C. M. WEED (*New Hampshire Sta. Bul. 91, pp. 45-48*).—A number of experiments are reported, during which it was found that carbon bisulphid furnished a rapid and easy means of ridding cultivated fields of woodchucks. The experiments were conducted chiefly by A. F. Conradi, W. F. Fiske, R. A. Cushman, and P. A. Campbell. In nearly every case the treatment of a burrow with bisulphid of carbon resulted in the death of all the woodchucks contained in it.

The suslik in Germany, A. JACOBI (*Arb. K. Gesundheitsamte, Biol. Abt., 2 (1902), No. 4, pp. 506-511, fig. 1*).—A circular letter was sent out to various parts of Germany for the purpose of determining the distribution, prevalence, and other data of economic importance bearing upon this mammal. It was found that the suslik has become quite widely distributed throughout the German Empire. Considerable damage to various crops, especially cereals and legumes, is reported as due to susliks, and the use of bisulphid of carbon is recommended for destroying them.

The ravages of rabbits in Germany and experiments in their control, A. JACOBI and O. APPEL (*Arb. K. Gesundheitsamte, Biol. Abt., 2 (1902), No. 4, pp. 471-505, figs. 7*).—Detailed notes are given on the numbers of rabbits in various parts of Germany, and on the early history of the spread of these animals over the country. The chief injury from rabbits to which the authors devote their attention is the destruction of young trees. It appears that when the rabbits occur in large numbers and their food is scarce, all kinds of trees and shrubs are attacked without much indication of preference. Rabbits are said to eat the needles from young pine, or if pressed with hunger, they destroy the pines, wood and all. Other trees are attacked in a similar manner. In discussing the various methods of controlling these pests it is stated that the traps which have thus far been devised are not effective in localities where rabbits occur in large numbers. Extensive experiments were conducted with

acetylene, Picotolin, and bisulphid of carbon. These substances were all applied as gases for the destruction of rabbits in their burrows. Acetylene was found to be ineffective. Picotolin is a mixture of sulphuric and liquid carbonic acids. When exposed to the air the substance volatilizes rapidly, and the experiments showed that it was fatal to rabbits. The application of this remedy, however, requires much time and is also expensive. It appears also to have an injurious effect upon the workmen. By far the best results were obtained by the use of bisulphid of carbon, which is recommended as the best substance for destroying rabbits in winter. It is urged also that attention should be given to the use of any remedy which has proved effective under local conditions in order to supplement the destructive effects of the bisulphid of carbon.

Combating the mouse pest by means of the mouse typhus bacillus of Mereshkowski, Y. KOZAI (*Bul. Col. Agr. Imp. Univ. Tokyo*, 4 (1902), No. 5, pp. 290-322).—The author conducted experiments in the use of the bacillus of Mereshkowski in destroying common field mice in the province of Ibaraki, northeast from Tokyo. The field mice upon which experiments were made belonged to the species *Arvicola hatusumi*. Notes are given on the behavior and growth of the bacillus on various nutrient media. In preliminary experiments in the laboratory moistened buckwheat meal was infected with material from a bouillon culture of the bacillus of 24 hours standing. The moistened meal was readily eaten by the mice and all became infected with the disease without exception. Field experiments were then undertaken in a similar manner but on a larger scale. The infected material was placed in a field under piles of tobacco stems which were frequented by the mice. After a period of 5 days the burrows underneath the piles of tobacco stems were carefully investigated, with the result that of the 20 mice which were found in them 17 (85 per cent) had contracted the disease. A number of additional experiments were made along the same line, with quite promising results.

The resistance of rats and insects to carbonic and sulphurous acids, J. P. LANGLOIS and A. LOIR (*Compt. Rend. Soc. Biol. Paris*, 54 (1902), No. 12, pp. 414, 415).—The experiments were undertaken on account of the possible agency of these animals in distributing bubonic plague in cities. Carbon dioxid and the fumes of sulphurous acid were found to be of little value in destroying rats and insects.

Protection of useful birds, C. W. PETERSON (*Rpt. Dept. Agr. Northwest Territories*, 1901, pp. 65, 66).—Brief notes are given on the relation between insectivorous birds and agriculture. The agency of birds of prey in the destruction of gophers and other rodents is discussed, and notes are given on various means which must be adopted for poisoning these animals in case they are not held in check sufficiently by birds. Experiments were made in infecting wheat with pathogenic organisms for the purpose of spreading disease among gophers. It was found during these experiments that the bacilli of fowl cholera or mouse typhus could be relied upon to kill the gophers in an infected burrow, but that the disease did not spread rapidly from one burrow to another.

On the necessity for the preservation of our insect-destroying birds, with an alphabetical list of the principal kinds, C. FRENCH (*Jour. Agr. Victoria*, 1 (1902), No. 1, pp. 69-73).—The author gives brief general notes on the relationship of birds to agriculture, and presents a list of the principal insectivorous birds of Victoria.

Two vanishing game birds—the woodcock and the wood duck, A. K. FISHER (*U. S. Dept. Agr. Yearbook 1901*, pp. 447-458, pls. 2, figs. 3).—Attention is called to the great destruction of these birds in their winter home in the Southern States. No protection is offered to them there, and they are slaughtered in large numbers. Notes are given on the habits, distribution, and natural enemies of these birds. The most important natural enemies of the woodcock are considered to be the cat, red squirrel, sharp-shinned hawk, and mink. The best preventive measure suggested

for protecting the woodcock is to abolish all spring and summer shooting. Similar measures may be profitably adopted for protecting the wood duck.

Notes on the winter habits of the red-headed woodpecker, H. A. WINKENWERDER (*Bul. Wisconsin Nat. Hist. Soc., n. ser., 2 (1902), No. 1, pp. 69-73*).—Numerous observations were made on the feeding habits of the red-headed woodpecker, and especially upon the habit of this bird in storing food for winter use. Attention is especially called to their habit of storing grasshoppers and other insects in cracks of wood and other locations, from which they may be removed and eaten by the birds during the winter. In order to obtain data concerning the distribution and habits of the red-headed woodpecker within the State, 150 circulars of inquiry were sent to different parts of the State, and 100 of these were filled out and returned. The answers thus received are presented in tabular form.

Regulations for the importation of eggs of game birds for propagation, J. WILSON (*U. S. Dept. Agr., Division of Biological Survey Circ. 37, pp. 2*).—In accordance with the act of Congress approved June 3, 1902, permits will be required for all eggs of game birds introduced into the United States. For the present permits will be issued for the importation of eggs of the following families of birds: Gallinæ, Otididæ, Rallidæ, Anatidæ, and Tinamidæ. All packages containing eggs must be properly marked and be subject to inspection at the custom-house.

Interstate commerce in birds and game, J. WILSON (*U. S. Dept. Agr., Division of Biological Survey Circ. 38, pp. 3*).—A brief statement is made of the important provisions in various laws relating to the shipment of game, marking packages, special restrictions regarding game in general and western and Alaskan game, and provisions concerning propagation and private use of game, insectivorous birds, and birds for millinery purposes.

Importation of reptiles into Hawaii, J. WILSON (*U. S. Dept. Agr., Division of Biological Survey, Circ. 36, folio*).—The present circular amends Circular 30, so that from July 1, 1902, until further notice permits are required for the entry of reptiles in all ports of the Hawaiian Islands. No permits are to be issued for the introduction of poisonous snakes.

Zoological yearbook for 1901, P. MAYER (*Zool. Jahresber., 1901, pp. VIII+499*).—This volume, as usual, contains detailed bibliographical lists, together with brief abstracts of the literature on Protozoa, Porifera, Coelenterata, Echinodermata, Vermes, Bryozoa, Brachiopoda, Arthropoda, Mollusca, Tunicata, and Vertebrata, as well as on general biology and embryology.

METEOROLOGY—CLIMATOLOGY.

The Chinook winds, A. T. BURROWS (*U. S. Dept. Agr. Yearbook 1901, pp. 555-566, figs. 3*).—This paper discusses the origin of the application of the name Chinook to winds and explains that there are 3 kinds of Chinook winds, all of which possess high temperatures. "One is moist and may be followed by rain. It occurs only near the ocean. Another is a dry wind, and rain seldom follows for some time after its occurrence. The third wind occupies an intermediate stage, and, from the present knowledge of it, seems a combination of the other two. From November to March these Chinooks play an important part in determining the character of the weather in the Northwestern States. They are active agents in tempering the severity of the winter. When they arrive cold waves vanish, the snow disappears, and a short period of bright, balmy, spring-like weather ensues. The Chinook aids the railroads in keeping their tracks free of snow, enables the stockmen to bring their cattle safely through the winter, and stores up water in the form of ice for future use, making irrigation in the summer possible. It is an ever-welcome guest, whose coming is indicative of good and whose absence would be a momentous evil."

Sun spots and wind, A. B. MACDOWALL (*Nature [London], 66 (1902), No. 1709, p. 320, fig. 1*).—Curves based on observations during 60 years on wind direction and

sun spots at Greenwich are given, which show "less northerly wind about maxima than about the adjoining minima [sun spots]."

Meteorological observations, C. B. RIDGAWAY (*Wyoming Sta. Rpt. 1902*, pp. 62, 63).—A summary of observations at Laramie, Wyo., on temperature, relative humidity, dew-point, atmospheric pressure, precipitation, evaporation, and direction and velocity of the wind during the year 1901.

Comparison of temperature and rainfall of 1900 with records of previous years, E. R. DEMAINE (*Pennsylvania Dept. Agr. Rpt. 1901*, pt. 1, pp. 680-683).—A monthly summary is given of observations at Harrisburg, Pa., during each month of 1900 on pressure, temperature, precipitation, humidity, dew-point, cloudiness, vapor pressure, and wind movement. The average temperature and rainfall for 1900 and for 11 previous years are also given. The mean temperature for the 12 years was 52.2°; for 1900, 54.3° F. The average rainfall for the 12 years was 38.44 in.; for 1900, 28.94 in.

The decrease of temperature with altitude, M. MORENO Y ANDA (*Mem. y Rev. Soc. Cient. "Antonio Alzate," 17* (1902), No. 1-2, pp. 53-61).

A study on the diurnal variations in the meteorological elements of the atmosphere, L. TEISSERENC DE BORT (*Compt. Rend. Acad. Sci. Paris*, 134 (1902), No. 4, pp. 253-256; fig. 1).—The author reports the results of observations by means of captive kites and balloons on the daily temperature variations in the atmosphere over Paris at a height of 11 kilometers during the period from January 27 to March 1, 1901.

Hail shooting in lower Austria, 1900-1901, J. VON JABLONCZY (*Das Hagelweterschiessen in Niederösterreich, 1900-1901*. Vienna: Niederöster. Landes-Ausschusses, 1902, pp. 55, pls. 5, figs. 4, charts 4).—The conclusions reached are in effect that the results of hail shooting have not been conclusive, although apparently effective in many cases when carefully done. Further studies are considered necessary to determine the practicability of the method and directions are given for the systematic application of the method.

Firing to prevent hail, E. VIDAL (*Compt. Rend. Acad. Sci. Paris*, 135 (1902), No. 2, pp. 92, 93).—A summary of observations tending to prove the effectiveness of the method.

Fog studies, A. G. McADIE (*Amer. Inventor*, 9 (1902), No. 14, pp. 209-211, 214, figs. 6).—A brief account of studies made in the vicinity of San Francisco, mainly on Mount Tamalpais.

Short period solar and meteorological variations, N. and W. LOCKYER (*Compt. Rend. Acad. Sci. Paris*, 135 (1902), No. 8, pp. 361-364, figs. 2).

The atmosphere, J. W. LEE (*Queensland Agr. Jour.*, 11 (1902), No. 1, pp. 50-52).—A brief popular discussion of properties of the air, especially as related to the soil and the best means of securing proper aeration of the soil through cultivation.

A new organic gas of the atmosphere, H. HENRIET (*Compt. Rend. Acad. Sci. Paris*, 135 (1902), No. 2, pp. 101-103).—The occurrence in small amounts in the air of a formamid with one replaceable hydrogen ($\text{HCON} \begin{smallmatrix} \text{H} \\ \diagup \\ \text{R} \end{smallmatrix}$) is reported.

Verification of the law of barometric heights, W. DE FONVILLIE (*Compt. Rend. Acad. Sci. Paris*, 135 (1902), No. 8, pp. 335, 336).

Observations on the climatology of Mexico, T. L. LAGUERENNE (*Mem. y Rev. Soc. Cient. "Antonio Alzate," 17* (1902), No. 1-2, pp. 43-51).

WATER—SOILS.

Experiments in evaporation, C. B. RIDGAWAY (*Wyoming Sta. Bul. 52*, pp. 43-55, fig. 1).—This is an account of observations on the rate of evaporation and rise of alkali in cylinders of soil 25 in. long and 6 in. in diameter, in which the water was kept at a certain level by subirrigation, and on evaporation from a water surface.

The effect of stirring the soil to certain depths was also studied and the influence of the alkali on the evaporation was noted. The apparatus used and the method of filling the cylinders with undisturbed soil are described. After filling, the cylinders were buried to their tops in the soil. Observations during 1901 are recorded. From these the following conclusions are drawn:

"The evaporation from the surface of the soil with the level of water maintained at 6 in. below was 95 per cent, at 12 in. below it was 70 per cent, at 18 in. below it was 45 per cent, and at 22 in. below it was 35 per cent of what it was at the surface of the water in the evaporation tank.

"Stirring the ground once a week to the depth of 2 in. retarded evaporation to the amount of 19 per cent, when stirred to a depth of 4 in. it was retarded 23 per cent, and when stirred to a depth of 6 in. evaporation was retarded 45 per cent. The water in all 3 of the pipes was maintained at a depth of 22 in. below the surface of the soil.

"Evaporation was retarded 43 per cent when the soil contained 0.0597 per cent of alkali and the level of water was maintained at 6 in. below the surface. The amount of retardation was 55 per cent in soil containing 0.5116 per cent of alkali and the level of water 12 in. below the surface. In soil containing 0.5375 per cent of alkali the amount of retardation was 50 per cent when the level of water was maintained at 18 in. below the surface; while the retardation was 57 per cent in soil containing 0.6205 per cent of alkali and the level of water kept at 22 in. below the surface. The amount of alkali is the average amount found in the entire 26 in. of soil.

"More alkali was found in the first 3 in. than in any other 3 in. of the soil.

"More alkali was found in the last 2 in. than in the 3 next above."

The progress in the field of chemistry of waters, including natural and artificial mineral waters, A. GOLDBERG (*Chem. Ztg.*, 26 (1902), No. 78, pp. 912-918).—A review of investigations on this subject, containing numerous references to articles, during the years 1899-1901.

The bacteriological analysis of drinking waters, BORDAS (*Ann. Chim. Analyt.*, 7 (1902), pp. 249, 250; *abs. in Chem. Centbl.*, 1902, II, No. 7, p. 537).

Seventh annual report for the year 1901 of the Agricultural Experiment Station of Ploti (*Sept. Rap. An. Sta. Expt. Agron. Ploty*, 1901, pp. XIV+180).—This report contains accounts in the Russian language, with résumés in French, of observations and investigations in the meteorological station, chemical laboratory, and experimental field. This work is in the main a continuation of that of previous years (*E. S. R.*, 14, p. 17.)

Report of the meteorological and agronomic station.—This includes a summary of observations on precipitation, humidity, cloudiness, evaporation, temperature of the air and of the surface of the soil, sunshine, solar radiation, atmospheric pressure, direction and force of wind, and miscellaneous phenomena.

Report on work in the experimental field.—This includes mainly experiments to test the effect of the growing of forage plants on the succeeding crops, rotation experiments, and cultivation of fallows. The results favor the introduction of forage plants of long periods of growth in rotation with winter and spring cereals. The results of tests of Owinsky's method of growing cereals, namely, seeding in strips 30 cm. wide (containing 6 rows) separated by bare strips 38 cm. wide, and cultivating 2 in. deep, indicates that this method possesses no advantages over ordinary methods of culture. From the description given, this method is very similar to that known as the Lois-Weedon system.

Report of the chemical laboratory.—As in previous years, the work of the chemical laboratory consisted mainly of determinations of the amount of ammonia, nitrites, and nitrates brought down in rain water; the nitrogen removed from the soil in some of the more common cereals, such as winter and spring wheat and rye; and a study of the influence of manure in rotation on yield and quality of crop. The

results of examination of rain water showed that the total amount of nitrogen brought down in the atmospheric precipitations amounts to only 5.216 kg. per hectare, or not more than 4 to 5 per cent of the amount of assimilable nitrogen necessary for a good crop. The influence of manure was studied in 4-year and 9-year rotations with wheat and oats. It was found that with favorable meteorological conditions the manure increased the total amount of nitrogen taken up by the crops. It increased the total yield but decreased the relative proportion of albuminoid substances in all parts of the plant. In fact it was observed in general that those conditions which favored the increase in yield caused a reduction in the relative proportion of nitrogenous compounds in the plant. Excessive humidity favored the process of assimilation of carbohydrates while drought hastened maturity and favored the production of grain relatively rich in protein and relatively poor in carbohydrates.

On the question of the productiveness of different soil layers, S. STSCHUSSEV (*Zhur. Opušn. Agron. [Jour. Expt. Landw.], 2 (1901), No. 5, pp. 611-624, figs. 2*).—Pot experiments with oats on chernozem soil from 3 depths—surface, 17.8 cm., and 26.7 cm.—are reported. The surface soil was much more productive than that of the other 2 layers. In the surface soil the nitrogen was the first constituent to become exhausted, in the other layers phosphoric acid.

Comments on the paper by S. Stschussev on the productiveness of different soil layers, D. RUDSINSKY (*Zhur. Opušn. Agron. [Jour. Expt. Landw.], 3 (1902), No. 1, pp. 38-43*).

On the water-soluble phosphates of the soil, T. SCHLOESING, JR. (*Compt. Rend. Acad. Sci. Paris, 134 (1902), No. 23, pp. 1383, 1384*).—Summarizing the results of numerous experiments the author concludes that the phosphates of the soil are constantly being rendered soluble in water and available for the use of plants. This process is slow in any case, but is more rapid in moist soils than in dry. The continued application of phosphatic fertilizers accelerates this process; that is, soils so fertilized yield a larger amount of phosphoric acid soluble in water than can be accounted for by the fertilizers applied. The amount soluble in water is always small, and can be obtained only by treating a small amount of soil with a large amount of water (100 liters of water to 100 gm. of soil), extracting by means of displacement rather than by shaking in flasks.

A contribution of the study of the influence of frost on the physical properties of soils, A. MITSCHERLICH (*Fühling's Landw. Ztg., 51 (1902), Nos. 14, pp. 497-503; 15, pp. 532-537*).—The author concludes from his observations on the influence of repeated freezing (as high as 23 times) of different classes of soil as measured by his *Benetzungswärme* method (*E. S. R., 10, p. 423; 14, p. 127*) that frost is without measureable effect in increasing the aggregate surface area of the individual soil particles.

On the question of the mechanical analysis of soils, P. KASCHINSKY (*Zhur. Opušn. Agron. [Jour. Expt. Landw.], 2 (1901), No. 3, pp. 315-336*).—The results of a study of the Osborne method are reported (in Russian with a summary in German).

Vegetation boxes for studying the water content of soils, C. VON SEELENHORST (*Jour. Landw., 50 (1902), No. 3, pp. 277-280*).—The construction of a lysimeter for the study of drainage, evaporation, water requirements of plants, etc., is described.

Analysis of the soil by the plant, T. LOKOT (*Selsk. Khoz. i Lyskov., 205 (1902), Apr., pp. 91-135*).—The author gives an extended survey of the literature on this subject and discusses its present status, explaining the principles underlying the methods employed in studying the fertilizer requirements of plants on different soils—chemical analysis of soil and plant, and vegetation experiments. Both these methods are considered unreliable in practice, although susceptible of much improvement by the exercise of greater care in sampling the products for examination. In the author's opinion it still remains for agricultural chemistry to devise an accurate method for determining the fertilizer requirements of plants, and this method will be purely chemical in character.—P. FIREMAN.

The nitrifying ability of normal soils and the loss of nitrates by leaching, A. V. KLYUCHAREV (*Izv. Moscov. Selsk. Khoz. Inst. (Ann. Inst. Agron. Moscou)*, 8 (1902), No. 2, pp. 107-149).—In continuation of previous work on the same subject (*E. S. R.*, 13, p. 535), the author undertook to investigate more fully and in greater detail the phenomena which take place when soils are in contact with solutions of nitrates. He found in experiments in cylinders containing from $2\frac{1}{2}$ to $3\frac{1}{2}$ kg. of soil that in case of soils containing a large amount of imperfectly decomposed organic matter, or those to which starch was added, there was a marked denitrification, while in soil in which humification was very advanced, like the chernozems, and to which no starch was added, there was little or no destruction of nitrates during 15 days. These results indicate that the rate of denitrification is dependent largely upon the amount of starch and similar compounds in the soil. It was shown in other experiments that plant roots which are rich in pentosans also accelerate denitrification to a marked degree. Chloroforming the soil prevented denitrification. The results further indicate that a considerable proportion of the nitrogen set free in the process of denitrification goes in organic combinations—P. FIREMAN.

The crop and the soil in their mutual relations, S. BOGDANOV (*Selsk. Khoz. i Iqesov.*, 205 (1902), Apr., pp. 51-90).—A review of a book by Bogoushevski entitled *Bad Crops and the Exhaustion of Lands—an Investigation of the Question of the Causes of the Exhaustion of the Fertility of Soils*, which minimizes the value of chemical theory of the exhaustion of soils and gives prominence to the physical causes of temporary unproductiveness due to improper management of the soil. The reviewer maintains that the chemical and physical factors are of equal importance, and that the use of fertilizers is an effective and necessary means of restoring and maintaining the fertility of exhausted soils.—P. FIREMAN.

Practical experiments in the restoration of worn-out soils, R. F. SCHWARTZ (*Pennsylvania Dept. Agr. Rpt. 1901*, pt. 1, pp. 489-494).—A brief account is here given of practical experience in restoring worn soils by means of leguminous plants—crimson clover, cowpeas, vetches, etc.

The purpose of a soil survey, M. WHITNEY (*U. S. Dept. Agr. Yearbook 1901*, pp. 117-132).—This article discusses the knowledge of conditions necessary for agricultural success, explains the deficiencies of older methods of soil investigation, and describes the methods, purposes, and some of the results of the soil survey developed in this Department.

FERTILIZERS.

The action of the solid constituents of stall manure, M. GERLACH (*Jahresber. Landw. Vers. Stat., Jersitz-bei-Posen, 1900-1901*, p. 26; *abs. in Centbl. Agr. Chem.*, 31 (1902), No. 10, pp. 663-665).—Pot experiments comparing the fertilizing effect of liquid manure and of manure which had been stirred up with 3 times its volume of water and afterwards pressed are reported. It was found that the nitrogen of the manure was in every case much less effective than that of nitrates, that the solid constituents of the manure exerted an injurious effect, and that the action of nitrate nitrogen was reduced when applied in connection with the pressed manure.

A new method of conserving manure and urine, P. RIPPET (*Fühling's Landw. Ztg.*, 51 (1902), Nos. 7, pp. 248-254, fig. 1; 8, pp. 278-285; 9, pp. 334-340).—Laboratory experiments to test the value of different methods of mechanical treatment and different kinds of preservative substances are reported. The results indicate the importance of keeping manure compact, as in deep stalls, and show the effectiveness of fluor-sulphuric acid, a by-product of superphosphate manufacture containing 10 to 12 per cent of free sulphuric acid and 20 per cent of fluorin, as a preservative as compared with other preservatives frequently recommended—superphosphate-gypsum, sulphuric acid, etc.

Manures and manuring, O. LEMMERMANN (*Die Düngerlehre. Leipzig: Moritz Schäfer, 1902, pp. 240, figs. 8*).—This book is based largely upon the author's own investigations and is intended for the general reader as well as for the use of students and teachers of agriculture. It contains chapters on the conditions of growth of plants, the general subject of manuring, and on the source, nature, and use of different kinds of fertilizing materials, including barnyard manure, green manures, and commercial fertilizing materials.

Commercial fertilizers, W. W. MILLER and N. W. LORD (*Offic. Rpt. Sec. Ohio State Bd. Agr. on Com. Fertls. 1901, pp. 92*).—This is a report of analyses of 537 samples of fertilizers examined by the State chemist during the year 1901, with a list of certificates filed by manufacturers, etc., under the State law. The analyses are accompanied by explanatory notes and the text of the State fertilizer law.

Analysis of commercial fertilizers sold in Maryland, H. B. McDONNELL ET AL. (*Maryland Agr. College Quart., 1902, No. 17, pp. 65*).—A report in the usual form of analyses and valuations of 494 samples of fertilizers examined from February to June, 1902, inclusive.

Fertilizer analyses, R. C. KEDZIE (*Michigan Sta. Bul. 202, pp. 219-243*).—Analyses of 91 samples of fertilizers, with explanatory notes.

On the relative availability for agricultural plants of the phosphoric acid of mineral phosphates, P. KOSSOVICH (*Zhur. Opitn. Agron. [Jour. Expt. Landtr.] 2 (1901), No. 6, pp. 711-732, pl. 1*).—Pot experiments are reported which show that mustard and buckwheat gave about the same yield with mineral phosphate as with Thomas slag; clover and flax showed less capacity for utilizing the mineral phosphate; and winter rye utilized the phosphoric acid of such phosphates to only a limited extent.

Basic superphosphate, its composition and use as a manure, J. HUGHES (*Jour. Bath and West and South. Counties Soc. [England], 4. ser., 12 (1901-2), pp. 65-78, fig. 1*).—See E. S. R., 13, p. 234.

Relation between the amounts of phosphoric acid and ammonia in plants, especially in sugar beets, H. PELLET (*Ztschr. Ver. Deut. Zuckerind., 1902, No. 555, pp. 390-393; abs. in Jour. Chem. Soc. [London], 82 (1902), No. 478, II, p. 526*).—Results of examinations of Egyptian beets grown on soil formed by the gradual accumulation of Nile mud and containing only traces of ammonia or nitric acid are reported, which confirm the conclusion of Champion and Pellet that plants contain ammoniacal nitrogen and phosphoric acid in the proportions to form ammonium magnesium phosphate.

Ammonia salts as a source of nitrogen for plants, P. KOSSOVICH (*Zhur. Opitn. Agron. [Jour. Expt. Landtr.], 2 (1901), No. 5, pp. 625-638, figs. 3*).—Experiments made under conditions which precluded the presence of any form of nitrogen except ammonia salts showed that peas utilize such nitrogen in their growth about as well as that of nitrates. Other investigations on this subject are reviewed and the apparatus and method used by the author are described in detail. The article is in Russian, but contains a summary in German.

The solvent action of ammonia salts on phosphorites, I. SHULOV (*Izv. Moscov Selsk. Khoz. Inst. (Ann. Inst. Agron. Moscow), 8 (1902), No. 2, pp. 161-167*).—Vegetation experiments which were carried out in the Moscow Agricultural Institute in 1900 under the direction of Professor Prianishnikov showed that ammonium sulphate and nitrate further the assimilation by the plants of phosphoric acid from phosphorites. The cause of this favorable assimilation is presumably the so-called physiologically-acid nature of the ammonium salts. Vegetation experiments carried out by the author with barley corroborated these observations. When calcium nitrate was used as nitrogen fertilizer with phosphorite the yield was only 7.2 gm., containing 11.38 mg. phosphoric acid; but the crop increased to 44.8 gm. with 151.15

mg. phosphoric acid when ammonium nitrate was used instead of calcium nitrate, the same phosphorite being applied.

Experiments made with a view to determining whether this action of the ammonium salts is not at least in part due to their solvent action on the phosphorites showed that this solvent action is very slight. Digestion for a month of 10 gm. phosphorite with 1,000 cc. of 1 per cent ammonium sulphate solution with frequent shaking caused the solution of only 4.98 mg. phosphoric acid. Ammonium nitrate exerted a still lower solvent action. It follows that the influence of the ammonium salts on the increase of the yield must be due to physiological causes.—P. FIREMAN.

The action of nitrogen in absence of other nutritive substances, H. WILFARTH (*Bl. Zuckerrübenbau*, 1901, p. 15; *abs. in Jour. Chem. Soc. [London]*, 82 (1902), No. 478, II, p. 526).—It was found that sugar beets grown with potash and with little nitrogen contained 11.03 per cent of sugar. With large amounts of nitrogen but no potash the beets contained only 0.0062 per cent of sugar. Potatoes similarly fertilized contained 14.6 and 9.76 per cent of starch respectively.

Effect of nitrogen in nitrates and of humus substances on the inoculation of leguminous plants, F. NOBBE and L. RICHTER (*Landw. Vers. Stat.*, 56 (1902), No. 5-6, pp. 441-448; *abs. in Jour. Chem. Soc. [London]*, 82 (1902), No. 478, II, p. 521).—Pot experiments are reported in which oats and soy beans were grown separately or in mixtures on humus soil or a mixture of the soil with sand, one series of pots being inoculated, the other being sterile. In case of the mixed soil there was an additional series of pots to which potassium nitrate was added. The effectiveness of inoculation was diminished both by the nitrogenous matter of the soil and by the nitrate added. The activity of the nodule bacteria was increased by growing oats with the beans, due, it is believed, to the fact that the oats removed nitrates from the soil. The yield of oats was greater when grown with beans than when grown alone.

Perchlorate of potash in plant growth; the harmlessness of nitrates of soda imported from Chile, L. GRANDEAU (*Jour. Agr. Prat.*, n. ser., 4 (1902), No. 35, pp. 271-273).—A brief review of investigations on the subject, from which it is concluded that while nitrate containing 1 per cent of perchlorate is injurious to crops, especially to ry, there is, under present conditions, little danger of such nitrate being shipped from Chile. However, for greater security, purchasers are advised to require a guaranty of less than 1 per cent of perchlorate.

FIELD CROPS.

Influence of environment on the chemical composition of plants, H. W. WILEY (*U. S. Dept. Agr. Yearbook* 1901, pp. 299-318, charts 3).—This article deals chiefly with the studies conducted by the Bureau of Chemistry on the composition of plants as affected by environment. A review is given of the early studies in this direction. Recent work has consisted of observations on the influence of environment on the chemical composition of cereals, sugar-producing plants, cantaloupes, and muskmelons.

In the earlier work with wheat, seed of many different varieties was sent to Colorado, Oregon, California, and North Carolina for growth, and the results showed that the Colorado-grown wheat was richer in protein than the original seed, while that grown in the other States was decidedly poorer in protein than the original seed. The general conclusion is drawn that the environment of Colorado increased the nitrogen content of wheat, and it is shown that this increase was made at the expense of the carbohydrate content. The results obtained in Oregon, California, and North Carolina showed an increase of carbohydrate content at the expense of the nitrogen. It is pointed out that "the soil, as a rule, has the least effect of all the important factors of environment on the chemical composition, provided, of course, that it contains the essential elements of plant food necessary to produce an average crop."

A study similar to the one with wheat was made with corn. The conclusions drawn from the results were that corn differs materially from wheat, since "it maintains about the same percentage of albuminoids under all circumstances and is not affected by its surroundings in this respect." Corn is considered as a crop tending more than any other to maintain a uniform composition and to vary less under environment.

A special investigation in this same line in collaboration with the Colorado, California, Indiana, Kentucky, Maryland, Missouri, and New York experiment stations is reported. The tabulated results of analyses of the original seed of the first crop of wheat grown show that the protein content of wheat is extremely sensitive to environment of a meteorological nature; that the starch content is also sensitive, but in an inverse ratio, and that the ash next to the protein shows a tendency to vary with environment. The soil and the fertilizer applications are considered the most potent factors in the variation of the ash content.

In a discussion of the effect of season and climate upon the wheat grain, the influence of the period of growth and the temperature are pointed out. "The shorter the period of growth and the cooler the climate, the larger the content of protein and the smaller the content of starch, and vice versa. . . . The general deduction which can be made . . . is to hasten the period of growth as much as possible where a high content of protein is desired." The results of foreign experiments given in this connection indicate that the elaboration of starch is arrested by the rapid desiccation of the plant.

The work with sugar beets treated in this article has been noted from previous publications of the Bureau of Chemistry and the experiment stations.

The influence of fertilization on the number and depth of the roots of different plants, C. VON SEELHORST (*Jour. Landw.*, 50 (1902), No. 1, pp. 91-104).—Rye, spring and winter wheat, barley, peas, beans, potatoes, and field beets were given varying quantities of a complete fertilizer application and the number of fibrous roots for each 25 cm. to a depth of 150 cm. ascertained. The figures are given in a table, and the results with the different plants are compared. The author cautions against the general application of the results, because the soil upon which these tests were made is absolutely uniform in substance and quality to more than an ordinary depth. The results indicate in general that a good supply of plant food tends to produce a strong, well-developed root system, with roots growing to greater depths than when the supply of plant food is limited. For this reason the author believes that heavily fertilized crops are better able to withstand drought than those having received but light applications.

Observations on the relation of different crops to the water content of the soil, C. VON SEELHORST (*Jour. Landw.*, 50 (1902), No. 2, pp. 151-164).—Rye, wheat, potatoes, clover, peas, oats and peas, and turnips were grown on plats and the moisture content of each plat determined on a series of dates. The data for the entire experiment are presented in tabular form.

The variation in the moisture content of the soil as here observed is attributed to the different moisture requirements of the several crops at various stages of their development, to the varying capacity of water absorption by the soil, and the fluctuating rate of evaporation due to the condition of the atmosphere and the density of the foliage of the plants grown. The author discusses the results observed in each case. It was found that rye drew less moisture from the soil than wheat, and this fact is considered of value in growing crops for green manuring immediately after the rye has been harvested. The moisture content of the clover plat was comparatively quite low, indicating that a crop following clover is at a disadvantage so far as soil moisture is concerned. The potato crop left the soil in a relatively moist condition. Peas, owing to the small quantity of water drawn from the soil, are considered a suitable crop to be followed by winter cereals. Oats, on the other hand, were found

not at all suitable for this purpose on account of the large quantity of plant food removed from the soil, and especially on account of the heavy withdrawal of soil moisture.

Progress in plant and animal breeding, W. M. HAYS (*U. S. Dept. Agr. Year-book 1901*, pp. 217-232, pls. 3, fig. 1).—After enumerating some of the most important and striking achievements in plant and animal breeding and suggesting what the purposes of breeding should be, the article describes the features of sugar beet, wheat, and corn breeding, and some of the methods of breeding used by farmers. Methods of cooperation in this kind of work are outlined.

The length of the growing season in North Dakota, E. F. LADD, J. H. SHEPHERD, and A. M. TEN EYCK (*North Dakota Sta. Bul. 52*, pp. 105-111).—Tables show the dates of the first killing fall and last killing spring frosts and the last spring and first fall frosts for 7 years, together with the length of time required to mature field crops as observed in a variety of experiments conducted at the station. A temperature of 26° F. is considered as a killing frost. The shortest time between killing spring and fall frosts during 7 years was 121 days, the longest 155 days, and the average length of time 136 days. The average length of time between light frosts was 111 days, with a range from 97 to 131 days. As to the number of days required for different crops to mature, the records show that wheat required from 95 to 106 days, oats 88 to 102 days, barley 82 to 94, flax 83 to 95, millet 81 to 112, spelt 91 to 92, and corn about 100 days. A discussion of how late small grain may be sown is based on these data.

The annual report of the Burdwan Experimental Farm for the year 1900-1901, D. N. MOOKERJI (*Calcutta: Dept. Land Records and Agr., Bengal, 1902*, pp. 14).—A description is given of the experimental farm, together with a financial statement and a report on experiments for the year 1900-1901. In fertilizer experiments with rice the use of bone meal and nitrate of soda was most profitable, and green manuring with jute proved more economical than the application of cow manure. In a series of experiments with jute, cow manure was more effective than castor pomace, bone meal, or a combination of superphosphate and nitrate of soda. Among different fertilizers for potatoes, castor pomace gave the best returns.

Sowing 60 lbs. of rice per acre was found more profitable than sowing 30 lbs. In growing potatoes the sets gave a larger yield than whole tubers. Of 4 varieties of sugar cane under test the Kajli was the only one grown with profit. The largest yield of different varieties of potatoes was obtained from Naini Tal grown from imported seed. Black-seeded sorghum yielded 2,180 lbs. of fodder per acre and red-seeded 18,939 lbs.

Experiments with field crops (*County Councils Cumberland, Durham, and Northumberland, Tech. Education. Rpt. 10 (1901)*, pp. 1-121, 125-150).—The results of cooperative fertilizer and variety tests with swedes, turnips, potatoes, mangels, cereals, and grass are reported. In addition to the results of these experiments, the composition of the crops as influenced by the fertilizers applied is shown. Analyses of soils are also given.

Pot experiments were made to investigate the absorption of arsenic by barley and the effect of an electric current passing through the soil on the growth of the plants. Arsenic was applied to the pots at the rate of 11 lbs. per acre, but the soil itself was found to contain a greater amount. Most of the arsenic occurred in the grain of the barley obtained. Soil electrolysis was found to be detrimental to plant growth in the experiments reported.

Report on the work at the Provincial Experimental Garden at Ghent in 1900-1901, P. DE CALUWE (*Exposé Cult. Exper. Jard. Gand, 1900-1901*, pp. 1-47, dgm. 1).—The work comprises fertilizer, variety, and culture tests with rye, oats, corn, peas, colza, chicory, fodder beets, prickley comfrey, sacchaline, turnips, potatoes, and grasses. The results for the season are briefly reported and discussed,

The management and improvement of the range, E. NELSON (*Wyoming Sta. Rpt. 1902*, pp. 34-37).—Methods of range management and improvement are briefly mentioned. Among the means described are resting, rotative pasturing, reseeding, harrowing, and discing.

Experiments with cereals on the development of roots and adventitious shoots from the nodes above ground, C. VON SEELHORST (*Jour. Landw.*, 50 (1902), No. 2, pp. 165, 166, pls. 4).—By covering the nodes of growing plants of wheat, oats, barley, and rye with soil, both roots and shoots were produced from the nodes. Wheat produced the best growth.

The influence of fertilizers on the form of cereal plants, H. CLAUSEN (*Jour. Landw.*, 49 (1902), No. 4, pp. 365-388).—From the results of experiments here reported it is concluded that applications of nitrogen lengthened the lower internodes, while the upper internode was relatively shortened. Nitrate of soda was more effective in bringing about this result than nitrogen in the form of ammonia. An increase in the length of the lower internodes increases the tendency to lodge, especially when the strength of the upper and lower internodes is out of proportion. The ammoniacal nitrogen not only produced the highest total yield, but also the strongest plants, as compared with nitrate of soda.

Changes of nitrogenous substances in cereals during ripening, N. NEDOKUTSCHAJEW (*Landw. Vers. Stat.*, 56 (1902), No. 4, pp. 303-310).—This article notes briefly the work and views of different investigators on this subject, and reports the author's own results. The grains of wheat, rye, oats, and barley were analyzed at 6 different stages during about 1 month preceding their maturity. The results are shown in tables. The data obtained indicated that the ripening of the grain is a gradual change of the soluble substances into solid and stationary form. The author states that the amid combinations in the grains under the influence of unknown causes seem to change to albumin. The increase in albumin in the grain takes place at the expense of the amid nitrogen. The proportion of the total nitrogen in the form of asparagin is shown in connection with the other data.

Alfalfa, F. E. EMERY (*Wyoming Sta. Rpt. 1902*, pp. 22-26).—The value of alfalfa for Wyoming is discussed and compilations from various sources are given showing the digestible nutrients in alfalfa hay and other feeding stuffs, together with the comparative money values.

Breeding and cultivation as a means of improving and increasing the culture of barley for brewing purposes, REMY (*Deut. Landw. Presse*, 29 (1902), Nos. 19, p. 155; 20, pp. 163, 164; 21, p. 176).—The results of observations on the plant food and moisture requirements of different varieties of barley are presented and discussed. Hanna barley produced a large total crop and a good yield of grain with a comparatively small moisture supply, and in addition did not prove very sensitive to a supply of soil moisture above the normal. It was found that this variety as compared with the Goldthorpe reaches its maximum water consumption 2 weeks earlier, enabling it to use more of the moisture stored in the soil during winter. The results of experiments indicated that by selecting plants having a small number of internodes, long upper internodes, and producing a high percentage of grain the productiveness of the variety can be increased. The possibility of obtaining varieties in which the moisture requirement is reduced and the period of maximum moisture consumption comes earlier in the season is discussed. Seed selection, improved cultural methods, and the rational use of fertilizers are recommended as means for improving the crop.

The culture of forage beets in different sections of France, P. P. DEHERAIN (*Ann. Agron.*, 28 (1902), No. 7, pp. 351-356).—This article discusses cooperative distance experiments with forage beets conducted at different times. Attention is called to the composition of beets grown at varying distances, and reference is made to previous recommendations of the author that good beets with a low content of

nitrate of potash and rich in dry matter can be grown by leaving the plants when thinning at intervals of 25 cm. in rows 40 cm. apart. This method it is stated produces beets of about 1 kg. in weight, and although giving a smaller total production, yields a larger amount of dry matter and sugar and reduces the percentage of nitrate of potash in the beets.

Forage-beet culture at Grignon in 1900 and 1901, P. P. DEHERAIN and C. DUPONT (*Compt. Rend. Acad. Sci. Paris*, 134 (1902), No. 17, pp. 953-958).—From the results for the 2 seasons the authors conclude that the new varieties tested, namely, Giant White and Giant Rose, having a high sugar content, are decidedly superior to the ordinary older varieties of field beets, and that the Giant Rose is adapted to dry soils and the Giant White to moist soils. Growing beets in rows 50 cm. apart, with the plants at intervals of 20 cm. in the row, is considered most advantageous. With this spacing 10 beets are grown per square meter.

Culture tests with red clover, O. BURCHARD (*Landw. Wechnbl. Schleswig-Holstein*, 52 (1902), No. 33, pp. 611-613).—Tests with red clover seed obtained from different European countries and Canada and from Wisconsin, Indiana, Ohio, and Maryland are reported. The clover from American seed stood the winter most satisfactorily and gave the highest yields.

Experiments with gypsum on clover and vetch, J. WITHERCOMBE (*Oregon Sta. Rpt.* 1902, pp. 50, 51).—The yields of green clover from plats having received different quantities of gypsum are reported without comment. An acre of fall-sown vetch received 100 lbs. of land plaster April 17 and yielded 9,031 lbs. of hay July 11, as compared with a yield of 7,394 lbs. of hay on an adjoining acre, which was used as the check plat. The result showed a gain of 22 per cent in favor of the gypsum.

Fertilizer, culture, and variety tests with corn and cotton, B. W. KILGORE, R. W. POT, and J. L. MCKINNON (*Bul. North Carolina State Bd. Agr.*, 23 (1902), No. 1, pp. 1-43, pls. 9).—A report of work on the department's test farms in 1901. The work is described and the weather conditions for the season are reported. The results of the different experiments are tabulated in detail.

The largest yield of corn was obtained from Weekly Improved at both test farms, the yield being 29.5 bu. per acre at Tarboro Farm and 18.95 bu. at Red Springs Farm. Russell Big Boll was the most productive of the varieties of cotton tested on both farms. No conclusions are drawn from the distance tests with either corn or cotton, but the data are reserved for further use.

The results in the fertilizer tests are tabulated in detail and the comments on the results have reference to the requirements of the respective soils. With corn, as well as with cotton, the fertilizer applications were more profitable in the wet season of 1901 than in the dry season of 1900. In the case of corn increasing the nitrogen, phosphoric acid and potash in the normal application gave considerable profit, the increase in yield being about equally in favor of nitrogen and phosphoric acid and the increase in value of product about equally in favor of phosphoric acid and potash. With cotton increases in the quantity of nitrogen gave larger yields and larger net profits than a similar increase in either phosphoric acid or potash. The largest yield and largest net profits were obtained on a plat which had received 423.6 lbs. of cotton-seed meal per acre, or treble the quantity of nitrogen given in the normal application.

The nonproductive black soils occurring in the State and locally known as "pocosin" soils are described and methods of treatment suggested.

Detasseling corn, A. D. SHAMEL (*Illinois Sta. Circ.* 56, pp. 4).—This circular outlines a method of investigating the effect of detasseling corn.

Number of barren stalks in Illinois cornfields, A. D. SHAMEL (*Illinois Sta. Circ.* 57, pp. 4).—A circular giving directions for determining the percentage of barren stalks in a cornfield.

Flax experiments, 1901 (*Jour. Dept. Agr. and Tech. Instr. Ireland*, 2 (1902), No. 4, pp. 636-653).—The results of fertilizer, variety, and scutching tests are tabu-

lated and discussed. The use of 5 cwt. of superphosphate per acre increased the yield of retted straw but reduced the yield of scutched flax, together with the quality. On foul land this application encouraged the growth of weeds. The use of superphosphate in conjunction with 3 cwt. of kainit per acre was also found unprofitable. An application of the same quantities of superphosphate and kainit, together with $\frac{1}{2}$ cwt. of sulphate of ammonia per acre also failed to give profitable results. A plat which had received 5 cwt. of kainit per acre gave a small profit as compared with the check plats, showing that kainit has no detrimental effect on the flax crop. Muriate of potash applied at the rate of 1 cwt. per acre gave better results than any other fertilizer application tested, indicating that potash fertilizers benefit the flax crop, and that muriate of potash is more effective in this respect than kainit. Flax seed grown in Ireland gave less profitable results than seed obtained from the continent. Pernau Crown flax was more productive and more remunerative than Riga Child. The Irish system of scutching was compared with the Courtrai system, and the results from a financial aspect were in favor of the Irish system.

Experiments with forage crops, T. VON WEINZIERL (*Ztschr. Landw. Versuchs. Oesterr.*, 5 (1902), No. 2, pp. 49-330, pls. 11, figs. 5, dgms. 24, plan 1).—This extensive report treats of the results obtained in culture tests with different forage plants conducted in an alpine grass garden from 1890 to 1900. In a brief summary of the results the author points out that certain forage plants ordinarily grown on the plains undergo a morphological, as well as physiological, change when grown in the mountains, which insures their successful culture at higher altitudes. It was further found that alpine species, such as *Poa alpina*, *Phleum michelii*, *P. alpinum*, could be successfully grown at an altitude as low as 800 meters in regions where a moist mountain climate prevailed. In general, however, alpine species produced seed best under the conditions prevailing at the altitudes where they normally occur.

The following species are recommended for profitable seed production in an alpine climate: *Poa violacea*, *P. distichophylla*, *Festuca rupicaprina*, *F. violacea*, *F. rubra fallax*, *F. scheuchzeri*, *Phleum alpinum*, *Trisetum subspicatum*, *Trifolium alpinum*, and *Phaca frigida*. For certain sections establishing meadows at altitudes varying from 1,300 to 1,600 meters is considered profitable. Grass mixtures for alpine meadows and for sodding steep slopes are given. A study of the root tubercles of different leguminous forage crops was made and the results tabulated. The length, thickness, form, and location of the tubercles are given.

Guide to the cultivation, harvesting, and marketing of the ginseng plant, with names of buyers; also, a treatise on the history, botany, and uses. (New York: Crowell & Kirkpatrick Co., 1902, pp. 52.)

The hemp industry in the United States, L. H. DEWEY (*U. S. Dept. Agr. Yearbook 1901*, pp. 541-554, pls. 3, fig. 1, map 1).—After describing the hemp plant and the principal uses of hemp fiber, the article enumerates the different regions, both foreign and domestic, in which hemp is cultivated; discusses the soils suited to the crop, and gives directions for its culture and treatment, including methods of harvesting, retting, and breaking. Statistical data on the price and production of hemp in Kentucky are also given.

Fertilizer experiments with oats, W. MÜLLER (*Fähling's Landw. Ztg.*, 51 (1902), No. 8, pp. 275-278).—From the results of experiments here reported it was concluded that the use of 40 per cent of potash salt applied either alone or in conjunction with other fertilizers is not profitable. A heavy application of 40 per cent of potash salt increased the yield of straw without increasing the yield of grain.

Experiments with winter oats, SCHACHT (*Deut. Landw. Presse*, 29 (1902), No. 41, pp. 353, 354).—The culture of winter oats is discussed, and the results of experiments in determining the germinative energy of small and large grains are reported.

Sowing oats and barley at different rates (*Reading Col., Agr. Dept. Rpt. 1901*, pp. 26-29).—The results with barley showed that 2 bu. of seed per acre in drills 11 in. apart gave the best yield of grain and that the greatest weight per bushel was

obtained where from 2 to 2½ bu. of seed were used. With oats the largest yield of best grain was in favor of drilling 11 in. apart. The average results also favored the wide drilling. Of the 2 varieties entering into these experiments, Black Tartarian gave the highest yield, with 4 bu. of seed per acre, while for Garton Abundance from 3½ to 4 bu. was apparently the best quantity.

Improving field peas, M. FISCHER (*Fühling's Landw. Ztg.*, 51 (1902), No. 15, pp. 529-532).—Experiments were conducted with the Swedish field pea, a variety of *Pisum arvense*. The seed selection was based on the color of the peas and the habits of growth of the plant. The results indicated that a selection of spotted seed varying in color from yellow to reddish brown, from bushy late blooming and late ripening plants, will lengthen the vegetative period and increase the yield of green forage. On the other hand, it is stated that the selection of smaller seeds of a solid green color but well ripened and taken from early blooming and early ripening plants will shorten the vegetative period and thus better adapt the variety to mixed culture with barley.

The effect of different amounts of water used in irrigation upon the yield of potatoes, B. P. FLEMING (*Wyoming Sta. Rpt. 1902*, pp. 31-34).—A study was made of the effect of different amounts of water in irrigating potatoes. In 1900 potatoes grown on 3 adjacent plats received from irrigation and rainfall 5, 7, and 10 in. of water, and yielded 1,176, 2,230, and 3,069 lbs. of potatoes per acre respectively: The following season the depths of water used on the respective plats were 17, 8, and 48 in., and the corresponding yields 3,332, 3,956, and 5,432 lbs. of potatoes per acre.

Progress of the beet-sugar industry in the United States in 1901, C. F. SAYLOR (*U. S. Dept. Agr. Rpt. 72*, pp. 1-89, pls. 11, figs. 5).—This is the annual report on the progress and condition of the beet-sugar industry in the United States in 1901. Similar reports have been published for previous years (*E. S. R.*, 13, p. 445). The report deals with the operations of the various beet-sugar factories, outlines methods for beet culture, and presents considerable statistical information relative to the industry. Lowering the cost of sugar production is discussed and the cost and profits of sugar-beet culture with and without irrigation are estimated. In discussing incidental benefits and by-products the author points out the improvement of land and farming methods incident to the culture of the crop, emphasizes the value of beet pulp for feeding, and suggests how beet leaves should be utilized. The manufacture of sirup and molasses in connection with beet-sugar manufacture is briefly noted. The factories in operation, in process of construction, and projected enterprises in this line are enumerated. The statistics presented relate to factory development; the consumption, production, and importation of sugar, and the factory results for 1901. The consumption and production of sugar in the States and Territories west of the Mississippi and Missouri rivers are graphically shown, and the factory operations for 1901 are reviewed for each State and individual factory. In connection with this statistical information detailed statements are made of the labor required to raise and market beets, together with the cost of the same. The discussion on methods of growing beets consists of notes on preparing the seed bed, planting, bunching and thinning, cultivating, harvesting, and delivering beets.

In 1901, 36 factories were in operation in California, Colorado, Michigan, Minnesota, Nebraska, New Mexico, New York, Ohio, Oregon, Utah, Washington, and Wisconsin. The total acreage of beets for the season was 175,083. The quantity of beets worked amounted to 1,685,688.6 tons and the quantity of sugar produced to 369,211,733 lbs. The average sugar content of the beet was 14.8 per cent, with a purity coefficient of 82.2. The average yield of beets per acre was 9.6 tons. The total consumption of sugar in the United States for 1901 is estimated at 2,372,000 tons.

Progress of the beet-sugar industry in the United States, C. F. SAYLOR (*U. S. Dept. Agr. Yearbook 1901*, pp. 487-502, pls. 4).—Information on this subject, comprising historical and statistical data reported in the publication noted above, is here given in abstract form.

The influence of weather conditions on the sugar-beet crops for 1891-1900, inclusive, W. RIMPAU (*Landw. Jahrb.*, 31 (1902), No. 2-3, pp. 471-487; *abs. in Deut. Landw. Presse*, 29 (1902), Nos. 53, pp. 452, 453; 54, p. 460).—The meteorological conditions for each season are given and discussed with reference to their effect on the growth of the sugar-beet crop. The points taken into consideration as the most important are precipitation, temperature, and duration of sunshine. The author finds that the observations do not warrant definite conclusions. The results showed that the sufficiency and distribution of rainfall has a marked influence on the beet crop, especially on the quantity. The recorded temperatures did not show a regular influence on the yield. The amount of sunshine during the entire growing period, with sufficient moisture in the soil, had a very marked influence on the quantity of the crop, and a large amount of sunshine in August and September was conducive to the production of beets of a high quality. In 1894, however, when the total amount of sunshine was the smallest for the 10 years excepting 1891, the largest yield for the series of years, with a sugar content of 14.24 per cent, was produced.

Instructions for growing sugar beets, C. G. HOPKINS (*Illinois Sta. Circ.* 52, pp. 5).—Brief popular recommendations for making culture tests with sugar beets are given, together with an outline for a report on the work and its results.

Sugar-beet seed, production and testing, A. J. PIERERS (*U. S. Dept. Agr. Rpt.* 72, pp. 101-106).—This paper discusses the production of sugar-beet seed, and gives a concise description of how the tests for germination are carried out. The importance of using first-class seed is pointed out, and some of the results of experiments with imported and home-grown seed are republished from a bulletin previously noted (*E. S. R.*, 11, p. 337). Tests of the same character made by private parties are also reported, and in both instances the results largely favored the domestic seed.

Variety tests of mangels and sugar beets (*Reading Col., Agr. Dept. Rpt.* 1901, pp. 36-42).—Two varieties of sugar beets and 6 of mangels were tested. Sutton Prizewinner mangel was the most productive, yielding 21.3 tons per acre, while Sutton Improved sugar beet yielded 7.5 tons, being the smallest yield in the test. The analyses of different varieties are given in tables.

Fertilizer and variety tests with sugar cane, J. P. D'ALBUQUERQUE and J. R. BOVELL (*Rpt. Agr. Work, Imp. Dept. Agr. West Indies, 1899-1901*, pp. 2-178).—This report gives in tabular form the results obtained on different plantations from 1899 to 1901. The rainfall for each month and its composition, and the chemical composition of soils on which the experiments were carried on, are also reported. The fertilizer experiments consisted of soil tests on the different plantations, and the applications used in this work were arranged to demonstrate the efficiency of various commercial fertilizers when applied with barnyard manure. In the variety tests Barbados Seedling 208 stood first, White Transparent second, and Barbados Seedling 147 third.

The culture of sugar cane and sugar beets in Egypt, M. TINARDON (*Ann. Min. Agr. [France]*, 21 (1902), No. 2, pp. 451-485, figs. 9).—This report contains a general description of soil and climatic conditions in Egypt and gives an account of the culture of sugar cane and sugar beets. Analyses of soils, sugar cane, and sugar beets are reported.

Can wrapper leaf tobacco of the Sumatra type be raised at a profit in Connecticut? E. H. JENKINS (*Connecticut State Sta. Rpt.* 1901, pt. 4, pp. 296-312).—A reprint of Bulletin 137 of the station (*E. S. R.*, 13, p. 947).

Culture and treatment of Dalmatian tobacco according to the Neumer method considered from a physiological standpoint, K. PREISSECKER (*Fachl. Mitt. K. K. Oesterr. Tabakregie*, 1901, No. 1; *abs. in Bot. Centbl.*, 39 (1902), No. 17, p. 511).—The method described consists essentially in topping the tobacco plants when in full bloom and lifting the plants in order to break off the thinner roots. After 10 days the wilted leaves are gathered and dried in the sun. The author attributes a

lighter weight of leaf and a higher percentage of mineral substance and resin to the change in transpiration and assimilation due to the lifting of the plants. This method is stated to be successfully practiced in a small district in Herzegovina.

Kansas and her wheats (*Kansas State Bd. Agr. Rpt. 1902, No. 81, pp. 1-157, figs. 28, maps 2*).—A collection of papers and abstracts dealing with the various phases of wheat culture in Kansas. The combined acreage and yield of winter and spring wheat for each county in 1901 is shown on a map. In addition to the discussions on the culture and uses of Kansas-grown wheat, the insect enemies of the crop are described and the experience and practice of wheat growing is reported by counties. The abstracts here given are mainly from bulletins of this Department and the experiment stations which have been previously noted.

Observations on wheat culture in 1902, DESPREZ (*Jour. Agr. Prat., n. ser., 4 (1902), No. 32, pp. 182, 183*).—This article is a general report on the experiments with wheat in 1902 at Cappelle. Soil, seeding, rotation, and cultivation are discussed. Attention is called to the progress made in the culture and improvement of wheat by referring to figures from the records of the station, which show that in 1852 Blé blanc de Flandre yielded from 1,600 to 2,400 kg. of grain and from 4,000 to 5,000 kg. of straw per hectare; in 1870 the yields varied from 2,400 to 3,000, and from 5,000 to 7,000 kg. of grain and straw respectively; and in 1896 the production ranged from 3,000 to 3,900 kg. of grain and from 7,000 to 8,600 kg. of straw per hectare.

Manure experiments with wheat, F. B. GUTHRIE and R. HELMS (*Agr. Gaz. New South Wales, 13 (1902), No. 6, pp. 661-666*).—Tabulated results of fertilizer experiments with wheat carried on at the Wagga Experimental Farm in 1901 are presented. The action of superphosphate was most marked, while sulphate of ammonia and potash had but very little effect. Superphosphate and Thomas phosphate gave about equal results.

HORTICULTURE.

A handy book of horticulture, F. C. HAYES (*London: John Murray, 1901, pp. 225, pls. 9, figs. 9*).—This book is not a scientific treatise on horticulture, but rather a popular, practical work, suitable for placing in the hands of beginners in gardening. In the first chapter the general principles of gardening are discussed and some practical notions given regarding the nature and management of soils, fertilizers, hotbeds, cold frames, garden pests, seeds, budding, etc. Part II discusses gardens and borders most suitable for different seasons of the year; here directions are given for the growing of roses, ferns, shrubs, climbers, vegetables, fruits, etc. Part III discusses the various types of hardy flowers, 21 different groups being noted. Part IV is a calendar of the garden for the different months. The work as a whole is very well adapted to the purpose for which it is written, viz, an introduction to the theory and practice of gardening.

Department of horticulture and gardening, G. COOTE (*Oregon Sta. Rpt. 1902, pp. 69-74*).—This is a brief report on the work of the horticulturist during the year, concisely indicating the results secured in tests of a large number of vegetables and small fruits. In a test of surface *v.* subirrigation for celery on a small scale, the results on the whole were in favor of surface irrigation. The Self-Blanching variety of celery proved a much earlier variety than the Golden Self-Blanching. Dry Weather cauliflower is stated to be especially adapted to the climate of the station, and has proved the best of all varieties tested for 3 years. It possesses the peculiarity of starting into new growth from the collar of the plant after the head has been cut away, thus producing a second crop during the latter part of August and first of September.

Electro-culture, S. LEMSTRÖM (*Gard. Chron., 3. ser., 32 (1902), No. 813, pp. 49, 50*;

Amer. Gard., 23 (1902), No. 399, pp. 535, 526).—The results of a number of experiments in the electro-culture of rye, barley, oats, wheat, and a number of garden crops are here briefly reported upon. In these experiments the growth of barley, wheat, and rye was increased 40 per cent by the aid of electricity obtained from a Holz machine. The plants were grown in pots. An isolated net of metal furnished with points was suspended above the pots, while the soil in the pots was connected with the ground by means of sheets of tin. In one series of pots the electricity passed from the wire net to the plants, in another series, the reverse direction was observed, while a third received no current whatever. Experiments on an extensive scale with garden crops gave an increase in yield as follows: Turnips, 107.2 per cent; potatoes, 76.2 per cent; mangel wurzels, 65.3 per cent; radishes, 59.1 per cent; parsnips, 54.5 per cent; leeks, 42.1 per cent, and white cabbage, 43.6 per cent. Strawberries subjected to the electro-culture ripened their crop in 26 to 33 days, while in control plats the crop was 54 days in maturing. It is believed that the time will eventually come when the use of electricity will be indispensable in the cultivation of various plants, like lettuce, asparagus, tomatoes, endives, cucumbers, radishes, etc., under glass in temperate climates during the winter season.

Note on some grafting experiments, R. H. BIFFEN (*Ann. Bot.*, 16 (1902), No. 61, pp. 174-176).—The outcome of a series of experiments to test the possibility of obtaining improved varieties of cultivated plants by grafting are reported. The most successful grafts were obtained by the use of seedlings having from 3 to 6 leaves, both for stocks and scions. Beets were one of the easiest plants to graft, nearly every graft being successful. The boundary line between the graft of different varieties of beets was very well marked in every instance, the crimson of the Mammoth Red not gradually blending with the white of the sugar beet. The grafted beets were slightly dwarfed in size. A light dwarfing tendency was noted when *Tropaeolum majus* was grafted on *T. canariense*, and vice versa. The flowering period was also retarded 6 to 8 weeks, and the grafted plants were especially subject to the attacks of slugs and caterpillars.

Radishes (*Raphanus raphanistrum*) were also seriously dwarfed and retarded in growth by grafting.

Successful grafts were also made between white (*Trifolium repens*), red (*T. pratense*), and alsike (*T. hybridum*) clovers; between red clover and alfalfa; red clover and sand clover (*Anthyllis vulneraria*); and between various Cruciferae, as kale broccoli, and Brussel sprouts on cabbage, and vice versa.

This series of experiments is believed to confirm Daniel's work in showing that the effect of grafting is to dwarf growth, retard the flowering season, and in some cases render the plants more subject to the attacks of pests. In none of these experiments was there any visible effect of stock on scion, or vice versa. In grafting potatoes, however, having smooth green skin and deep eyes, upon potatoes with thick, rough, brown skin and shallow eyes, the same plant often produced tubers of both types. In some instances one end of the tubers resembled one type and the other end the other type. Sometimes there was a short constriction between the two ends, and again the yellowish green skin of one end gradually passed over into the rough, corky skin of the other, and the tubers were regular in shape. "Tubers in which the 2 types were blended never occurred." In halving the tubers transversely each portion was indistinguishable from one of its parents. The tubers showed all the characteristics of the parent, and not certain dominant ones. The graft hybrid is therefore not comparable with the sexually produced hybrid in this respect.

The propagation of plants, L. C. CORBETT (*U. S. Dept. Agr., Farmers' Bul.* 157, pp. 24, figs. 22).—A popular discussion of the different methods of growing plants, more especially from cuttings and by layering, grafting, and budding. The details of these various operations are described and illustrated.

A comparative study of different colored glass for greenhouses, E. ZACHAREWICZ (*Jour. Soc. Nat. Hort. France*, 4. ser., 3 (1902), Apr., pp. 265-268).—A brief review is given of earlier experiments by different workers along this line, and the author presents the results of his own work along the same line with strawberries. In this work the largest and greenest plants were obtained when yellow glass was used, but the quantity, size, and earliness of the fruit was decreased by the use of yellow-colored glass. The largest and earliest fruits were obtained by using colorless glass. The largest number of fruits was obtained when violet-colored glass was used. With this glass the size of the fruit was decreased, the quality injured, and the earliness retarded. Red, blue, and green glasses were all injurious to the vegetation of the plants. From these results the author concludes that in greenhouse work where foliage is desired, yellow glass may be used; but for the fruit the ordinary colorless glass is best.

Forcing tomatoes at the Iowa Experiment Station, H. C. PRICE (*Amer. Gard.*, 23 (1902), No. 394, p. 449, fig. 1).—The results are given of a test of varieties of tomatoes for forcing in the greenhouse. The plants were set 15 in. apart and trained to a single stem on a trellis of wire. Lorillard and Holmes Supreme were the earliest varieties grown; Frogmore Selected furnished the most uniformly sized fruit; Mayflower, the largest number of large fruits; Holmes Supreme, the greatest amount of small unmarketable fruit, and Mayflower the most solid fruit. Frogmore Selected was the strongest grower of all the varieties tested, and Holmes Supreme the poorest grower. Frogmore Selected and Sutton Best of All gave the largest cash returns per plant. All things considered, it is stated that Frogmore Selected was the most satisfactory variety tested. The average cash returns with this variety was \$2.53 per plant, while with Sutton Best of All it was \$2.06.

Vegetables for a farmer's garden in northern Illinois, J. W. LLOYD (*Illinois Sta. Circ.* 45, pp. 5).—This gives an assortment of vegetables best suited for farmers' gardens in northern Illinois, indicates how they should be planted, and time of year when each will be available for table use.

Manuring fruit trees, J. P. WAGNER (*Monatsber. Gesell. Förder. Wiss., Ackerb. u. Künste, Unter-Klass.*, 36 (1902), No. 5, pp. 145-172, figs. 6).—A discussion of the principles of manuring fruit trees, with some illustrations and data showing the effect of fertilizing a few orchard fruits. The effect of different fertilizing elements on the growth of trees and production of fruits is brought out, and formulas given for the application of commercial fertilizers. As showing the advantages of fertilizing fruit trees, an instance is cited in which 6 pear trees that bore an excessive crop of fruit in 1900 were subjected to a fertilizer experiment. Four of the trees were well cleaned, pruned in the fall, and the ground under the trees well spaded. Each of these trees then received 5 kg. of slag, and 5 kg. of kainit. During the winter following each tree received 15 to 16 litres of night soil additional, and in the spring $\frac{1}{2}$ kg. of nitrate of soda. The 2 control trees received neither fertilizers nor other care. The manured trees fruited heavier, the fruits were more perfect, hung on better, and the foliage more luxuriant than on the trees not manured. Less fruit set on the unmanured trees, the foliage was ravaged by pests, and most of the fruit fell off before the middle of September. At a cost of a little more than \$1 the fertilized trees gave an increase of 125 kg. of apples, having a value of about \$7.50.

Observations on the fertilization of peach orchards, E. H. JENKINS (*Connecticut State Sta. Rpt.* 1901, pt. 4, pp. 283-285).—The season's record of 1901 is given of the number of baskets of fruit obtained, and the number of trees that have died, in the station peach orchard, which is being used to test the value of different combinations and amounts of commercial fertilizers for this fruit. The experiment began in 1896, and the records obtained have been published from time to time (*E. S. R.*, 13, p. 138), but, as in the present case, without drawing conclusions. The following table gives

a summary of the total number of trees that have died since the orchard was planted, the total yield obtained during the past 3 years on different plats, and the fertilizers that are being used on each plat. Each plat consists of 48 trees. Trees that die are replaced with others.

Yield of peaches on plats differently fertilized.

Plats.	Fertilizers used.	Total number of trees that have died.	Total number of baskets of fruit obtained in 3 years.
A	65 lbs. muriate of potash, 160 lbs. acid phosphate	31	271.75
B	65 lbs. muriate of potash, 160 lbs. acid phosphate, and 170 lbs. cotton-seed meal	16	428.5
C	65 lbs. muriate of potash, 160 lbs. acid phosphate	17	366.25
D	130 lbs. muriate of potash, 160 lbs. acid phosphate	14	413.50
E	260 lbs. muriate of potash, 160 lbs. acid phosphate	1	602.50
F	260 lbs. high-grade sulphate of potash, 160 lbs. acid phosphate	2	556.75

The thinning of fruit. S. A. BEACH (*California Fruit Grower*, 29 (1902), Nos. 727; 728, p. 4; 729, pp. 4, 5).—This article includes the data on thinning apples previously presented by the author (E. S. R., 9, p. 448), and in addition the results of some experiments in thinning apricots, peaches, and plums. Early thinning, leaving the fruits in one instance at least 1 in. apart when ripened, and in another at least 2 in. apart, was practiced, as was also thinning 4 weeks later, leaving the fruits the same distances apart. The best results with apricots followed early thinning 2 in. apart. The fruits were thinned when they had attained about the size of hazelnuts. Like results are reported with plums. With both fruits there was an increase in the size of the thinned over the unthinned fruit, but in both years the yield was greater on the unthinned than on the thinned trees. Peaches were considerably increased in size by thinning and the early thinning appeared to be most effective for this purpose. The effect of thinning the first year was not as marked in increasing the yield on the same trees the following year as was anticipated. The author believes that pruning is the most economical method of thinning the crop whenever this appears necessary. In the light of the author's experiments, it is believed that thinning fruits in commercial orchards with the expectation of inducing regular bearing and increased yields in succeeding years is of doubtful value. Nevertheless, other evidence indicates "that systematic thinning of fruit, combined with skillful care in other directions, may materially strengthen the tendency of the tree to bear annually." Young trees, and sometimes older ones, may be severely impaired in vigor by maturing too heavy loads of fruit. Thinning should constitute the last resort, after all the details of fertilizing, cultivating, draining, pruning, etc., have been attended to.

Culture of the citrus in California. B. M. LELONG (*Sacramento: California State Bd. Hort* 1902, rev. ed., pp. 267, pls. 27, figs. 85).—This report contains a complete account of the culture of citrus fruits in California, from the early orchards to the present time. It includes a discussion of the methods observed by the best orchardists in propagating, planting, cultivating, irrigating, pruning, harvesting, and fertilizing oranges, lemons, citrons, and limes and an account of the diseases and insects affecting them. The varieties of the various citrus fruits are described more or less in detail. A chapter is given on the products of citrus fruits, such as perfumes, oils, acids, wines, essences, etc.

Report of the fruit expert. W. J. ALLEN (*Agr. Gaz. New South Wales*, 13 (1902), No. 5, pp. 506-528).—A review is given of the various orchard fruits, including citrus fruits in certain instances, grown at the Wagga, Hawkesbury, Pera Bore, Moree, and

Wollongbar experimental farms. Lists of the varieties grown are cited in many instances, and notes given as to their character and growth.

The home fruit garden, L. C. CORBETT (*U. S. Dept. Agr. Yearbook 1901*, pp. 431-446).—This article was published as a Farmers' Bulletin and has been noted as such (*E. S. R.*, 14, p. 147).

The farmer's fruit garden, E. V. STUBENRAUCH (*Illinois Sta. Circ. 40*, pp. 7, *dgm. 1*).—Suggestions regarding kinds of fruit to plant, best methods of planting them, with a diagram showing the arrangement of a fruit garden of 1 acre.

List of fruits recommended for a farmer's garden of one acre in northern Illinois, W. S. HOTCHKISS (*Illinois Sta. Circ. 42*, pp. 4).—The list includes the best varieties of apples, pears, peaches, plums, cherries, blackberries, grapes, and other small fruits, suitable for planting in northern Illinois.

Little-known fruit varieties considered worthy of wider dissemination, W. A. TAYLOR (*U. S. Dept. Agr. Yearbook 1901*, pp. 381-392, *pls. 7*).—Among the fruits mentioned and described are Ingram apple, McIntosh apple, Carman peach, Red June plum, Wickson plum, Downing grape, Mulgoba mango, and Advance loquat. Colored plates are given of these different fruits.

Commercial apple orcharding, G. B. BRACKETT (*U. S. Dept. Agr. Yearbook 1901*, pp. 593-608, *pls. 4*).—This is a popular discussion of the whole matter of apple growing, including soils, methods of planting, varieties valuable for commercial purposes, methods of cultivation and pruning, insects and diseases affecting, and the handling and disposition of the crop.

Grafting resisting apple scions (*Pacific Coast Fruit World*, 13 (1902), No. 21, p. 18).—An account of the importation from New Zealand of apple stocks resistant to the aphid. About 20 varieties were imported and have been grafted.

Fruit storage experiments, J. C. BLAIR (*Illinois Sta. Circ. 44*, pp. 18, *pls. 24*).—The details of construction are given of a fruit storage house erected by the station, and of 2 cellars so made that they would be suitable for fruit storage. A number of plates and figures illustrating different phases of the work are included. The fruit storage house was built to hold 2,500 bbls., and cost, when completed, \$3,080.41. The details of construction were made as simple as possible in order to reduce the amount of expert service required to a minimum. Fruit growers in Illinois are allowed to store fruits in the building free of charge, subject to the rules of the station. The fruit stored during the first season with the results, and the temperature observations, are to form a subsequent report.

The experiments in preparing the cellars for cold storage have shown that where the stone walls of the cellar are made to form the walls of the storage room, or the bottom of the cellar is covered with nothing more than a 6-in. layer of cinders, the temperature can not be kept down when the outside and surrounding ground is above the desired temperature. The details of this work are to be published later.

Tinting ripe pickled olives, E. W. HILGARD (*California Fruit Grower*, 27 (1902), No. 731, p. 8; *Pacific Rural Press*, 63 (1902), No. 22, pp. 360, 361).—The author discusses the probable effect on the food value of olives by coloring them with a small amount of copperas or iron sulphate. The use of coloring matter or preservatives of any kind in food products is deprecated.

The art of canning and preserving as an industry, J. PACRETTE (*Jersey City: Jules H. Dommergue, 1901*, pp. 194+X, *figs. 33*).—Recipes are given for preparing and processing candied, glacéed, and brandied fruits, sirups and fruit juices, cordials and marmelades, various spirits, puddings, vegetables of all kinds, fish, milk, meats (including game), sauces, soups, etc. A brief chapter on bacteriology as related to canning is included in the work.

Small fruits for the northern half of the State, and how to grow them, J. W. LLOYD (*Illinois Sta. Circ. 41*, pp. 3).—Brief cultural directions.

Strawberry culture in Mississippi, A. B. MCKAY (*Mississippi Sta. Bul. 75*, pp. 15, *figs. 7*).—Popular directions are here given for the location and planting of the

strawberry bed, methods of cultivation, manuring, mulching, and gathering the fruit. Reliable sorts for culture in Mississippi are Hoffman, Cloud, Lady Thompson, Bubach, Gandy, Excelsior, and Klondyke. These varieties are briefly described. Of the newer varieties Hunn, Clarence, Noble, and Gardner, in the order named, are mentioned as very promising sorts. Cotton-seed hulls is stated to be the best of all the materials used at the station as a mulch for strawberries.

Growing strawberries under cloth, O. W. BLACKNALL (*Amer. Gard.*, 23 (1902), No. 392, pp. 416-418).—The author has successfully used thin muslin, known as tobacco-plant bed cloth, as a protection for strawberries. In his experience the berries grow larger, the blossoms are better pollenized, and the plants more productive under cloth than when grown in the open. The author considers also that the slight increase of warmth obtained by lessening the radiation at night was very beneficial to the growth of the strawberries. Taking one year with another, he estimates that this kind of protection adds from 50 to 100 per cent to the yield of berries, makes them larger and more reliable, and ripens them earlier. Care should be taken not to use a cloth too thick and impervious to sunlight. The tar-treated kind, such as is used in large quantities for tobacco-plant beds, is considered just right. The cloth is fastened down over the bed by driving 18 in. stakes into the ground about 1 ft. deep. A wire hook is attached to the top of the stakes, by which the plant cloth is held in place. The stakes are set the width of the cloth apart, in straight rows, and 54 in. apart in the row. The original cost of a protection of this kind is estimated at \$150 per acre. The cloth lasts about 3 years, and the stakes, if carefully protected, from 5 to 10 years.

Houses for strawberry forcing (*Garden*, 61 (1902), No. 1592, p. 343).—Low span-roofed houses are considered most suitable and economical when houses are built especially for forcing strawberries. Such houses are usually 100 to 200 ft. long, 10 ft. wide inside and 6 ft. high to the apex of the roof. A sunken path, 20 to 24 in. wide, runs down the center with 6 rows of pots on each side.

Cranberry culture in southeastern Massachusetts, J. BURSLEY (*Massachusetts State Bd. Agr. Rpt. 1901*, pp. 389-397).—Some statistics are given on the cranberry production of New England and suggestions made regarding the establishment of cranberry bogs and the culture of cranberries in southeastern Massachusetts.

Grapes, A. DICKENS and G. O. GREENE (*Kansas Sta. Bul. 110*, pp. 223-250, pls. 2, figs. 6).—This bulletin includes a discussion of the varieties of grapes best suited for culture at the Kansas Experiment Station, the results of a test of 6 different kinds of trellises for grapes, a test of the value of bagging grape fruit bunches, a classification of grapes with reference to the suitability of different varieties for culture in Kansas, brief descriptions of 145 varieties of grapes, and a chart showing when they were first in bloom, in full bloom, and out of bloom.

With such varieties as Green Mountain, Campbell Early, Brighton, Eldorado, Worden, Concord, Agawam, and Catawba, a succession may be secured from early in August until well into October. Among the perfectly hardy white varieties are Elvira, Martha, Faith, and Pearl. For table use and the family trade Brighton, Brilliant, Massasoit, Catawba, Woodruff, Wyoming, Berkman, Agawam, and Delaware, among the red grapes, are considered very satisfactory. Varieties and hybrids of the common wild grape (*Vitis riparia*) have stood severe droughts well and are recommended for testing in especially trying situations. Elvira, Grein Golden, Faith, and Pearl are perfectly hardy, regular and prolific in bearing. Marion has been the best of the pure Riparias.

Relative to pruning grapes in Kansas it is the judgment of the authors that the annual renewing of the entire arm is preferable to spur pruning.

But little difference has been noted in the productiveness of grapes on the different forms of trellises used. The bunches have been more easily cut from the high-renewal trellis than from the low trellis, and the period of ripening has been uniformly a few days earlier. The difference in time, however, has in no case

exceeded a week. The quality of the grapes has been about the same on all the different trellises. The fruit was more subject to sunburn on the Kniffen 2-wire, 4-cane trellis than on any other. This was controlled by training the new growth over the bunches. The greatest amount of injury from birds occurred on the Kniffen 2-wire, 4-cane trellis and the Kniffen overhead telegraph trellis. The least injury from this source occurred on the umbrella and fan systems. The fan system is considered the most satisfactory for varieties that are not perfectly hardy, since the young canes can be readily laid down for winter protection. The high-renewal forms are thought preferable to the low-renewal fan systems for localities where fungus diseases are prevalent. On the whole, the trellis for the fan system of training is considered the simplest and cheapest in construction and is commended to Kansas growers.

Experiments in bagging the bunches of fruit with manila paper bags as a protection from the birds have shown results that justify this practice, especially when the grapes are grown for a fancy market or the home table. The cost for this work is about 1 ct. per pound of fruit. The lengthening of the season of fresh grapes by bagging was determined with a number of varieties to be as follows, expressed in days: Agawam, 2; Brighton, 15; Catawba, 0; Concord, 14; Delaware, 40; Diamond, 8; Eldorado, 28; and Moore Early, 20. With most varieties bagging improved the condition of the bunches, though in a few instances the varieties were not quite so highly colored and the flavor was not always up to the standard of the variety. The difference, however, in the color and flavor was so slight as not to injure the market value of the fruit.

A record is given of the injury sustained by the different varieties of grapes at the station during the winter of 1898-99, and of their subsequent growth. Tender grapes are trained according to the fan system and laid down and covered in winter.

Nitrate of soda in the culture of grapes, G. CHAPPAZ (*Prog. Agr. et Vit. (Éd. L'Est)*, 23 (1902), No. 22, pp. 628-632).—On a clay-lime soil, very stony and rich in potash, the effect of nitrate of soda on the yield of grapes and quality of wine produced was studied. Commercial fertilizers had never been used in the vineyard before and no manures had been applied for a long time. The control plat on which no fertilizers was used yielded 5,550 kg. per hectare, the wine from which analyzed 12.8° alcohol. The plat receiving nitrate of soda at the rate of 400 kg. per hectare yielded 8,510 kg. of grapes per hectare, the wine from which analyzed 12.6° alcohol. Superphosphate at the rate of 500 kg. per hectare was applied with the nitrate of soda, but when this same amount was used in connection with 300 kg. of sulphate of ammonia per hectare no increase in yield over the control plat was obtained. The important fact in the experiment is the increase of 2,960 kg. of grapes per hectare by the use of nitrate of soda without any material decrease in the quality of the wine produced.

Report of the viticultural expert, M. BLUNNO (*Agr. Gaz. New South Wales*, 13 (1902), No. 5, pp. 528-537).—This is a report of the viticultural expert for New South Wales. He notes that native white wines of the hock and muscat types have been produced rivaling those of European origin. Port and sherry wines, however, do not come up to the standard of the Portuguese and Spanish brands. A list of the phylloxera-resistant stocks grown at the Viticultural Station at Howlong is included in the report.

The home vineyard, with special reference to northern conditions, W. H. RAGAN (*U. S. Dept. Agr., Farmers' Bul. 156*, pp. 24, figs. 15).—Popular directions are given in this bulletin for the planting and subsequent care of a small vineyard such as is likely to be desired by farmers for home use. Some of the best varieties for Northern planting are Concord, Worden, Moore, and Niagara.

Budding the black walnut (*Pacific Coast Fruit World*, 13 (1902), No. 12, p. 6).—It is stated that the California black walnut has been successfully budded with

Mayette and other good French varieties of soft shell walnut. Annular or ring budding is considered the safest plan of budding. Otherwise, the bud should be cut deep and the wood gouged out, the object being to get more of the inner bark surface.

Notes on the caoutchouc trees of the Amazon, J. HUBER (*Bul. Soc. Bot. France*, 49 (1902), No. 1-2, pp. 43-51).—A discussion is given of the botany of the various species and varieties of *Hevea*, *Castilloa*, *Sapium*, and other less well known caoutchouc trees.

The ether treatment of lilacs in the trade, F. LEDIEN (*Gartenwelt*, 6 (1902), No. 19, pp. 219-221).—The author states that the etherization of plants is being rapidly adopted in the German trade. The etherizing room used by a grower of lilacs is described. When etherized the middle of November, Charles X. was ready to sell 24 days later; when etherized the first of December it was ready for market in 18 days. In November, 50 gm. of ether per hectoliter were used, and in December only 40 gm. The cost of etherizing was about 2½ cts. per pot. In these experiments only summer-planted lilacs were used. In tests at the experiment station in Dresden, both summer-planted and potted lilacs were used. The details of the station work are withheld for future publication, but it is stated that old plants which had been once etherized and forced, when heavily fertilized but not transplanted, responded readily to etherization again, and by the end of October were in full foliage—an important consideration when plants are sold in pots. It is stated that the foliage must be kept confined within certain bounds by pruning, as otherwise the flower buds are likely to remain undeveloped.

Key to garden classification of roses, L. BARRON (*Amer. Gard.*, 23 (1902), No. 377, p. 171).—A key is given to summer flowering roses which bloom but once and to summer and autumn flowering roses which bloom more or less continuously.

Influence of stock on scion, J. DALLAS (*Amer. Gard.*, 23 (1902), No. 377, p. 166).—When *Ophirie*, a coppery colored and cup-shaped rose, was used as a stock for *Maréchal Niel* it transmitted a large percentage of its character and color to the latter. The use of *Lamarque*, a pure white rose, as a stock for *Maréchal Niel* resulted in buds of normal size but almost white at the points. Cloth of Gold, when used as a stock for *Maréchal Niel*, produced flowers of the deepest yellow.

Horticultural monograph of the genus *Deutzia*, E. LEMOINE (*Jour. Soc. Nat. Hort. France*, 4. ser., 3 (1902), Apr., pp. 298-314, figs. 2).—This is confined to a study of the different species and varieties cultivated in the garden from the horticultural standpoint.

Native vines in Wyoming homes, A. NELSON (*Wyoming Sta. Bul.* 50, pp. 15, pls. 9, figs. 2).—This bulletin was written for the purpose of acquainting the people of the State with the valuable native vines that may be used in the adornment of their homes. General descriptions and cultural directions are given for the American ivy, Western clematis, River Bank grape (*Vitis vulpina*), wild hops, and wild balsam apple (*Micranthella latifolia*). Two valuable introduced species are the well-known morning glory and the moon vine, both of which do well in Wyoming.

The "why" of the late planting of dahlias, J. W. WITHERS (*Amer. Gard.*, 23 (1902), No. 386, pp. 318, 319).—The author states that he has been successful in growing dahlias only when plantings were made after June 15. By planting late the injurious effects of the usual summer drought are largely obviated and the plant kept continually growing. This is considered to be the main reason of success in late planting.

A new yellow calla, E. O. ORPET (*Amer. Gard.*, 23 (1902), No. 395, p. 463, fig. 1).—This calla is the result of crossing *Richardia elliptica* with *R. albo-maculata*. It promises to be of considerable value for an outdoor summer plant. Dormant bulbs planted about the latter part of May flower freely until fall, when the tops are cut off with a scythe, the tubers thoroughly ripened, and then stored in the cellar like potatoes, until planting time again.

Leaf mold for orchids, E. O. ORPET (*Amer. Gard.*, 23 (1902), No. 399, p. 530).—As the result of the author's experiments he considers leaf mold unsuited to the culture of orchids under the conditions prevailing in the United States.

The farmer's flower garden, A. C. BEAL (*Illinois Sta. Circ.* 46, pp. 3).—Suggestions as to the planting of hardy flowers and shrubs suitable for flower borders.

The window garden, A. C. BEAL (*Illinois Sta. Circ.* 47, pp. 3).—Brief notes on the flowers best suited for window gardens, with suggestions as to their planting and care.

FORESTRY.

Grazing in the forest reserves, F. ROTH (*U. S. Dept. Agr. Yearbook* 1901, pp. 333-348, pls. 8).—A general discussion is given of the function of forests and the object and character of forest reserves, after which the regulations for grazing in forest reserves are stated and the forms of permits shown. The extent of grazing in the forest reserves for the year 1901 is shown in tabular form, in which the number of sheep, cattle, and horses which were permitted to enter the different reserves are stated. The different methods of handling stock in the reserves and the effect on the range are shown, and to prevent the impairment of the reserves it is suggested that the ranges should be subdivided and each stock owner allowed a well-defined area. In addition it is recommended that a per capita tax or rental should be imposed on all stock grazing in the reserves.

Administration of the United States forest reserves, I, F. ROTH (*Forestry and Irrig.*, 8 (1902), No. 5, pp. 191-193).—An outline is given of the organization and administration of the forest reserves of the United States.

New forest reserves (*Forestry and Irrig.*, 8 (1902), No. 5, pp. 187, 188, fig. 1).—On April 16, 2 forest reserves were established by presidential proclamation in the sand-hill district of Nebraska. One of these, known as the Dismal River Reserve, contains 86,000 acres; and the other, called the Niobrara Reserve, contains 125,000 acres. These reserves lie near the center of the great sand-hill district, which includes nearly one-fourth of Nebraska. The main purpose of establishing these reserves is to try on a large scale the practicability of forestation. The conditions seem favorable, and it has been proved that the region is adapted to the growth of pine timber. The demand for timber in the region is great, and the main question hinges upon the development of a practicable and economical method of getting the forest started. On April 11 the San Isabel Forest Reserve, containing 77,980 acres, in south-central Colorado, was formally established by presidential proclamation, and a few days later the San Francisco Mountains Forest Reserve of Arizona was increased by 999,950 acres. With these new reserves and the increases of the older ones, the total area of all the forest reserves of the United States is now 48,002,101 acres.

The timber resources of Nebraska, W. L. HALL (*U. S. Dept. Agr. Yearbook* 1901, pp. 207-216, pls. 6).—A review is given of the timber resources of Nebraska, in which attention is called to the ratio of planted timber to natural forest. Probably in no other State is there relatively as much planted timber as in Nebraska, the ratio being nearly 1 acre of planted timber to 8 acres of natural forest. A description is given of the distribution, character, and extent of the natural forests, and an account of the various attempts at tree planting is outlined. The value of timber for wind protection, shade, fuel, and construction purposes is briefly shown, and as indicating the commercial value of planted timber an account is given of the returns from a 3-acre cottonwood grove planted in 1860. This tract has yielded an annual profit of \$5.32. The experiments being conducted by the Bureau of Forestry of this Department in reforesting the sand-hill region of western Nebraska are briefly described.

Forestry in Minnesota, S. B. GREEN (*Minneapolis: Geol. and Nat. Hist. Survey of Minnesota, 1902, pp. 401, pls. 63*).—This is a revised edition of the manual on forestry in Minnesota previously noted (E. S. R., 10, p. 856). This edition covers all the ground of the first, but the matter has been reclassified and a considerable extension of material is provided. New chapters are given on forest mensuration, forest problems in Minnesota, forest economics, etc.

A working plan for southern hardwoods and its results, J. FOLEY (*U. S. Dept. Agr. Yearbook 1901, pp. 471-476, pls. 3*).—An outline is given of a working plan established by the Bureau of Forestry of this Department for a tract of land owned by The University of the South, at Sewanee, Tenn. The forest comprises 7,255 acres, of which 6,555 are wooded. The more important trees are walnuts, hickories, oaks, tulip, and basswood. Under the method of treatment recommended, the revenue obtained in the first 9 months of management was \$1,314.61. This revenue was considered satisfactory by the owners, and the statement is made that it was obtained with little or no injury to the forest and equaled that which would have been secured under the usual methods of lumbering.

The improvement of uncultivated farm land, E. H. JENKINS (*Connecticut State Sta. Rpt. 1901, pt. 4, pp. 350-352*).—A brief outline is given of the work which has been recently undertaken by the station in studying means of improving the waste farm lands of the State. This work will not only include forestry and tree planting, but also the cropping and grazing of waste lands for their improvement. Primarily the station work is being conducted in the interest of the individual holders of woodland, pastures, and other waste lands, which are at present nearly worthless.

Annual report of the forester, W. MILFORD (*Connecticut State Sta. Rpt. 1901, pt. 4, pp. 353-364, pls. 3*).—The station has undertaken 2 lines of work, the first of which is considered station work proper, and is outlined in the report on the improvement of uncultivated land (see above); while the second line of work is carried on under the act of the general assembly concerning the reforestation of barren lands. At present studies on the condition of the woodland and idle land are being conducted, and work begun in reclaiming the waste land, in the treatment of woodland to improve its present condition, and in the dissemination of information regarding forestry. Under these different headings the details of the work are described. The act of the general assembly of the State providing for the forest work is given and commented upon.

Fire and the forest reserves, C. S. NEWHALL (*Forum, 33 (1902), No. 1, pp. 109-120*).—The author discusses the harm arising from forest fires, their sources, and the means to be taken for the protection of forests against fires, and the resources for combating forest fires.

Forest fires during June (*Forestry and Irrig., 8 (1902), No. 7, pp. 296-298, figs. 2*).—A compilation is given showing the extent of forest fires during the month of June, 1902. The damage to standing timber is conservatively estimated at \$5,000,000, most of which was done in the States of Washington, Colorado, and California.

Practical silviculture, G. VERT (*Bol. Agr. São Paulo, 3. ser., 1902, No. 5, pp. 340-343*).—Brief directions are given for the planting, organization, and exploitation of forests in Brazil. The yearly growth of a number of varieties of trees is shown, and suggestions given for their proper rotation in a conservative system of forestry.

Forest trees adapted to Chile, F. ALBERT (*Los bosques en el país. Santiago de Chile: Imprenta Moderna, 1901-2, pp. 184, figs. 55*).—After a historical review of the forest conditions of Chile and the present status of forestry, descriptions are given of the indigenous species, as well as of a large number of foreign species which are thought to be suitable for introduction in that country.

White pine planting in New England, H. B. KEMPTON (*Forestry and Irrig., 8 (1902), No. 7, pp. 238-291, figs. 3*).—It is stated that the tree most commonly used for forest planting and which gives the best results in New England is the white

pine. This is due to its adaptability to various conditions of soil and climate, its rapid growth, and the value of its timber. The various plantings of white pine in New England are divided into watershed plantings, plantings on sand barrens and seaside dunes, on bare lands and worn-out pastures, on cut-over land, and planting for the home wood lot. The value of the pine for these different plantings is shown, and it is stated that in many regions the bare lands are slowly being covered by a natural growth of white pine. The most practical forest planting for the general public is said to be the home wood lot. When combined in wood lot and wind-break, the protection afforded is of great value, and the excess of posts and fuel will be readily marketable for those living near the towns.

The *Pinus attenuata* as a water conserver, T. P. LUKENS (*Forestry and Irrig.*, 8 (1902), No. 6, pp. 246-249, figs. 3).—A description is given of *Pinus attenuata*, or *P. tuberculata*, as it is more commonly called, and attention drawn to its value as a forest cover for protecting the slopes of the mountains in California. On account of the peculiar manner in which the cones of this tree are produced its distribution seems to be very little affected by fires. There seems to be evidence that, in some instances at least, fires have proved advantageous in spreading this tree, by causing the cones to open and distribute their seed. The heat of the fire, while it may destroy the tree, melts the resin with which the cone is sealed, and within a few days after the fire the winged seeds are scattered over a greater area than that over which the trees previously existed. A peculiarity of this tree is that the cones are frequently inclosed by the growth of the tree, precluding its use for timber. The principal usefulness of this species is that of a water conserver and to prevent erosion. The seeds of this species retain their vitality for a long time, fertile seed having been found in cones almost surrounded by the growth of the trunk of the tree.

The red cedar in Nebraska, L. C. MILLER (*Forestry and Irrig.*, 8 (1902), No. 7, pp. 282-285, figs. 2).—An account is given of the distribution and reproduction of the red cedar in Nebraska. The reproduction of red cedar is said to be good. In no locality where seed trees occur is reproduction lacking, but where seed trees are scarce the young growth is naturally limited. The planting of the red cedar on a large scale has not yet been undertaken, but from experiments that have been conducted it is believed that excellent results will be obtained in planting this tree over a considerable portion of the State. The adaptability of the red cedar to various soils and its value for fence posts, telegraph, telephone, and electric-light poles, and railroad ties are believed to be so great as to result in its wide future planting throughout the State.

***Taxodium distichum* and related species, with notes on some geological factors influencing their distribution**, R. M. HARPER (*Bul. Torrey Bot. Club*, 29 (1902), No. 6, pp. 383-399).—The results of field observations on the bald cypress have led the author to the conclusion that there are at least 2 well-marked species in the southeastern United States. In addition to the well-known species, *Taxodium distichum*, the author proposes a second species, *T. imbricarium*, which is common in swamps and ponds from Florida to North Carolina, etc.

A notable California fir, W. R. DUDLEY (*Forestry and Irrig.*, 8 (1902), No. 5, pp. 193-198, figs. 4).—An account is given of the distribution and characteristics of what is known as the Santa Lucia silver fir (*Abies venusta*). The author shows that this fir is distributed over a considerably wider area than has been previously known, and it is believed that this species will prove one of the best for propagation over large rocky tracts where few other trees naturally grow. It should probably be accompanied by such hard woods as tan bark and Valparaiso oaks, both of which are of great economic value.

A volatile oil in the wood of *Cryptomeria japonica*, C. KIMOTO (*Bul. Col. Agr. Imp. Univ. Tokyo*, 4 (1902), No. 5, pp. 403-405).—The wood of this highly

prized coniferous tree is said to possess an agreeable odor, something like that of peppermint, and is extensively used as a material for the manufacture of sake casks. The sake stored in them acquires a peculiarly agreeable aroma, which is supposed to be due to the presence of some principle in the wood. In order to ascertain the nature of this principle, the author distilled 2 kg. of the wood and obtained 13 cc. of an oily substance, which had the characteristic smell of the original wood. This was subjected to a fractional distillation, the greatest quantity coming off at a temperature of between 260 and 270° C. To this the author has given the name sugiol, from the Japanese name of the tree. It is an oil of neutral reaction, almost completely insoluble in water, but readily soluble in alcohol, ether, and chloroform. Its boiling point is 264° C. and specific gravity 0.935.

The effect of lightning on trees, D. T. MACDOUGAL (*Jour. New York Bot. Gard.*, 3 (1902), No. 31, pp. 131-135).—The effect of lightning on a number of trees in the New York Botanical Garden is described, and an examination showed that the part of the tree containing the greatest proportion of starch, glucose, or other sugars offers the least resistance to the passage of electric currents, and the parts containing oily material offers the greatest resistance. In consequence, lightning discharges generally pass through a tree trunk in the growing layers and sap wood, and the actual amount of mechanical injury will depend upon the size of the discharging flash. A more or less constant discharge is said to be taking place through trees, and it is only when the difference in potential becomes very great that a lightning stroke results.

The work in dendro-chemistry, W. H. KRUG (*Forestry and Irrig.*, 8 (1902), No. 5, pp. 202-205).—An outline is given of proposed investigations in the laboratory which has been established in connection with the Bureau of Chemistry of this Department. The first work taken up by the laboratory was the study of the chemical composition of the wood and bark of a number of species of oaks, to which have been added the investigations of the Western hemlock, and other species will be taken up in time.

The lumber industry, H. GANNETT (*Twelfth Census United States, Census Bul.* 203, pp. 97).—According to this bulletin, at the time the twelfth census was taken there were 33,035 establishments engaged in the lumber industry in the United States. The amount of lumber produced by mills was 35,084,166 ft. B. M., valued at \$566,-832,984. Comparative summaries are drawn showing the condition of the lumber industry as revealed by the different census reports from 1850 to 1900. The ownership, capital, and product of the different establishments are shown, together with the different logging establishments, sawmills, shingle, and planing mills. The different timber regions of the United States are outlined, and statements given relative to the average stand of the timber and its ownership. The distribution and cut of the more important woods, such as white pine, spruce, hemlock, cypress, Southern yellow pine, Western yellow pine, sugar pine, red fir, redwood, and hard woods are given, and the timber regions of the different States described.

SEEDS—WEEDS.

Agricultural seeds—where grown and how handled, A. J. PIETERS (*U. S. Dept. Agr. Yearbook* 1901, pp. 233-256, pls. 4, figs. 2).—A brief review is given of the production of agricultural seeds in the United States, the centers of production of a number of the more important varieties being given. The seed production of different cereals, clovers, grasses, fiber plants, and miscellaneous agricultural products is briefly described, the distribution indicated, and methods of harvesting shown. Charts are given showing the distribution of seed-producing centers throughout the United States.

A test of the vitality of seed corn, A. D. SHAMEL (*Illinois Sta. Circ. 49*, pp. 4).—A method of testing the vitality of seed corn is outlined and the application of the results suggested.

Tests of the vitality of vegetable seeds, E. H. JENKINS (*Connecticut State Sta. Rpt. 1901*, pt. 4, pp. 286-294).—In continuation of the previous report (E. S. R., 12, p. 563), the results of testing 689 samples of vegetable seeds are given. Tables presented showing the average, maximum, and minimum vitality of all seeds tested at the station since the adoption of the methods of testing recommended by the Association of American Agricultural Colleges and Experiment Stations. A report is also given on the vitality of onion seed as affected by age, as well as comparisons between California and Connecticut grown seed. As in the previous report the vitality of the California-grown seed surpasses that of the local-grown. A report is given showing the vitality of Connecticut-grown onion seed of various crops from 1894 to 1900, in which considerable fluctuation in the average germination is shown. As in the previous report, differences are observed in the sprouting capacity of different varieties of onion seed, the White Portugal appearing to be distinctly inferior to the other varieties.

Conditions influencing the vitality and germination of seeds, J. W. T. DUVEL (*Abstr. in Science*, n. ser., 16 (1902), No. 395, p. 137).—The effect of various climatic conditions, especially the deleterious influence of warm, moist climates on the vitality of seed, is shown. Necessary conditions for keeping seed in such unfavorable climates were discussed at some length, showing that the first requisite for prolonged vitality of seed is a reduction in the amount of hygroscopic moisture present, thereby diminishing the respiratory activity and consequently prolonging the life of the seeds.

The removal of the wings from the seeds of conifers, F. MAIN (*Jour. Agr. Prat.*, n. ser., 4 (1902), No. 40, pp. 436-438).—The wings which occur on the seed of many species of conifers to aid in their natural dissemination, are said to be more or less troublesome in handling the seed and in sowing them in nurseries. On this account various mechanical means have been suggested for the removal of the seed wings, and a method in use in France is described at considerable length.

The destruction of weeds, G. HEUZÉ (*Jour. Agr. Prat.*, n. ser., 4 (1902), Nos. 35, pp. 283-285; 41, pp. 473, 474).—Descriptions are given of a number of troublesome weeds and suggestions for their eradication.

DISEASES OF PLANTS.

Notes on plant diseases, F. D. CLEMENT (*Delaware Sta. Bul. 57*, pp. 16, figs. 6).—Notes are given on some diseases of cantaloupes, pear and apple canker, treatment of asparagus rust, winterkilling of dewberries, sun scald of Japanese plums, and fire blight of pears. The portions of the bulletin describing the diseases of cantaloupes and pear canker are essentially reprinted from the Annual Report of the Station (E. S. R., 14, p. 260). For the prevention of the leaf blights or cantaloupes thorough spraying with Bordeaux mixture at intervals of 2 weeks during the growing season is recommended. For the prevention of stigmoneose spraying with kerosene emulsion or other insecticide for the destruction of melon aphid is advised. For the pear canker the formaldehyde-glycerin treatment is again recommended as the most efficient remedy.

In 1901 the asparagus rust was less destructive than during the 2 preceding summers, but was serious enough to demand careful investigation. Asparagus was sprayed with Bordeaux mixture, to which 2 lbs. of resin soap was added to each barrel of fungicide. The results warrant the recommendation of this treatment as a rust preventive; it should be used wherever the rust has been especially troublesome the previous season.

The winterkilling of dewberries has been under investigation. It is believed that

the weather conditions are not the primary cause of the destruction of plants, but that it is due to a weakened condition of the vines brought about by attacks of parasitic fungi. Tying up the vines too early in the season is not advisable, and the middle of April is believed to be a better time than the middle of March. If delayed until this time there is not the liability to the destructive action of the high, dry winds of the early spring.

The sun scald of the Japanese plum has been called to the author's attention for a number of seasons, and the disease seems to be of considerable importance. The trouble begins in longitudinal cracks in the south side of the body of the tree, and continues until the trunk is more or less decayed. The cause of the cracking of the bark is the successive freezing and thawing, which is most marked on the side exposed to the sun's rays. It may be prevented by protecting the south side of the tree, by heading the trees low so that the tops will shade the body, by giving the trees a slight inclination to the south, thus keeping off the full force of the sun, or by sheltering by mechanical means.

The control of fire blight of pears is said to be one of great practical importance to the fruit growers of Delaware, and the value of pruning is shown. Two spring prunings are recommended, the first before the blossoms open and the second about a month after blossoming, to be followed by a third inspection in the fall before the leaves drop, cutting out at this time all evidence of blight which may have escaped the previous operation.

A new bacterial disease of the potato, G. DELACROIX (*Bul. Min. Agr. [France]*, 20 (1901), No. 5, pp. 1013-1033).—This disease, which has been noted previously (E. S. R., 13, p. 864; 14, p. 263), is reported upon at some length, the author giving the results of his investigations made at the request of the Minister of Agriculture. An historical statement is given relative to the appearance and distribution of the disease, which it is believed has long been present in Ireland as well as in Germany. The characters of the disease, which is due to *Bacillus solanincola*, are described. In addition to attacking the potato, the tomato is said to be subject to the disease, exhibiting the same symptoms, although being more resistant than the potato. The organism causing the disease is described at length, and it is said that there is frequently associated with it the mycelium of a number of fungi. Among those noted are a species of *Fusarium* which is quite similar to *Fusarium lycopersici*, the sclerotia and mycelia of a species of *Vermicularia* and of *Torula concoluta*, and a sterile form which seems to be identical with *Rhizoctonia solani*. Of these the *Rhizoctonia* is thought to be the only parasitic form, the others being present as saprophytes. Infection experiments were conducted with the bacteria as well as the fungi, and the disease was produced in stems artificially inoculated with the bacteria, but the experiments with the other organisms gave negative results. The conditions for infection seem to require a humid spring which is late and cold, followed suddenly by very hot, dry weather. Marked differences are noted as to the susceptibility of different varieties of potatoes to the disease, the early ones being particularly subject to injury. Contrasting characters are presented by which this disease may be differentiated from other fungus and bacterial diseases of the potato. When first discovered, the author considered the organism identical with that described by E. F. Smith as causing a bacterial disease of tomato, eggplant, and Irish potato (E. S. R., 8, p. 895), but subsequent investigations show that the organism described by Smith develops rapidly and produces a great number of bacteria in the vessels of the plant, but does not produce thylles nor gum, while the organism of the new disease liquefies gelatin in cultures. A series of experiments was undertaken for the control of the disease, and the author recommends the selection of sound tubers for planting or of tubers from noninfested regions, a 4-year rotation of crops, and the planting of entire tubers, which should be treated before planting by immersion for an hour and a half in a 1:120 solution of formalin. The plantings should be made as late as possible to insure the ripening of the crop.

Concerning the bacterial disease of the potato, E. MARRE (*Prog. Agr. et Vit. (Éd. L'Est)*, 23 (1902), Nos. 14, pp. 415-417; 15, pp. 439-441; 16, pp. 462-470).—A description is given of the bacterial disease of potatoes caused by *Bacillus solanincola*. This disease is said to have made a sudden appearance early in August, 1901, and it is reported as having been observed to a more or less extent in 20 departments of France. The characteristics of the disease and descriptions of the organism are given at some length, the previous publications of Delacroix being drawn upon. Although only recently demanding attention, this disease is said to have been known for a number of years, and quite a number of local names are given which are more or less descriptive of it. The conditions for the development of the disease and its spread and treatment are discussed at some length.

Concerning a bacterial disease of the potato, A. CARRÉ (*Prog. Agr. et Vit. (Éd. L'Est)*, 23 (1902), No. 15, pp. 429-430).—In a brief note the author calls attention to the presence of a bacterial disease of potatoes recently described by Delacroix (see above), and suggests the stimulation of the growth of potatoes by the application of fertilizers, particularly those containing superphosphates, as a means for combating the disease.

Some diseases of the sugar beet, C. O. TOWNSEND (*U. S. Dept. Agr. Rpt.* 72, pp. 90-101, pls. 4).—Popular descriptions are given of a number of the more injurious diseases of the sugar beet, and so far as known directions are given for their prevention. Among the diseases described are damping off, curly top or blight (also called Western blight, bacteriosis, and California beet disease), leaf spot, leaf rust, leaf scorch, crown rot, root rot, scab, and crown gall.

Field treatment of cane cuttings in reference to fungus diseases, A. HOWARD (*West Indian Bul.*, 3 (1902), No. 1, pp. 73-86).—The author's attention has been called to the fact that many cane cuttings either do not grow at all when planted or the young shoots die shortly after their appearance above ground. In some plantations as much as 30 per cent of the cuttings fail to grow. This loss is generally attributed to drought, but a careful examination showed that the loss was doubtless due to the presence of fungi. The fungus found is believed to be identical with that which causes the disease of cane cuttings in Java, known as the pineapple disease. For the protection of cuttings against this fungus (*Thielariopsis ethacetensis*) it has been recommended in Java that the cut ends of the cuttings be coated with tar before planting. The author has investigated the value of such treatment, also the treatment of the cuttings with Bordeaux mixture, and Bordeaux mixture and tar. The results showed that Bordeaux mixture alone or in combination with the tar is very effective in preventing infection, and is considerably better than tar used alone. The relative value of tops and cuttings of the lower part of the cane for seed purposes was tested, and it was found that the tops were much less liable to disease than the lower cuttings. This is explained by the difference in the sugar content of the lower and upper part of the cane. The greater amount of the sugar in the lower cuttings is believed to favor the development of the fungus. The cost of treatment of cuttings with Bordeaux mixture and tar would be about \$12 per hundred acres where the cuttings are planted at the rate of 1,200 per acre. It is recommended that in exchanging cuttings from one country to another they be treated with the Bordeaux mixture and tar solution prior to shipment. A brief bibliography of the subject concludes the bulletin.

The root disease of sugar cane (*Agr. News [Barbados]*, 1 (1902), No. 1, p. 3).—An account is given of experiments for the prevention of the growth of the fungus *Marasmius* sp. On account of the economic importance of this root disease, experiments were made in which plats of 100 holes each of first-crop cane attacked by the disease were treated by stripping the canes and spraying with Bordeaux mixture, stripping and spraying with Bordeaux mixture and the application of lime, stripping and liming, and untreated. The canes were planted October 17, 1901, and cut and weighed February 27, 1902. The results of the experiment show that none of the

treatments is of any practicable use. Indirect methods must be adopted for the control of this disease, among them rotation of crops and trenching about diseased areas to prevent the further spread. After cutting the cane the stumps should be collected and burned, together with all the trash remaining on the field. In connection with the crop rotation, attention is called to the fact that sweet potatoes are probably affected by the same fungus as that occurring upon the cane.

A foot rot of wheat, A. B. CORDLEY (*Oregon Sta. Rpt. 1902*, pp. 66, 67).—A disease of wheat is described as occurring in a number of regions in Oregon in which every stalk is infested at the base by a fungus, and the plants are seriously injured. The disease is characterized by a blackening of the tissues in the lower part of the stem, and microscopic examination showed the presence of a fungus mycelium which as yet has not been determined. Whether the disease is a new one or not and whether it is liable to become of economic importance are subjects for further investigation.

Inquiry concerning amount of loss from smut of wheat and oats in Illinois, A. D. SHAMEL (*Illinois Sta. Circs. 54, 55*, pp. 3 each, fig. 1 each).—Brief descriptions are given of the smuts of wheat and oats. In order to secure data relative to the prevalence of these diseases and the loss occasioned by them, reports of the percentages of smut are requested in the circulars.

The gummosis of fruit trees, P. PASSY (*Rev. Hort [Paris]*, 74 (1902), No. 11, pp. 269, 270).—A description is given of gummosis, the real cause of which the author says is probably not known. It manifests itself by the accumulation in cavities under the bark of a substance analogous to gum arabic and which results in the breaking down of the cells of the plant, particularly of the medullary rays. Humidity of soil, sudden variations in temperature, the destruction of the foliage, or other factors which bring about marked physiological changes in the plant seem to favor the production of the gummosis. In addition to these physiological causes, the author states that certain fungi, among them *Coryneum beyerinckii*, are able to produce similar conditions in certain of the stone fruits. Marked differences are noted of the susceptibility of different varieties of stone fruits, peaches being exceptionally susceptible, while apricots and cherries continue to live for a long time after being attacked. As preventive measures the author recommends the aeration and proper draining of the soil and subsoil in order to secure a better development of the trees and, where the disease is due to attacks of fungi, spraying with Bordeaux mixture.

Field work with bitter rot during 1901, J. C. BLAIR and A. V. STEUBENRAUCH (*Illinois Sta. Circ. 43*, pp. 27, figs. 2).—An account is given of field work undertaken in cooperation with the Division of Vegetable Physiology and Pathology of this Department. The efficiency of Bordeaux mixture was tested and information sought regarding the value of winter treatments, of early spraying, and the relative value of other fungicides in controlling this disease. The work was conducted by a number of individuals under the immediate direction of the horticulturist, and the results indicate that Bordeaux mixture when properly made and applied will protect apples to a reasonable extent from bitter rot. The winter treatment of dormant trees seems to be of no practical assistance in checking the disease, and early sprayings are no more advantageous than reasonably late sprayings. In the comparative tests of fungicides, Bordeaux mixture was found superior to the ammoniacal copper carbonate solution.

Prevention of bitter rot, T. J. BURRILL and J. C. BLAIR (*Illinois Sta. Circ. 58*, pp. 3).—The object of this circular is to call attention to a recent discovery which seems to give an opportunity for combating the bitter rot of apples. In general it may be said that the distribution of the disease in the tree shows a conical shaped area with the apex upward. The primary infection occurs at the apex of this cone and this infection is said to start from a canker upon the limbs of the tree. These cankers are described, and as preventive measures it is recommended that the trees

should be carefully examined, the infected spots cut out, and the diseased material burned.

Cockscomb fasciation of pineapples, J. W. HARSHBERGER (*Proc. Acad. Nat. Sci. Philadelphia*, 1901, pp. 609-611, fig. 1).—A remarkable case of fasciation of pineapple is described in which several pineapples produced on a single plant were united into a fan-like mass of considerable size. The monstrosity had a pleasant aroma, was succulent, but very fibrous.

A preliminary report on the nature of the banana disease prevalent at Alexandria, LOOSS and G. P. FODDEN (*Jour. Roy. Hort. Soc. [London]*, 26 (1902), No. 4, pp. 844-848).—A description is given of a nematode disease of bananas which has previously been described from another source (*E. S. R.*, 14, p. 264).

How fungi gain entrance to living trees, J. W. HARSHBERGER (*Forest Leaves*, 8 (1901), No. 6, pp. 88-91).—A discussion is given of the means of infection of living trees either by the natural growth of the fungus or through mechanical, meteorological, or chemical injuries, as well as injuries produced by grafting and budding.

Canker of oak trees, M. C. PORTER (*Trans. Eng. Arboricult. Soc.* 1901-1902, p. 105, figs. 4; *abs. in Bot. Centbl.*, 89 (1902), No. 16, p. 463).—Cankered oak trees, *Quercus robur*, are said to be common in the north of England. The canker begins at the insertion of a dead branch, and passes thence to the living wood. The disease is characterized by a brownish discoloration of the medullary rays. Spores sown upon sterile oak blocks developed, producing mycelium, and finally the form by which the affinities of the fungus was determined. It proved to be a new species of *Stereum*, to which the name *S. quercinum* is given.

A bacterial blight of strawberry, A. B. CORDLEY (*Oregon Sta. Rpt.* 1902, pp. 61-64).—During the autumn of 1901 strawberry plants were noted that were apparently suffering from bacterial disease. Many of the leaves were entirely dead, dark brown in color, and leathery in texture. On other leaves the dead areas were observed between the principal veins, and blackened and shrunken spots were also observed on the stems. A careful microscopic examination of the diseased material failed to show the presence of any fungus, but when examined bacteriologically it was found to be infected with a *Micrococcus*. This was isolated and cultivated in a number of media. Plants inoculated with pure cultures when placed under bell jars showed the characteristics of the disease within 48 hours. In 1902 the disease reappeared, and when examined the *Micrococcus* was found again present. The organism apparently is distinctly aerobic, and whether the disease is to be considered a serious enemy to strawberry culture or only a sporadic attack can not be determined at present.

Experiments for the prevention of mildew, L. RAVAZ and A. BONNET (*Prog. Agr. et Vit. (Éd. L'Est)*, 23 (1902), No. 13, pp. 372-379).—A report is given in which the efficiency of copper and cadmium salts, of different copper fungicides, and the action of copper on the growth of a vine were studied. In experiments to compare sulphate of copper and sulphate of cadmium, a simple solution of each salt was tested, as well as a solution containing lime to which was added 0.5, 1, and 2 per cent of the salts. These different solutions were applied to equal plats of grapevines upon 4 occasions, and the efficiency noted at the end of the season. Upon the untreated plats the mildew proved quite destructive, but the different fungicides, with the exception of the simple solution of copper sulphate, proved equally efficient in preventing the attacks of the fungus. In the second series of experiments reported, in which the efficiency and adhesiveness of fungicides were tested, comparisons were made between Bordeaux mixture, Burgundy mixture, Bordeaux mixture containing turpentine, and Bordeaux mixture to which resin was added, a verdigris solution, and a simple solution of copper sulphate. All of these fungicides were sprayed over grapes, 3 applications being given, the first upon May 14. An examination was made of the foliage on October 30 and but little difference was noted in the adhesiveness of the different fungicides, except the simple solution of

copper sulphate. There was some difference noted where 2 applications were given, the most adhesive being the Bordeaux mixture containing resin, but where 3 applications were given the vines the relative efficiency of all was the same. The effect of copper and cadmium upon the growth of plants is discussed at some length, quotations being given from a number of authors regarding the effects of these fungicides. In a limited experiment to test the number of organisms developed on the leaves when treated with copper and cadmium, the average results obtained were the same.

The influence of the gray rot of grapes on the yield and quality of wine, A. MUNTZ (*Ann. Agron.*, 28 (1902), No. 4, pp. 177-208).—The season of 1900, according to the author, was abnormal in many ways. The summer was unusually hot and the grape crop extraordinarily abundant in every grape district of France. The period of ripening of the grapes was considerably delayed by fogs and rain, and at the time of harvesting in some regions the gray rot (*Botrytis cinerea*) was so bad that nearly the whole crop was destroyed. In other regions where the grapes were used in making wine the quality was said to be very inferior. The author studied the effect of this fungus as shown in the wine of a certain region, and gives the results of his investigations, which were quite extensively pursued. The attack of the fungus was found to reduce the amount of grapes gathered, and also lowered the amount of wine produced from a given amount of grapes. There was a marked reduction of the alcohol and tartaric acid, due to the same cause. The color of the wine was likewise affected, the clear vinous color of the wine from sound grapes being changed to a brownish color, and finally to a peculiar yellowish liquid having little resemblance to wine, the degree of the alteration being due to the stage of the disease. The tannin content of wine was greatly reduced by the presence of the fungus, and the actual loss due to this cause is estimated at 30 per cent of the wine production. Among the practical suggestions of the author to be followed upon the recurrence of similar conditions, it is recommended that upon the appearance of disease the grapes should be immediately cut, as delay only tends to increase the loss. Where the disease is present it will be found advantageous to collect only the sound grapes or, where it is possible, to make white rather than red wine. Other suggestions are given for the handling and final disposition of the wine.

Development of black rot, A. PRUNET (*Jour. Agr. Prat.*, n. ser., 3 (1902), No. 21, pp. 674-676).—As a result of 5 years' investigations on the development of the black rot fungus (*Guignardia* or *Levstadia bicknellii*), the author states that the fungus does not winter on the host plant but is carried over in the sclerotia which form in great abundance on the diseased grapes. The sclerotia germinating in the spring have their spores transferred to the green parts of the vine, forming the first or, as the author calls it, the primary attack of the black rot. The attacks which arise from the development of the fungus on the grape leaves are called secondary. The time of appearance of the different invasions has been investigated, and the first seems to occur between April 20 and 25. The secondary attacks occur at different intervals during the growing season. The length of the period of incubation depends largely upon the temperature. In general, it is from 16 to 22 days in April and May, 14 to 16 days in June, and 10 to 14 in July and August. Drought or low temperature retards the formation of the pycnidia and, so far as the author's observations go, fogs are not beneficial to the development of black rot, although favoring that of the mildew. For the black rot, rain appears to be necessary and the period of development depends somewhat on the abundance of the rain and on its continuance.

The fire disease of narcissus, J. RITZEMA BOS (*Tijdschr. Plantenziekten*, 7 (1901), No. 1, pp. 12-24).—A description is given of a disease of narcissus caused by *Heterosporium gracile*, a fungus not hitherto recorded as attacking this host. Differences in susceptibility of varieties are shown, some being not attacked by the disease, while others seem especially subject to it. The disease causes the death of the leaves,

which first become yellow, afterwards shrivel, dry up, and are covered with black masses of conidia. The disease usually causes the destruction of the leaves a month before the usual time, leaving the bulbs in a poorly ripened condition. It is claimed that many growers have found that the disease could be held in check by pulling out the flower stalks some time before the usual date of the appearance of the disease. If the flower stalks are merely cut off, the disease shows itself upon them. Investigations of the author show that the flower stalks are usually the first part attacked, and experiments with Bordeaux mixture showed conclusively that this disease in narcissus could be successfully prevented. An analysis is reported of the relative starch content in the bulbs in sprayed and unsprayed plants, where it was found that the sprayed plants contained 28 per cent more starch than a similar lot which had not been sprayed. Plats of equal size, sprayed and unsprayed, yielded 14 kg. of bulbs for the sprayed and 9 kg. for the unsprayed plats.—H. M. PIETERS.

Bordeaux mixture containing sugar, and bee culture. E. JACKY (*Ztschr. Pflanzenkrankh.*, 11 (1901), No. 4-5, pp. 212-214).—On account of the claim that the use of Bordeaux mixture containing sugar is injurious to bees, the author conducted a series of experiments, using Bordeaux mixture containing different amounts of sugar, both in crystallized form and as molasses, and numerous tests were made with different strengths of solution. Apple and other trees were sprayed with the solutions and careful watch kept to ascertain whether such trees were visited by bees or not. The results obtained were wholly negative, no bees being observed to visit the sprayed plants. The fungicide prepared in a similar manner was placed about the hives but the bees did not touch it, and when exposed on glass plates and dishes, both in liquid form and filter paper soaked in the mixture, similar results were obtained. The author concludes that the use of Bordeaux mixture to which sugar has been added to increase its adhesive property is not injurious to bees, as they seem to shun rather than seek such a mixture.

ENTOMOLOGY.

Department of entomology. A. B. CORDLEY (*Oregon Sta. Rpt. 1902*, pp. 59-61; 64-66).—In 1901 specimens of *Xyleborus dispar* were sent to the station with the statement that the insect was injuring small apple limbs. No further record was obtained until April, 1902. An examination of the orchard in which the insect occurred showed that injury was due only in a slight degree to the bark beetle. The trees were infested with a parasitic mushroom, apparently a species of *Agaricus*, and it is believed that the bark beetle had attacked the trees after they were already infested with the fungus.

Experiments were made in spraying Italian prune trees with fish oil and water in proportions varying from 5 to 25 per cent, and with California crude petroleum and water in the same proportion. After 48 hours it appeared that the leaves which had been sprayed with fish oil were injured where the drops had collected on the under surface. These areas died and fell out of the leaves. No injury was produced on the foliage, however, from the use of crude petroleum, even when applied in a 25 per cent mixture. It appears, therefore, that California crude petroleum may be safely applied to Italian prune trees in the summer.

Report of the entomologist. R. C. SCHEIDT (*Pennsylvania Dept. Agr. Rpt. 1901*, pt. 1, pp. 325-328).—Notes are given on the prevalence, habits, and life history of the emperor moth, peach lecanium, forest tent caterpillar, oyster-shell bark louse, peach-twig borer, and San José scale. The usual remedies are recommended for these insects. In the destruction of the tent caterpillar, spraying with Paris green or kerosene emulsion was found very effective. It is stated that in wet weather large numbers of the tent caterpillars are destroyed by a bacterial disease.

Insects, J. M. SOUTHWICK (*Rhode Island State Bd. Agr. Rpt. 1901, pp. 94-111*).—Brief notes on the life history, habits, and means of combating imported elm-leaf beetle, tussock moth, ermine moth, fall webworm, *Edignone aceris*, brown-tail moth, yellow-necked apple-tree caterpillar, cutworms, ants, and fish moths.

The importance of parasitic insects in agriculture, A. BERLESE (*Bol. R. Scuola Superiore Agr. Portici, 2. ser., 1902, No. 4, pp. 27, figs. 12*).—Descriptive, biological, and economic notes are given on the common species of parasites which infest scale insects, lepidopterous caterpillars, and other insects. A brief account is given of predaceous and parasitic insects, and also on artificial insecticide treatments.

The present status of the Mexican cotton-boll weevil in the United States, W. D. HUNTER (*U. S. Dept. Agr. Yearbook 1901, pp. 369-380, fig. 1*).—This insect was described in 1843, but first acquired importance as an injurious insect in the United States in 1894. Its distribution is at present confined to the State of Texas, where it occupies more than half of the cotton belt of that State. The State of Texas has appropriated considerable funds for making a study of suitable means of combating the weevil, and recently special provision has been made by Congress for this purpose. The insect is not killed by freezing in winter, and while several parasites of an insect and fungus nature are known to attack it, they are of little practical importance. The writer believes that the insect will migrate northward and will soon be outside the boundaries of Texas. The remedies most strongly recommended are cultural methods, the chief of which is early planting, the total destruction of plants in the field as soon as the gathering of the late crop becomes doubtful, and grazing of such green plants by cattle. Some importance should be attached to planting the rows as far apart as the soil will permit. Special machines have been devised for spraying the cotton plant, for jarring the insects or infected squares from the plants, and for picking up fallen squares from the ground.

Spraying tests for codling moth—New Zealand experience (*Jour. Agr. and Ind. South Australia, 5 (1902), No. 2, p. 904*).—Notes are given on the results obtained from spraying experiments by W. A. Boucher. The experiments included the use of Paris green in limewater; the same mixture with the addition of resin wash; a mixture containing white arsenic, washing soda, and limewater; and arsenate of lead. The last insecticide burned the foliage quite severely. Excellent results were obtained from the use of Paris green, 90 per cent of the fruit proving to be sound and uninfested with the codling moth.

Spraying orchards for the codling moth, F. GARCIA (*New Mexico Sta. Bul. 41, pp. 26, pls. 3*).—The codling moth is becoming a serious pest in New Mexico. It was introduced into the Territory about 10 years ago and is now quite abundant in infested localities. Notes are given on the habits and life history of this insect and formulas are presented for preparing the usual arsenical sprays for application in destroying the codling moth. Experiments were made in spraying 5 varieties of winter apples. The trees were sprayed at intervals of 2, 3, and 4 weeks and some of the trees were banded and examined at intervals of 2 weeks, while the other trees were left without bands. The results of the authors' observations and experiments indicate that from 65 to 95 per cent of the apples on unsprayed winter trees are usually destroyed by the codling moth. A considerable number of worms were found under the bands in most cases and this remedy, therefore, appeared to be of some value. As a rule, the more frequent the spraying, the more effective was this treatment. It is believed that spraying in New Mexico will reduce the percentage of wormy apples very materially. Two early sprayings are not considered sufficient. Arsenite of soda is considered more satisfactory than Paris green. Early apples are quite free from worms while the second brood of codling moths is more injurious and destroys a larger percentage of late apples.

The apple-tree tent caterpillar, W. E. BURTON (*Connecticut State Sta. Bul.*

139, pp. 12, pls. 3, figs. 3).—The apple-tree tent caterpillar was unusually abundant in Connecticut in 1902. Its common food supply is the wild cherry, but during the year it was noted on a considerable variety of trees. The author gives a description of the insect in its various stages, and notes on its habits, life history, and natural enemies. It is recommended that egg masses be destroyed in winter. The twigs on which the eggs are fastened may be readily detected and clipped off by means of a tree pruner with a long handle. A special wire brush has been devised for removing the nests from infested trees. Trees should be sprayed about the time the leaves appear, with a solution containing 3 lbs. arsenate of lead or $\frac{1}{2}$ lb. of Paris green to 50 gal. of water. The author does not recommend the burning of the nests on the tree.

Some destructive caterpillars, E. D. SANDERSON (*Delaware Sta. Bul.* 56, pp. 28, figs. 14).—In this bulletin the author presents notes on the appearance, habits, life history, and means of combating fall webworm, white-marked tussock moth, and apple-tree tent caterpillar. The usual methods for controlling these insects are recommended. They include banding the trees, collecting the eggs, burning the nests of caterpillars, and spraying.

Coccidæ of Japan, S. I. KUWANA (*Contrib. Biol. Hopkins Seaside Lab. Leland Stanford Jr. Univ.*, 1902, No. 27; reprinted from *Proc. California Acad. Sci.*, 3. ser., Zool., 3 (1902), No. 2, pp. 39-98, pls. 7).—The author presents an account of the life history, habits, and distribution of a large number of Coccidæ from Japan, and a list of species recorded from Japan but not discussed in detail is also given.

Insecticide experiments for the San José scale (*Illinois Sta. Circ.* 53, pp. 2).—This circular contains a brief abstract of Bulletins 71 and 72 of the station (E. S. R. 14, p. 270).

The rose scale (*Diaspis rosæ*), J. B. SMITH (*New Jersey Stas. Bul.* 159, pp. 14, figs. 6).—This insect has been noted as injurious for a number of years. It causes most damage to the rose, blackberry, and raspberry. The winter may be passed in any stage. Twigs which were examined in December, in 1901, contained all stages except the active adult male. The larvæ are usually hatched by the beginning of March, and by the following November all stages are found on infested twigs. Breeding is apparently almost continuous after the beginning of the season, but there are probably not more than 3 broods per year. Detailed notes are given on the mouth parts of the insect, and on the manner in which it feeds. The insect seldom kills growing blackberry or raspberry canes, but its injuries may be serious on badly infested rose bushes. Infested shoots of blackberries or raspberries should be cut off as soon as the fruit is harvested. If infestation becomes serious during the summer, the plants may be sprayed with a weak solution of whale-oil soap or a 10 per cent mechanical mixture of kerosene or crude oil with water. Nearly all of the scales were killed by an application of 1 lb. whale-oil soap in 1 gal. of water, and no injury was caused to the canes by these applications. Similar methods of treatment, with slight variations, may be adopted in case of infested rose bushes. It is suggested that lime, salt, and sulphur mixture may prove very effective in controlling this insect.

Lime, sulphur, and salt wash for scale insects, C. P. LOUNSBURY (*Agr. Jour. Cape Good Hope*, 20 (1902), No. 13, pp. 768-776).—Brief notes are given on the origin and history of the use of this mixture in various English colonies and in the United States. It is stated that the lime, sulphur, and salt wash was first introduced into Cape Colony by P. J. Cillie in 1893, and has since been used with pronounced success in treating fruit trees and other plants for scale insects as well as fungus diseases. A number of experiments were conducted with this insecticide for the purpose of determining the necessary ingredients and their proper proportions in the preparation of the wash. It was found that the compounds of lime and sulphur are the effective agents in the wash. Spraying experiments with this insecticide indicated that, as noted by other investigators, the action of the wash may be extremely slow. Soon

after its application it may appear that a large number of the scale insects have escaped destruction; they are gradually destroyed, however, during a period of a month or more. The scale insect against which this remedy was chiefly used was *Diaspis pentagona*.

Cyanid gas remedy for scale insects, C. P. LOUNSBURY (*Dept. Agr. Cape Good Hope, Pamphlet 11, 1901, pp. 27, pls. 2, figs. 11*).—In this pamphlet the author discusses the various materials which are required in making tents and transporting them from tree to tree. Notes are also given on the chemicals required for generating the gas, the method of mixing the chemicals, and the most satisfactory vessels to be used in these operations. The treatment of trees with hydrocyanic-acid gas is said to exterminate the red and brown scale by a single application, and in general to be the most effective remedy for the extermination of scales in orchards.

The spraying and cleaning of fruit trees, A. G. CAMPBELL (*Jour. Dept. Agr. Victoria, 1 (1902), No. 3, pp. 290-292*).—Brief notes are given on methods of combating codling moth, woolly aphis, plant lice on peaches, and leaf rust and leaf curl of peaches.

The grass thrips, L. R. CARY (*Maine Sta. Bul. 83, pp. 95-128, pls. 7*).—The life history, extraordinary appearance, and gross and microscopic anatomy of *Anophthrips striata* are described in detail. Notes are given on the habits of the insect. It attacks a number of common grasses, but is most injurious to June grass and timothy. It may be destroyed by spraying with kerosene emulsion or whale-oil soap, but these remedies can not be applied successfully on a large scale. Considerable help may be obtained from burning the ground over in the fall and thorough cultivation under a system of rotation.

Thrips on cocoa (*Bul. Bot. Dept. Jamaica, 9 (1902), No. 5, pp. 70, 71, figs. 2*).—A species of thrips is reported as causing a discoloration of cocoa pods. It was a difficult matter to determine when the discolored pods became ripe, on account of the presence of the discoloration. The pods are attacked when about half grown. Little damage was done to the leaves, except where thrips were very abundant. A spray of kerosene emulsion is recommended for destroying this insect.

Means of combating Tortrix ambiguaella, H. GROSJEAN (*Bul. Soc. Vaudoise Agr. et Vit. [Lausanne], 1902, No. 151, pp. 17-24*).—Notes are given on the various remedies which have been found most successful in combating this insect in its various stages.

Methods of combating Cleonus punctiventris, S. SKRZIHNSKI (*Selsk. Khoz. i Lysov., 204 (1902), Feb., pp. 337-368*).—This beetle is said to be quite widely distributed, and is especially injurious to beets. A number of experiments were made for the purpose of determining the value of fungus diseases in combating the insect. The fungi used for this purpose were *Oospora destructor* and *Sorosporella agrotidis*. These fungi are said to occur spontaneously in fields infested with the beetles, and a certain number of beetles are annually destroyed by them. Experiments reported in this article indicate that satisfactory results may be obtained from distributing the fungi in infested fields so as to destroy the larvæ and pupa of the beetle while in the ground. It is estimated that not less than 1 lb. of the fungus material is required for each acre of ground upon which beets are raised in 5 or 6 year rotations. In some cases 2 or 3 lbs. per acre were required, while on ground where beets had never been raised it is recommended that 9 to 10 lbs. be used.—P. FIREMAN.

Botys sticticalis in the summer of 1901, V. P. POSPELOV (*Izv. Moscow Selsk. Khoz. Inst. [Ann. Inst. Agron. Moscow], 7 (1901), No. 3-4, pp. 313-324*).—This species is found chiefly on the southern Russian steppes. It does not usually attack cultivated plants, but in 1901 was found on cabbage, cucumber, watermelon, canteloupes, and other garden and field crops. The methods recommended for combating it are fall or early spring plowing of infested soil, burning over the ground, and spraying with Paris green and lime.—P. FIREMAN.

A sawfly on turnips, BOUVIER (*Rev. Gén. Agron. [Louvain], 11 (1902), No. 4, pp.*

210-212).—Brief notes are given on the habits and life history of *Athalia spinarum*, a sawfly which is reported as injurious to turnips in various parts of France. The species is usually of rare occurrence in France. A number of parasites of this species are known which help to check its undue multiplication.

Notes on a Phytoptus, A. KEMPEL (*Bol. Agr. São Paulo, 3. ser., 1902, No. 2, pp. 87-90, fig. 1*).—The author gives brief descriptive, biological, and economic notes of a species of mite injurious to fuchsias. The species is described as new under the name *Phytoptus fuchsiv*. The mite is said to be quite susceptible to ordinary remedies which are used for similar pests.

Experimental work with fungus diseases of grasshoppers, L. O. HOWARD (*U. S. Dept. Agr. Yearbook 1901, pp. 459-470, figs. 3*).—Among the fungus diseases which have been used in combating grasshoppers, mention is made of *Empusa grylli*, a South African fungus belonging to the genus *Mucor*, and a species of *Sporotrichum* from Argentina. While persistent efforts have been put forth in various countries and in various States of this country in spreading disease among grasshoppers, it is held by the writer that "the results obtained so far do not justify very sanguine hopes." L. Bruner, who experimented with fungus diseases of grasshoppers in the Western States, believes that the importance of this remedy has been much exaggerated, and that little is to be hoped from the use of fungus diseases. Some apparently good results, however, have been obtained, and notes are given on a number of these cases in the article.

Lantern traps, P. COSTE-FLORET (*Prog. Agr. et Vit. (Éd. L'Est), 23 (1902), No. 28, pp. 38-44, figs. 6*).—Notes are given on the success obtained from the use of various kinds of lantern traps, using different substances for illumination.

Spraying for city and country, A. H. KIRKLAND (*Rhode Island State Bd. Agr. Rpt. 1901, pp. 202-217, pls. 2*).—Brief notes on formulas for the preparation of Paris green, arsenate of lead, kerosene emulsion, and Bordeaux mixture, together with an account of apparatus desirable for ordinary spraying operations and directions as to time and method of spraying apple, pear, stone fruits, small fruits, vegetables, flowers, and shade trees. A special discussion is given on San José scale and gypsy moth.

Directions and formulas for spraying, A. V. STUBENRAUCH and J. W. LLOYD (*Illinois Sta. Circ. 39, pp. 11*).—A discussion is presented on the following subjects: Pure materials for spraying, proper proportion of mixtures, proper method of application, and time of application. Formulas are given for the preparation of the more important insecticides and fungicides.

Spraying calendar, L. R. TAFT (*Michigan Sta. Spec. Bul. 15, folio*).—Suggestions are presented in a tabular form regarding the treatment to be applied to some of the more important economic plants in case of the attack of insect or fungus enemies. Formulas are also given for the preparation of Bordeaux mixture, copper sulphate solution, potassium sulphid, Paris green, white arsenic, hellebore, pyrethrum, kerosene (in emulsion or mechanical mixture with water), and whale-oil soap.

The white ant (Termes flavipes), C. L. MARLATT (*U. S. Dept. Agr., Division of Entomology Circ. 50, 2. ser., pp. 8, figs. 4*).—A revised reprint from Division of Entomology Bulletin 4, new series (E. S. R., 9, pp. 62-66).

Cockroaches, C. L. MARLATT (*U. S. Dept. Agr. Division of Entomology Circ. 51, 2. ser., pp. 15, figs. 5*).—A revised reprint from Division of Entomology Bulletin 4, new series (E. S. R., 9, pp. 62-66).

The bedbug (Cimex lectularius), C. L. MARLATT (*U. S. Dept. Agr., Division of Entomology Circ. 47, 2. ser., pp. 8, figs. 3*).—A revised reprint from Division of Entomology Bulletin 4, new series (E. S. R., 9, pp. 62-66).

The house centipede (Scutigera forceps), C. L. MARLATT (*U. S. Dept. Agr., Division of Entomology Circ. 48, 2. ser., pp. 4, figs. 2*).—A reprint from an earlier publication (E. S. R., 9, p. 63).

The silver fish (Lepisma saccharina), C. L. MARLATT (*U. S. Dept. Agr., Divi-*

sion of *Entomology Circ.* 49, 2. ser., pp. 4, figs. 2).—A revised reprint from Division of Entomology Bulletin 4, new series (E. S. R., 9, pp. 62–66).

Hydrocyanic-acid gas against household insects, L. O. HOWARD (*U. S. Dept. Agr., Division of Entomology Circ.* 46, 2. ser., pp. 4).—The author reviews the recent literature on the various uses to which this remedy has been applied. Hydrocyanic-acid gas has been used successfully in destroying insects in houses, granaries, greenhouses, and stores, as well as on living trees and other plants. Attention is called to the great danger from inhaling the fumes of the gas.

Some mosquitoes of Mississippi, and how to deal with them, G. W. HERRICK (*Mississippi Sta. Bul.* 74, pp. 31, figs. 15).—The author gives a popular account of the relation of mosquitoes to malaria and yellow fever. The most common species in the State is *Culex pipiens*. Detailed notes are given on the life history and habits of this species. Two species of malarial mosquitoes are reported from Mississippi, viz: *Anopheles punctipennis* and *A. maculipennis*. Notes are given on the breeding habits and life history of the first-named species. The duration of the immature stages of this mosquito, under normal conditions, in Mississippi was found to be 16 to 18 days, of which the egg stage occupied 2, the larval stage 12, and the pupal stage 2 days. The yellow fever mosquito (*Stegomyia fasciata*) is commonly known as the "day mosquito" in Mississippi, and is reported as being common throughout the State. A number of other species are reported, including *Culex punyensis*, *C. tarsalis*, *C. confinis*, *C. consobrinus*, *Psorophora ciliata*, and *Conchlytiastes musicus*. Notes are given on the various breeding places of mosquitoes and on the number that may be produced from small vessels containing water. As remedies for mosquito plagues the author recommends drainage, stocking water with fish, and the use of kerosene oil. In small open drains with a moderately rapid current it was found that pouring oil on the water was not successful, since the oil did not reach the sides of the ditch. Better results were obtained by spraying oil upon the water, and it was found that by this method many adult mosquitoes, which were resting on the grass and weeds were destroyed. It is recommended that an application of oil be made at least twice per month in order to be effective in destroying the mosquitoes. An observation is reported from which it appears that flooding drains can not be depended upon to carry away the mosquito larvae.

The mosquito plague in the City of Mexico in 1901, A. L. HERRERA (*Mem. y Rev. Soc. Cient. "Antonio Alzante,"* 16 (1901), No. 5–6, pp. 207–228).—The author gives a general account of the mosquito plague of 1901, with notes on the methods which were adopted for destroying the mosquitoes, and the cost of such work. Special attention was given to locating the breeding places of the mosquitoes and destroying them in such locations by drainage or the application of kerosene. The species chiefly concerned was *Culex punyensis*. It is believed that all of the mosquitoes in the City of Mexico could be destroyed by draining away stagnant water in the vicinity of the city, and using kerosene upon the small pools.

Some parasites of mosquitoes, A. LAVERAN (*Compt. Rend. Soc. Biol. Paris*, 54 (1902), No. 8, pp. 233–235).—The author reports the finding of a number of parasites in mosquitoes, including *Tyroglyphus siro*, *Chyrtetus eruditus*, and a number of undetermined species of mites, as well as micro-organisms of a bacterial nature.

The sting of certain Hemiptera, R. BLANCHARD (*Arch. Parasit.*, 5 (1902), No. 1, pp. 139–148).—Notes are given on the appearance, habits and life history of a number of Hemiptera which may cause more or less serious consequences by puncturing the skin of man and domesticated animals. The species to which most attention is given are *Ilyctocoris campestris*, *Reduvius personatus*, and *Onomorphinus sanguisuga*.

Fowl tick, A. A. BROWN (*Jour. Agr. Victoria*, 1 (1902), No. 1, pp. 86–90, figs. 7).—Notes are given on the appearance, habits and life history of *Argas americanus*. In combating these pests the author found that kerosene alone was not an effective remedy but that better results were obtained by the use of kerosene and soap emulsion. An effective dip was found in a solution of 40 per cent formalin in the propor-

tion of 1 part to 250 parts of water. It is recommended that on badly infested premises, old wooden henhouses be pulled down and corrugated iron buildings be erected in their place.

Bee culture, C. C. MILLER (*Pennsylvania Dept. Agr. Rpt. 1901*, pt. 1, pp. 334-427, figs. 14).—This article constitutes a general treatise of a practical nature covering all of the subjects ordinarily included under apiculture. Among the various subjects treated in the article, mention may be made of fertilization of flowers by bees, locations for colonies, kinds of honey, honeycomb, hives, different varieties of bees, apparatus for use in managing bees, artificial feeding, comb foundation, clipping queens, extracting honey, prevention of swarming, rearing of queens, division of swarms, enemies and diseases of bees, care in winter, and a brief discussion of the more important literature relating to bees.

Practical bee keeping, A. E. MANUM (*Rhode Island State Bd. Agr. Rpt. 1901*, pp. 213-231).—Brief notes are given on the selection of hives and frames, as well as on the spring management, preparation for summer harvest, spring dwindling, stimulative feeding, and notes on wintering and putting on section boxes.

Long-tongued bees, A. GALE (*Agr. Gaz. New South Wales*, 13 (1902), No. 2, pp. 233-235).—The author presents a brief digest of the literature on the subject of breeding bees so as to secure an elongation of the tongue. This subject is considered of some importance for New South Wales on account of the fact that heretofore it has been found impossible to introduce bumblebees for the purpose of fertilizing red clover. The possibility of securing a honeybee with a tongue of sufficient length to obtain honey from these flowers is worth considering for the reason that such honeybees would be induced to visit the red clover and thus fertilize it.

The embryology of the silkworm, K. TOYAMA (*Bul. Col. Agr. Imp. Univ. Tokyo*, 5 (1902), No. 1, pp. 73-118, pls. 5, fig. 1).—The author discusses the literature relating to the early developmental stages of the silkworm, in connection with an extensive bibliography. The discussion is confined largely to a description of the early stages of development, with special regard to indicating the origin of the various embryonic organs of silkworms.

Healthy and diseased silkworms, S. EGIDIO (*Staz. Sper. Agr. Ital.*, 35 (1902), No. 1, pp. 35-45).—The author made a careful analysis of the excrement and contents of the alimentary tract of healthy and diseased silkworms, in order to determine whether the presence of uric acid or urea should be considered as indicating a diseased condition. It was found that in the excrement of healthy silkworms no uric acid, hippuric acid, or urea was to be found.

FOODS—NUTRITION.

Cereal breakfast foods, L. H. MERRILL and E. R. MANSFIELD (*Maine Sta. Bul.* 84, pp. 129-152).—Continuing the investigations reported in an earlier bulletin (E. S. R., 12, p. 69), the authors studied the composition and nutritive value in proportion to the cost of a number of cereal breakfast foods. In the case of malted cereal goods and some others the methods of manufacture are briefly discussed. The average percentage composition of the corn, oat, and wheat breakfast foods, which constitute the larger proportion of the foods examined, follows:

Average composition of corn, oat, and wheat breakfast foods.

	Water.	Protein.	Fat.	Crude fiber.	Nitrogen-free extract.	Ash.	Heat of combustion per pound.	Average price per pound.
	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Calories.</i>	<i>Cents.</i>
Corn foods	10.2	8.7	0.6	0.3	79.9	0.3	1,750	5.7
Oat foods	8.4	16.0	7.2	.9	65.6	1.9	1,950	6.0
Wheat foods	9.0	12.4	1.9	1.3	73.9	1.5	1,800	10.6

^a Omitting 4 extreme cases.

According to the authors "All the cereal foods examined were good articles and the average prices as a rule are not exorbitant. On the contrary, when compared with the meats and vegetables, the most of them must be classed as very economical foods. The prices are exceedingly variable and, so far as ordinary chemical analysis shows, furnish no measure of the value of the goods. On the other hand, while their comparative digestibility has not yet been well worked out, there can be no doubt that the attempts to increase the digestibility of some of these goods by special treatment has been successful and persons of weak digestion would find it to their advantage to base their selection upon other data than that here given. Fortunately the invalids are still in the minority, and the average consumer, who will experience difficulty with any of these foods, is not justified in paying 20 cts. per pound for a cereal preparation when another, that will serve his purpose exactly as well, can be had at 5 or 6 cts."

The relative cost of home cooked and purchased food (*Massachusetts Labor Bul.*, 1901, No. 19, pp. 67-98).—The committee on domestic service of the Boston branch of the Association of Collegiate Alumnae studied the possibility of providing an acceptable diet from foods cooked out of the house, and the comparative cost of the same foods if cooked at home. Two tests were made, one of 3 and one of 6 days, as well as a study of the time required and the comparative cost of preparing food when coal, gas, and oil were used as sources of heat. The latter study also covered 6 days. It was found: "(1) That a well-varied menu of good quality could be provided for a large family from food prepared outside the house; (2) that the expense was greater when the food was bought outside; and (3) that there was a great saving in time and labor by the purchase of food outside." In the first test the average cost per person per meal, including fuel and labor, when the food was cooked outside the house was 25.569 cts.; when the same food was prepared at home the average cost was 16.485 cts. In the second test the corresponding values were 19.533 cts. and 15 cts. "The saving in time by the purchase of the food ready cooked was very great. In the first experiment $4\frac{1}{2}$ hours were required to prepare the cooked food for the table. It took $32\frac{1}{2}$ hours to cook the same food in the house. In the second experiment the difference was also very marked. The time needed for preparing the food cooked outside was 11 hours, while it took $41\frac{1}{2}$ hours for the home-cooked articles." The fact was recognized that it would only be possible to provide a satisfactory menu with ready-cooked foods in large towns offering the necessary market facilities.

The nutritive value of hens' eggs, G. LEBBIN (*Therap. Monatsh.*, 15 (1902), pp. 552, 553; *abs. in Ztschr. Untersuch. Nahr. u. Genussm.*, 5 (1902), No. 14, p. 664).—A digestion experiment is reported, in which a healthy man consumed 22 eggs in 2 days. Especial interest attaches to the fact that the lecithin and neutral fat were determined. The coefficients of digestibility obtained follow: Dry matter 95.01, protein 97.59, total ether extract 95.77, lecithin 91.03, neutral fat 98.00, and ash 70.38 per cent.

The composition and nutritive value of biltong, W. D. HALLIBURTON (*British Med. Jour.*, 1902, No. 2154, pp. 880-882).—The author reports an analysis and artificial digestion experiments. Biltong, which is the sun-dried flesh of the springbok, is prepared in considerable amounts in South Africa and will keep in good condition for a long time. When used as food the hard strips are usually scraped or grated. According to the author this material has the following percentage composition: Water 19.4, protein 65.9, fat 5.1, glycogen 0.1, sugar 0.1, extractives (by difference) 2.8, and ash 6.6. As shown by the artificial digestion experiments, biltong was somewhat less soluble than dried fibrin, or dried rabbit muscle. It was, however, according to the author, quite thoroughly digested.

Effect of preserving meat by covering it with different salts, P. KUSCHEL (*Arch. Hyg.*, 43 (1902), No. 2, pp. 134-150).—Experimental data are reported.

The estimation of the fat content of wheat bread, and the possibility of determining whether bread is made with milk or water, or whether it con-

tains added fat, J. C. BERTROP (*Ztschr. Angew. Chem.*, 15 (1902), No. 6, pp. 121-125, figs. 2).—The author notes that according to earlier investigators, all the fat present in materials from which bread is made is not recovered in the baked products. He reports a method of estimating fat, which it is claimed gives more satisfactory results than the usual method, and shows that all the fat may be recovered. The method advocated is as follows: 150 gm. fresh bread (or more if desired) with 500 cc. water and 100 cc. strong hydrochloric acid is placed in a suitable flask connected with an inverted condenser and heated over a free flame for 2 hours. After cooling, the brown liquid which contains the undissolved cellulose and fat is filtered, the residue washed with cold water until an acid reaction is no longer observed, dried for an hour at 100 to 110° C, and ground in a mortar with a little ignited sand. The pulverized material and the filter paper from which it was removed are together extracted with petroleum ether, ether or carbon tetra-chlorid in an extraction apparatus of special construction, which is described. In a test reported, the flour and milk from which bread was made together contained 4.93 gm. fat. The author obtained from dough 4.95 gm. and from bread baked from the same quantities 4.92 gm. fat. A sample of bread made from flour and water contained theoretically 1.64 per cent fat. The author found 1.60 per cent fat in the bread, the results being in both cases calculated on the dry matter basis. Other tests are reported. According to the author, the determination of the Reichert-Meissl number of the bread fat furnishes a means of determining whether the bread was made from water, whole milk, or skim milk, and also whether it contained added fat other than milk fat.

Commercial wheat and maize starch, O. SAARE (*Ztschr. Spiritusind.*, 24 (1901), pp. 502, 512, 513; *abs. in Ztschr. Untersuch. Nahr. u. Genussmtl.*, 5 (1902), No. 8, p. 364-366).—The chemical composition of a number of samples of wheat and maize starch is reported.

The composition of hard wheats and the constitution of hard-wheat gluten, E. FLEURENT (*Compt. Rend. Acad. Sci. Paris*, 133 (1901), pp. 944-947; *abs. in Chem. Centbl.*, 1902, I, No. 3, p. 214).—Samples of hard wheat from Russia, Africa, and Canada were examined.

Banana meal, H. H. COUSINS (*Jour. Jamaica Agr. Soc.*, 6 (1902), No. 7, p. 268).—An analysis of banana meal, or flour, is reported.

Banana flour (*Rev. Hort. [Paris]*, 74 (1902), No. 15, p. 353).—An analysis of banana flour is quoted and its nutritive value briefly discussed.

Cassava, E. LEUSCHER (*Ztschr. Oeffentl. Chem.*, 8 (1902), pp. 10-11; *Chem. Centbl.*, 1902, I, No. 8, p. 493; *abs. in Jour. Soc. Chem. Ind.*, 21 (1902), No. 7, p. 492).—Cassava flour and other cassava products are described and discussed.

Composition and nutritive value of certain Colonial vegetables, A. DE VILLELE (*Rev. Agr. Réunion*, 8 (1902), No. 1, pp. 16-23).—The composition of a number of vegetable products is reported, including black night shade (*Solanum nigrum*) chayote (*Sechium edule*), taro (*Colocasia esculenta*), squash (*Cucurbita pepo*), sea blight (*Amaranthus blitum*), Chinese mustard (*Sinapis sinensis*), moringa (*Moringa pterygosperma*), and 2 species of cabbage palm (*Areca crinica* and *A. alba*).

Some unusual food plants, JULIA D. CHANDLER (*Amer. Kitchen Mag.*, 17 (1902), Nos. 2, pp. 59-62; 3, pp. 99-102).—Many unusual foods of vegetable origin are described and discussed.

On Hamana-natto, a kind of vegetable cheese, S. SAWA (*Bul. Col. Agr. Imp. Univ. Tokyo*, 4 (1902), pp. 419, 420).—The composition of Hamana-natto, a sort of vegetable cheese made from soy beans, is reported, as well as data obtained in a bacteriological examination of the product.

Concerning the Japanese nori, K. OSHIMA and B. TOLLENS (*Ber. Deut. Chem. Gesell.*, 34 (1901), pp. 1422-1424; *abs. in Ztschr. Untersuch. Nahr. u. Genussmtl.*, 5 (1902), No. 8, p. 369).—A chemical examination of nori (*Porphyra laciniata*), one of the marine algae used as food in Japan, is reported.

The composition of food from horse chestnuts (*Æsculus hippocastanum*), E. LAVES (*Pharm. Centralhalle*, 42 (1901), pp. 333-336; *abs. in Ztschr. Untersuch. Nahr. u. Genussmitt.*, 5 (1902), No. 8, p. 369).—The composition is reported of horse chestnuts after extraction with alcohol.

Chemistry of confectioners' materials and processes, W. JAGO (*Jour. Soc. Arts*, 50 (1901), No. 2562, pp. 93-101; 50 (1902), Nos. 2563, pp. 106-115; 2564, pp. 118-128; 2565, pp. 134-142).—In these lectures, which were delivered before the Society of Arts, the chemistry of the materials employed by confectioners is discussed, as well as the chemistry of the changes such materials undergo in cooking and related topics.

Sugar in the diet of man, L. GRANDEAU (*Rev. Gén. Agron. [Louvain]*, 11 (1902), No. 6, pp. 316-322).—In an article quoted from *Bul. Assoc. Chim. Sucr. et Distill.* the value of sugar as a source of energy is discussed.

Diet in relation to age and activity, Sir HENRY THOMPSON (*London and New York: Frederick Warne & Co.*, 1902, pp. 134, pl. 1).—The first part of this volume is a reprint of the author's earlier work on the subject; the second part contains a detailed discussion of the diet suited to persons of advanced age. The author believes that in a large measure each person must learn by careful observation the diet which is suited to his individual needs, but in all cases recommends extreme moderation. He believes that simple foods are most desirable for the aged and that animal food should be eaten in great moderation, fish, poultry, and game being preferable to meats.

Dietaries in public institutions, W. O. ATWATER (*U. S. Dept. Agr. Yearbook 1901*, pp. 393-408).—The general problem of feeding large groups of persons under more or less uniform conditions is discussed and results of the author's dietary investigations in the New York State hospitals for the insane are quoted.

The physiology of nutrition, H. P. ARMSBY (*Agr. Education*, 4 (1901), No. 2, pp. 33-35).—A general discussion.

Food and energy, H. P. ARMSBY (*Pennsylvania State Dept. Agr. Rpt. 1901*, pt. 1, pp. 670-679).—A discussion of nutrition from the standpoint of thermodynamics.

Theory and practice of infant feeding, with notes on development, H. D. CHAPIN (*New York: William Wood & Co.*, 1902, pp. XII + 326, figs. 97).—The food requirements of infants are discussed, as well as the characteristics of milk and other feeding stuffs suited to infants, methods of feeding, and related topics. The author states that special attention is devoted to the discussion of milk in relation to its influence on the development of the digestive tract of the young animal. In discussions of milk American authorities have been cited, as the author designs his work especially for American readers. It is worthy of note that the author has made extended use of the investigations and publications of the U. S. Department of Agriculture and the agricultural experiment stations.

The feeding of infants, J. E. WINTERS (*New York: E. P. Dutton & Co.*, 1901, pp. VIII + 47).—The food requirements of infants is discussed and directions given for modifying milk at home.

Concerning temperature regulation in newborn infants, E. BARÁK (*Arch. Physiol. [Pflüger]*, 89 (1902), No. 3-4, pp. 154-177).—Experiments are reported in which calorimetric measurements and determinations of the respiratory quotient were made. A bibliography is included.

Second annual report of the State Food Commissioner of Illinois (*Illinois State Food Com. Rpt. 1901*, pp. 258, figs. 8).—In addition to the usual legal and statistical matter, the author reports analyses of a number of samples of cocoa and cocoa products, milk, honey, sirup, jams, jellies, vinegar, etc.

Sixteenth annual report of the Ohio Dairy and Food Commissioner (*Ohio State Dairy and Food Com. Rpt. 1901*, pp. 129).—This volume contains the usual legal and statistical matter.

ANIMAL PRODUCTION.

Concentrated feeding stuffs, L. A. VOORHEES and J. P. STREET (*New Jersey Stat. Bul.* 160, pp. 79, figs. 3).—In accordance with the provisions of the State Feeding Stuffs Law, a large number of samples of feeding stuffs were analyzed, including cotton-seed meal, linseed meal, cocoanut cake, germ-oil meal, gluten meal, gluten feeds, hominy meal, and similar corn breakfast food by-products, corn bran (or sugar feed), malt sprouts, dried brewers' grains, dried distillers' grains, mixed feeds (including cereal breakfast food by-products), rice meal, calf meal, ground meat, poultry feeds, wheat bran (from winter, spring, and unclassified wheat), wheat feed, wheat middlings, brown middlings, feeding flour, buckwheat bran, buckwheat feed, rye bran, rye middlings, rye feed, barley feed, corn meal, cob meal, ground corn and oats, and other mixed ground grains, flaxseed meal, wheat bran and oil, sugar-beet pulp, and nutrium milk powder.

"Of the 287 samples which were guaranteed and of which an examination was made, 76 failed in their promises, 60 of these being deficient in protein. Among the 249 samples of feeds not required to be guaranteed, 14 were found to be contaminated or adulterated with foreign matter, principally offal of milling.

"There are on the feed market a considerable number of very inferior feeds, which consist of oat hulls, rice hulls, coffee hulls, etc., which can not form a profitable purchase at any price. In buying feeds to supplement his home-grown supply, the dairyman's aim should be to secure digestible and palatable protein on the most reasonable terms and in the most economical forms. Fully half of the different and distinct brands of feeds [analyzed] do not meet his requirements in this respect."

Descriptions are given of rice hulls and coffee hulls, which the authors state are new adulterants in the feeding stuffs sold in New Jersey.

The losses in the fat of corn meal due to the action of molds were studied. On the basis of a large number of analyses the fat in normal corn meal was found to average in amount 47 per cent as much as the protein. Samples which showed under the microscope the presence of *Penicillium glaucum* had lost from 4.2 to 67.7 per cent of the fat which should have been present if the meals were originally of normal quality. To determine whether the growth of mold was the real cause of the diminished fat content, samples of normal corn meal of known composition were inoculated with *P. glaucum* and the mold allowed to grow for 9 days at an average of 71° F. under different conditions as regards moisture. The percentage loss of fat was found to range from 1.85 to 12.24, the smallest loss being found in the sample in which there was 10.73 per cent of water present and the greatest in the sample having the largest amount of water, viz, 36.24 per cent. In other words, the percentage loss of fat increases with the amount of moisture present. Other tests are very briefly reported, which bear out this opinion.

The composition of the commercial feeding stuffs sold in Connecticut, E. H. JENKINS ET AL (*Connecticut State Sta. Rpt.* 1901, pt. 4, pp. 343-349).—During the year 1901 a number of feeding stuffs were analyzed, in accordance with the provisions of the State law. These included cotton-seed meal, linseed meal (old and new process), bran, middlings, mixed wheat feeds, corn meal, gluten meal, gluten feeds, hominy feeds, rye feed, malt sprouts, buckwheat shucks, buckwheat middlings, commercial and proprietary feeds (including cereal breakfast food by-products), animal meal, beef scrap (and similar poultry feeds), and several condimental and medicinal feeds. A table showing the weight per quart of a number of commercial feeds is also given.

Analysis of feed stuffs sold in Maryland, H. B. McDONNELL (*Maryland Agr. Col. Quart.*, 1902, No. 16, pp. 7).—Analyses are reported of samples of cotton-seed meal, linseed meal, gluten meal and feed, germ-oil meal, malt sprouts, dried brewer's

grains, wheat middlings, wheat bran, ground oats, corn meal, meat-and-bone meal, and meat scrap.

Modern cattle foods and cattle-food controls, W. FREAR (*Pennsylvania State Dept. Agr. Rpt. 1901, pt. 1, pp. 682-689*).—The benefits of regulating the sale of feeding stuffs are discussed, as well as some of the laws on the subject which have been enacted in this country and Europe.

Forage from Russian thistles (*Kansas State Bd. Agr. Quar. Rpt. 1902, June, pp. 5-23*).—Feeding Russian thistles, green and cured, methods of curing and related topics are discussed on the basis of information received in answer to inquiries made by the State board of agriculture. The general conclusion is drawn that while Russian thistles, both fresh and cured, constitute a fairly satisfactory feed, their growth should not be encouraged, since they are in other respects troublesome weeds.

Nutritive value of the Russian thistle, E. H. S. BAILEY and C. F. GUSTAFSON (*Kansas State Bd. Agr. Quar. Rpt. 1902, June, pp. 24-27*).—Analyses are reported of green and cured Russian thistles, the data serving as a basis for a discussion of the nutritive value of this plant.

Cattle food from sugar cane in the West Indies, G. SAWTER (*U. S. Consular Rpts., 69 (1902), No. 263, p. 562*).—A brief note on a cattle feed called "molaseuit," made from molasses and bagasse.

Corn as a stock food, H. J. WATERS (*Missouri State Bd. Agr. Rpt. 1902, pp. 142-181, pls. 3, fig. 1*).—The feeding value of corn and corn products is discussed, the results of numerous investigations carried on at the experiment stations in different States being cited.

Fenugreek a stock food (*Farm Students' Rev., 7 (1902), No. 2, p. 21*).—The feeding value of fenugreek, which is an ingredient of many condimental feeds, is briefly discussed.

Intensive feeding of farm animals with fenugreek seed, SCHLAGDENHAUFEN and REEB (*Bul. Agr. Algérie et Tunisie, 8 (1902), No. 9, pp. 225-227*).—Abstracted from another publication (see below).

Fenugreek, its influence on general nutrition, E. REEB (*Monatsber. Gesell. Förd. Wiss. Ackerb. u. Künste, Unter-Elsass, 36 (1902), No. 2, pp. 62-64*).—The author notes the favorable effects which follow the feeding of fenugreek and attributes them to the lecithin found in the oil. The percentage of this constituent is rather high, being, according to the author, 1.51 per cent.

Concerning the depression digestibility of fodder when an excessive amount of carbohydrates is fed, E. A. BOGDANOV (*Izv. Moscov. Selsk. Khoz. Inst. [Ann. Inst. Agron. Moscow], 7 (1902), No. 3-4, pp. 139-156*).—From an extended review of the literature the author concludes that the lowering of the coefficient of digestibility observed when carbohydrates are added to a ration is sometimes real and sometimes apparent; being due in the one case to increased undigested residue, and in the other to increased metabolic products in the feces.—P. FIREMAN.

Comparison of silage and shock corn for wintering calves intended for beef production, H. W. MUMFORD (*Illinois Sta. Bul. 73, pp. 269-282, figs. 4*).—With 2 lots, each containing 25 grade steers 8 months old, the relative merits of corn silage and shock corn were tested, these materials being fed ad libitum in addition to an average daily ration of 2 lbs. of oats and 4.55 lbs. mixed hay in the case of corn silage, and 2 lbs. of oats and 4 lbs. of mixed hay in the case of the shock corn. The average amount of corn silage eaten per head daily was 26 lbs., the average amount of shock corn 13.22 lbs. It was the author's purpose to feed the calves a maintenance ration during the winter of such a character that they would be in satisfactory condition for subsequent fattening. During the 88 days of the test the average daily gain per head of the lot on silage was 1.68 and on shock corn 1.42 lbs., the dry matter required per pound of gain being 6.52 and 8.57 lbs. respectively.

Ten pigs followed the steers fed shock corn for 70 days, gaining on an average 6.8

lbs. per day; the number was then increased to 15 pigs, until the close of the test. The average daily gain of the lot was now found to be only 4.9 lbs., showing that the number of pigs was too large. At first 10 pigs followed the steers fed corn silage. They did not make satisfactory gains except when corn was fed in addition to the feed which they gathered. The number was finally diminished until only 1 was left. The author believes that without additional feeding 1 or possibly 2 pigs might have secured feed enough to make good gains, and calculates that during the test the total gains made by the pigs following the lot fed silage was 87 lbs.

The author's principal conclusions were as follows:

In the feeding of 5.33 acres of silage to calves 8.69 acres of crops other than corn were used. In the feeding of 5.33 acres of shock corn to calves 5.68 acres of crops other than corn were used. This difference may or may not be found unavoidable. It requires a third longer time to feed an acre of corn silage than an acre of shock corn.

So far as the cost of harvesting and feeding crops for the production of beef is concerned, in the net profits of the enterprise, it should be borne in mind that it will probably require nearly twice as great an expenditure of labor and capital in a system of silage feeding as in a system of shock corn feeding. The silage-fed steers were in much better thrift and flesh at the end of the experiment than were the shock-corn-fed steers. In case of the silage-fed steers 97.69 per cent of the meat produced was beef and 2.31 per cent pork. In case of the shock-corn-fed steers 84.22 per cent of the meat produced was beef and 15.78 per cent was pork. This clearly shows that pork production is an important factor in a system of feeding shock corn for beef production, while it may be entirely eliminated from a system of silage feeding for beef production practically without loss.

"Under conditions comparable with those prevailing in this experiment one steer would be able to make an average daily gain of 1.68 lbs., for a period of 6 months on . . . 0.31 of an acre . . . devoted to corn for silage, 0.23 of an acre to oats, and 0.28 of an acre to hay. One steer receiving shock corn, oats, and hay would be able to make an average daily gain of 1.42 lbs. for a period of 6 months on . . . 0.45 of an acre devoted to growing the corn, 0.23 of an acre to oats, and 0.24 of an acre to hay, making a difference of 0.26 of a pound of meat per day per steer and 0.1 acre of land for the season, both being in favor of the steers receiving their corn in the form of silage for the period designated."

Factors in beef production, F. B. MUMFORD (*Missouri Sta. Circ. of Information* 12, pp. 22, figs. 5).—A general discussion reprinted from the Missouri State Board of Agriculture Bulletin, 1902, April.

Characteristics of the prime steer, H. W. MUMFORD (*Illinois Sta. Circ.* 38, pp. 3).—Under the headings of form and quality the author discusses the characteristics of first-class beef steers.

The characteristics of stockers and feeders, H. W. MUMFORD (*Illinois Sta. Circ.* 48, pp. 4).—The author enumerates the points which characterize steers designed for feeding for beef of prime quality.

A scale of points as a means of judging cattle, and the standard of the race found in Limoneuse, A. LONAY (*Bul. Cercle d'Études Agron. [Brussels]*, 1902, No. 4, pp. 105-125).—The author discusses judging cattle with special reference to local conditions.

Sheep feeding on the range; lamb feeding—second trial, F. E. EMERY (*Wyoming Sta. Bul.* 51, pp. 19-40, pls. 2, figs. 6).—In studying the possibility of profitably fattening cull sheep on the range in preference to selling them at a low price, a test is reported which included at the beginning 2,843 ewes having broken teeth or spoiled udders, averaging at least 7 years, and 500 wethers 2 years old culled from a flock of over 9,000. It is stated that these sheep would not have sold for over \$1, or at most \$1.25 per head. All the sheep were fed for 80 days on an average of 1.01 lbs.

corn and 0.2 lb. oats per head daily. A few were sold to local butchers, but the greater number were sold in eastern markets, the total sum received being equivalent to \$1.49 per head. This test, according to the author, indicates that it is more profitable to fatten such sheep than to sell them for a low price.

Continuing earlier work (E. S. R., 13, p. 582), the author tested the comparative merits of native hay and alfalfa hay in addition to corn, with 2 lots each containing 50 lambs. At the beginning of the trial the average weight of the lambs fed native hay was 46.2 lbs., and of those fed alfalfa hay, 45.3 lbs. The test covered 70 days. During that period the average daily gain per head was 0.221 lb. for the lot on native hay, and 0.343 for the lot on alfalfa hay. Following this period all the lambs were fed alfalfa hay with corn, and were sold for slaughtering in lots of 25, the last lot being sold some 5 months after the beginning of the trial. The average daily gain per head was 0.186 lb. The total cost of feeding the lambs was estimated at \$4.23 per head; they were sold for 5.21 cts. per pound. The author states in effect that up to the conclusion of the comparative feeding of alfalfa and native hay there was a profit, the high price for feed being balanced by the high price the lambs were then worth. But at the end of the test, although the lambs continued to make good substantial gains, there was a heavy loss, aggregating nearly three times the profit up to the end of the comparative period.

Breeding experiments with sheep, F. B. MUMFORD (*Missouri Sta. Bul.* 53, pp. 167-188, figs. 7).—Cross-bred ewes were bred to registered Hampshire, Shropshire, and Delaine Merino rams, and records kept of the weight of the lambs, etc. The principal conclusions follow: The birth weight of lambs is largely or entirely controlled by the mother, those weighing most at birth being from the heaviest ewes. Apparently the birth weight of the lambs and the weight of the ewes are closely related and vary together. Neither the breed nor the size of the rams used were determining factors in fixing the birth weight of the lambs, which was found on an average to be 7.7 lbs. At birth the male lambs were 16 per cent heavier than the female lambs, the former averaging 8.10 lbs. and the latter 6.98 lbs. The average birth weight of twin lambs was only 0.5 lb. below the general average. For an average period of 7 weeks after birth the male lambs gained 4.01 lbs. per week and the female lambs 3.97 lbs. Lambs having the heaviest weight at birth made the largest weekly gains during the 7 weeks covered by the author's observations. Those weighing 10 lbs. and over at birth gained on an average 4.5 lbs.; those weighing below 7 lbs. at birth, 1.7 lbs. The average milk yield of ewes is recorded as well as their feed requirements. Lambs fed cows' milk from a bottle in 11 weeks gained on an average 3.09 lbs. per week; those fed ewes' milk from a bottle, 4.11 lbs.; and those nursing their dams, 3.7 lbs. According to the author the lambs receiving ewes' milk developed a fleece with a more abundant yolk and of a more uniform color than the lambs fed cows' milk, while the oiliness of the fleece of the lambs fed ewes' milk was also thought to increase more rapidly.

Mohair and mohair manufactures, G. F. THOMPSON (*U. S. Dept. Agr. Yearbook* 1901, pp. 271-284, pls. 2, fig. 1).—Suggestions for improving Angora goats as mohair producers are given, as well as descriptions of some of the manufactured mohair fabrics. The use of the skin for rugs, etc., is also noted.

Horse feeding, L. A. MERRILL (*Utah Sta. Bul.* 77, pp. 129-164, figs. 9).—In addition to reviewing briefly the previous work on horse feeding at the station (E. S. R., 6, p. 751), a number of experiments are reported on the value of alfalfa hay for horses, as compared with timothy hay, when fed with grain and when fed alone. The alleged diuretic properties of alfalfa were also investigated, as well as the amount of water consumed on different rations, and the comparative merits of oats and a mixture of bran and shorts.

In the first period of the first test reported 2 farm work horses fed a ration of 25 lbs. of alfalfa hay and 10 lbs. bran and shorts lost 4 lbs. in 95 days; 2 similar horses

fed the same ration except that timothy hay replaced alfalfa, lost 124 lbs. The average cost of the 2 rations was 9.9 cts. and 12.3 cts. per day. The rations were then reversed for 56 days, and the horses fed alfalfa hay gained 75 lbs. while those fed timothy hay lost 60 lbs.

In a second test under practically the same experimental conditions, except that the grain ration was larger, averaging a little over 12 lbs. per day, the 2 horses on alfalfa hay gained 55 lbs. in 91 days while those fed the timothy hay lost 41 lbs. When the rations were reversed the horses on alfalfa hay gained 65 lbs. in 68 days, and those on timothy hay lost 100 lbs.

The rations were also tested for 39 days with 2 driving horses used for light work. In addition to some 12 lbs. of grain per day, 1 horse ate 8.3 lbs. timothy and the other 16 lbs. of alfalfa hay, on an average. On the former ration there was a loss of 50 lbs., on the latter a gain of 10 lbs.

In the fourth test all the horses previously used were included, and also 2 additional driving horses used for light work. The work horses were fed 15 lbs. of hay and 12 lbs. of oats per head daily, and the driving horses 12 lbs. of hay and 9 lbs. of oats; in each case 2 horses were fed timothy and 2 alfalfa hay. In 180 days the horses fed timothy lost 189 lbs., while those fed alfalfa made a total gain of 8 lbs.

Using 2 of the work horses a test covering 60 days was made in which the rations were reversed every 10 days. The horses were fed the same amount of hay and grain, yet they ate 253 lbs. more alfalfa than timothy during an equal number of days, which also "brings out very clearly the fact that individuality is an important factor in feeding."

In all of these tests the alfalfa ration was the cheaper. The author notes that generally speaking the uneaten residue, i. e., waste, was also less on the alfalfa ration.

The merits of alfalfa hay fed without grain were also studied. In a 10-day test 2 work horses (idle during the test), weighing nearly 1,400 lbs. each, practically maintained their weight on an average daily ration of 19.8 lbs. alfalfa per head. The same horses fed alfalfa hay without grain for 21 days (working 9 hours a day) consumed on an average 32.6 lbs. alfalfa hay daily. One horse lost 2 lbs., the other 76 lbs. With very severe work 40 lbs. of alfalfa hay was not an adequate ration, though it was apparently as large a quantity as could be eaten. It was noted that the team was not as lively as on a ration of hay and grain.

The author's principal conclusions regarding the feeding of alfalfa are in effect as follows:

In comparing alfalfa and timothy as roughage for horses, the results of the tests, under varying conditions of work, show that it is not as difficult to maintain the weights of horses when fed alfalfa as when fed timothy. With timothy at \$6 and alfalfa at \$4 per ton the cost of maintenance was greater in every case, except one, on timothy than on alfalfa. The appearance of the horses in every comparison of alfalfa and timothy was in favor of the alfalfa-fed horse. When alfalfa and timothy were fed ad libitum much greater quantities of alfalfa were consumed.

No ill results were noted on the health of the horses by long-continued alfalfa feeding. Attacks of colic and other digestive disorders can be prevented by a judicious system of feeding. The amount of hay fed on most Utah farms could be reduced at least one-half. It may be economical to reduce the amount of hay and increase the amount of grain fed to horses.

Twenty pounds of alfalfa per day proved sufficient to maintain the weights of horses weighing nearly 1,400 lbs. when at rest. When at heavy work, 32.62 lbs. of alfalfa per day was barely sufficient to maintain the weights of the same horses.

The author discusses the amount of feed required by horses, and emphasizes the fact that rations often fed are too large. In the experiment reported above, in which horses weighing 1,400 lbs. practically maintained their weight on a daily ration of 15 lbs. of timothy hay and 12 lbs. of oats, it was calculated that the ration furnished in

digestible nutrients 1.72 lbs. protein, 0.667 lb. fat, 10.5 lbs. carbohydrates, the nutritive ratio being 1:7. Similar values for the ration made up of 15 lbs. alfalfa hay and 12 lbs. of oats were protein 0.299 lb., fat 0.519 lb., and carbohydrates 10.93 lbs., the nutritive ratio being 1:4.4. As noted by the author, these values are considerably below the amounts called for by Wolff's standard for a horse doing heavy work.

The diuretic effect of alfalfa hay was studied with 2 horses in a test covering 60 days. Each horse was fed 15 lbs. of oats; in addition one was given 25 lbs. of alfalfa hay, the other a like amount of timothy. The rations were reversed every 10 days. The attempt was made to collect all the urine, and the results include only the days on which this was successfully accomplished. On the timothy ration the average amount of water consumed per horse was 81.92 lbs. per day, the average daily excretion of urine 16.4 lbs. Corresponding values for the alfalfa ration were 90.76 lbs. and 27.26 lbs. This confirms the fact observed at the station that alfalfa increases the amount of urine. The test was discussed with especial reference to the effect of early, medium, and late cut first crop alfalfa. It appeared, according to the author, that the early cut alfalfa hay caused the greatest excretion of urine and the late cut alfalfa the least, although the consumption of water did not vary in the same way. The greater consumption of water when horses are fed alfalfa resulted in a greater elimination by the kidneys, "but we have no evidence that this greater elimination is in any way detrimental to the health of horses." That the amount of water in the feeding stuffs did not cause the increased amount of urine is shown by the fact that the timothy hay contained 10.7 per cent and the alfalfa hay from 9.64 to 10.53 per cent. The specific gravity of the urine on the alfalfa ration was greater than that on the timothy ration, as was also the nitrogen excreted. The author calculates the balance of income and outgo of nitrogen, i. e., the metabolism of this element.

Considering the tests as a whole the author discusses the comparative value of oats and a mixture of bran and shorts. In his opinion "it is evident, from a study of the experiments during 4 periods of which bran and shorts were used and during 1 when oats made up the grain ration, that bran and shorts may be substituted for the oats whenever the horses are fed alfalfa or timothy."

What is a maintenance ration for a horse? F. E. EMERY (*Wyoming Sta. Rpt. 1902, pp. 26-31*).—A feeding test made with 4 farm horses required to perform light work showed that they maintained their weight on an average daily ration of 13.5 lbs. good alfalfa hay. The horses were allowed free access to water and a pile of oat straw, but were fed no grain. The amount of straw eaten was not recorded. In a second test made with 2 horses it was found that weight was maintained on an average daily ration of 13.75 lbs. alfalfa hay and 2.25 lbs. oat straw per 1,000 lbs. live weight. It was calculated that this ration would furnish 1.85 lbs. protein, 0.14 lb. fat, and 6.27 lbs. nitrogen-free extract, the nutritive ratio being 1:3.5. As pointed out, this ration furnishes more protein and less carbohydrates and fat, and has a narrower nutritive ratio, than is called for by Wolff's standard.

Maintenance ration for driving horse, F. E. EMERY (*Wyoming Sta. Rpt. 1902, pp. 41, 42*).—In a test made with a driving horse required to perform a moderate amount of work it was found that his weight—1,100 to 1,200 lbs.—was maintained on a ration of 21.25 lbs. alfalfa hay and 3.4 lbs. oat straw, or 17.71 and 2.83 lbs., respectively, per 1,000 lbs. live weight. In this test the horse was driven daily some 6 miles at a pace which it is stated was well up to the limit of his road gait. The author calculates that this ration will furnish 2.38 lbs. protein, 1.8 lbs. fat, and 8.22 lbs. carbohydrates per 1,000 lbs. live weight, the nutritive ratio being 1:3.6. It is noted by the author that the amount of protein is greater, the amount of fat and carbohydrates less, and the nutritive ratio narrower, than is called for by Wolff's standard for a horse at light work.

The breakage of eggs, H. FÄBER (*Ugeskr. Landm., 47 (1902), No. 14, pp. 161-164*).—Investigations showed that the relative breakage in different months of Danish eggs shipped to the English market, on the basis of an average breakage of a hun-

dred, was as follows: January, 85; February, 128; March, 116; April, 75; May, 73; June, 101; July, 106; August, 127; September, 110; October, 104; November, 88; and December, 87. The deductions were drawn from the examination of many thousands of boxes. The author also found that large eggs broke more easily than small ones. He recommends supplying poultry liberally with lime throughout the year, grading the eggs before packing, and carefully packing, since the loss due to breakage considerably exceeds the additional cost of packing material.—F. W. WOLL.

Eggs of hens fed meat, E. THIERRY (*Jour. Agr. Prat.*, n. ser., 3 (1902), No. 10, p. 319).—A comparative study showed that hens fed flesh produced more and heavier eggs than those fed grain.

DAIRY FARMING—DAIRYING.

Alfalfa v. wheat bran for milch cows, F. E. EMERY (*Wyoming Sta. Rpt.* 1902, pp. 39, 40).—One cow was fed a ration containing 8 lbs. of wheat bran in addition to native hay for 2 periods of 10 days each, and a ration containing 3 lbs. of wheat bran in addition to alfalfa hay in the morning and native hay in the evening for an intervening period of 10 days. The hay was fed ad libitum. The ration containing alfalfa gave the lowest yield, but was the most economical.

The flat pea (*Lathyrus sylvestris*), its culture and feeding value for milch cows, G. ANDRÉ (*Landw. Jarb.*, 31 (1902), No. 1, pp. 55–80).—The culture and feeding value of the flat pea are discussed at some length and feeding experiments are reported. In rations having practically the same composition flat-pea hay was compared with clover hay. The experiment included 8 cows and lasted nearly 3 months. The results showed no variation in the composition of the milk, as regards total solids and fat, due to a change of rations. On the flat-pea ration, however, the average daily yield was decreased to the extent of 510 gm. of milk and 18.9 gm. of fat per cow. The live weight of the cows increased uniformly throughout the experiment.

Individual differences in the value of dairy cows, W. J. FRASER (*Illinois Sta. Circ.* 50, pp. 8, figs. 4).—An extract from Bulletin 66 of the station (E. S. R., 13, p. 883).

The production of milk and butter, L. MALPEAUX (*Compt. Rend. Cong. Soc. Aliment. Rat. Bât.*, 6 (1902), pp. 26–50).—This has been noted from another source (E. S. R., 13, p. 883).

The use of milking machines in dairying, F. BORDAS and S. DE RACZKOWSKI (*Compt. Rend. Acad. Sci. Paris*, 135 (1902), No. 8, pp. 371, 372).—Milk drawn by hand contained a much smaller number of bacteria and remained sweet for a longer period.

The composition of milk, H. D. RICHMOND (*Analyst*, 27 (1902), No. 317, pp. 240–243).—The average composition of 13,936 samples of milk analyzed during 1901 was as follows: Specific gravity, 1.0321; total solids, 12.63 per cent; fat 3.72 per cent, and solids-not-fat, 8.91 per cent. The evening's milk contained on an average 0.38 per cent more fat than the morning's milk. The lowest fat content occurred during May and June and the highest during November and December.

Studies of the proteids of milk led the author to conclude that casein and albumin are not decomposition products of one albuminoid existing in milk, and that casein is an acid having a strength greater than carbonic acid or boric acid, less than organic acids such as acetic and lactic, and the same as the second hydroxyl of phosphoric acid.

Analyses of 4 samples of human milk are reported. The sugar in human milk, according to the author, differs from lactose as regards polarization and reducing power.

The composition of colostrum, W. F. SUTHERST (*Chem. News*, 86 (1902), No. 2223, pp. 1, 2, *dgm.* 1).—Colostrum was obtained from a Shorthorn cow twice a day for 10 days, and analyzed, the data being given in detail. The percentages of the different constituents for the first and last milkings, respectively, were as follows: Total solids, 22.878 and 16.058; ash, 1.034 and 0.814; fat, 2.302 and 4.796; lactose, 2.742 and 4.874; total albuminoids, 12.236 and 3.242; casein, 4.858 and 2.250; globulin, 5.321 and 0.198, and albumin, 1.454 and 0.562. The specific gravity decreased from 1.068 to 1.030. The percentage of globulin decreased very rapidly for the first 3 milkings and then remained practically constant. All the other constituents increased or decreased gradually, equilibrium being reached at about the ninth milking.

Variation in the phosphoric acid in milk during lactation, F. BORDAS and S. DE RACZKOWSKI (*Compt. Rend. Acad. Sci. Paris*, 135 (1902), No. 5, pp. 302, 303).—Analyses of the milk of 7 cows in different stages of lactation showed a maximum content of phosphoric acid and lecithin at the beginning of lactation and a gradual decrease during the remainder of the period.

The hygiene of milk, W. FRIEGER (*Die Hygiene der Milch*. Leipzig: M. Heinsius Nachfolger, 1902, pp. VIII + 244, pls. 15, figs. 113).—This treats in a general way of the production, handling, and preservation of milk and its products under hygienic conditions. Methods of testing are described and the feeding of infants is considered at some length.

The care and handling of milk, O. F. HUNZIKER (*New York Cornell Sta. Bul.* 203, pp. 18, figs. 2, *dgm.* 1).—The author discusses the source of bacteria in milk and the means of infection; straining, cooling, and aerating milk; pasteurization and sterilization; and storage and transportation. A strainer consisting of a wire gauze and 4 layers of cheese cloth has been found the most practical and efficient at the station. Milk kept at 50° F. remained practically unchanged for several days, while milk kept at 98, 80, 70, and 60° curdled at the end of 27, 30, 48, and 72 hours, respectively. Many practical suggestions are made throughout the bulletin, which is popular in character.

Aeration of milk, C. E. MARSHALL (*Michigan Sta. Spec. Bul.* 16, pp. 58).—This is a detailed account of studies of the effect of aeration, considered apart from cooling, upon the condition and germ content of milk. Analyses were made of the gases in milk before, during, and after aeration. Experiments were conducted to determine the influence of bacteria and antiseptics upon the interchange of gases between milk and air. The effect of different percentages of carbon dioxide upon the development of bacteria was studied and many other experiments were performed. The gas content of the milk was found to contain on an average 81.5 per cent of carbon dioxide and 2.42 per cent of oxygen. Aeration reduced the percentage of carbon dioxide to about 35 and increased the oxygen content to about 20 per cent. The presence of carbon dioxide in quantities exceeding 33 per cent was found to restrain or prevent bacterial growth. The author draws the following conclusions:

"Milk undergoes aeration when exposed to air from the time it leaves the milk duct of the cow until it is consumed or made into milk products.

"This aeration is demonstrated by the reduction in the amount of carbon dioxide and the increase in the amount of oxygen.

"It has been shown that aerating methods which increase the surface of the milk exposed facilitate aeration greatly.

"Below a certain percentage the elimination of carbon dioxide becomes very difficult.

"By this interchange of gases between air and milk there is a great opportunity offered for the absorption of noxious gases by the milk, unless the interchange takes place in absolutely pure air.

"Agitation of milk favors the interchange of gases, because of the increased surface exposure.

"Odors and taints resulting from aromatic foods, physiological processes, and disease processes may be greatly reduced permanently.

"Odors and taints resulting from bacterial fermentations may be greatly reduced, but they will return upon the further development of bacteria.

"The oxidation of milk is a slow process in the presence of antiseptics.

"Where the oxygen disappears rapidly and carbon dioxide is formed in a confined air space over milk, this change is evidently due to bacterial activities.

"Closing milk cans from the air consequently reduces the amount of oxygen supply, therefore must change the conditions of germ life.

"Aeration does not change the germicidal action of milk.

"Aeration does not reduce the number of bacteria.

"Directly confined milk does not ferment more readily than aerated milk.

"Aeration does influence the amount of oxygen supply to the bacteria present. . . .

"The fermentations of milk are therefore influenced by aeration, favoring the production of nontoxic substances."

Aeration of milk, C. E. MARSHALL (*Michigan Sta. Bul.* 201, pp. 214-216).—This is a popular summary of the above suggestions as to the manner of conducting aeration being given substantially as follows: Aeration should be conducted at body temperature and carried out slowly over the most extensive surface possible. It should take place only in a pure atmosphere and immediately after milking, and should precede cooling. Aeration and cooling conducted simultaneously can not yield the most satisfactory results.

Standard milk and cream, W. J. FRASER (*Illinois Sta. Bul.* 74, pp. 283-296, pls. 2; *Circ.* 51, pp. 12, pls. 2).—The food value of milk and selling milk on the basis of composition are briefly discussed. The term "standard" is applied to milk or cream in which the fat has been brought to a certain percentage by the addition or removal of fat or skim milk. The author considers that a law requiring the standardization of milk and cream sold for direct consumption would result in justice to both seller and buyer, and argues for the adoption of such a system.

Standardization of milk and cream, O. ERF (*Illinois Sta. Bul.* 75, pp. 297-309).—Detailed directions are given for standardizing milk, which is defined as bringing the content of butter fat to a given percentage, regardless of the quality of the milk as produced by the cow. The necessary steps are the determination of fat by the Babcock method and the addition or removal of cream as may be necessary for this purpose. Skim milk may, of course, be used instead of cream. The same methods apply to the standardization of cream.

Use of hydrogen peroxid for the preservation of milk, J. HUWART (*Rev. Gén. Lait*, 1 (1902), No. 8, pp. 180-183).—The pasteurization of milk immediately after the addition of hydrogen peroxid removed about two-thirds of this antiseptic, and pasteurization at the end of 18 hours removed all traces. The estimation of hydrogen peroxid in milk by the liberation and determination of iodine gave satisfactory results.

Hydrogen peroxid for preserving milk, R. LEZÉ (*Jour. Agr. Prat.*, n. ser., 4 (1902), No. 34, p. 249).—The advantages of this preservative are pointed out, but its practical use in the preservation of milk is considered doubtful.

The acidity of milk: Its accurate and rapid determination, origin, variation under different influences, and importance, P. DORNIC (*Rev. Gén. Lait*, 1 (1902), Nos. 10, pp. 217-224; 11, pp. 241-249; 12, pp. 268-277; 13, pp. 298-303; 14, pp. 319-324).

Composition of separator slime, C. BARTHEL (*Rev. Gén. Lait*, 1 (1902), No. 9, pp. 193-196).—The average of analyses made by the author is as follows: Water 67.50, casein 12.56, cellular matter 13.28, nonnitrogenous organic matter 3.99, and ash 2.67 per cent.

Study of rapid and slow creaming milks, M. HENSEVAL (*Rev. Gén. Lait*, 1 (1902), No. 16, pp. 366-373, figs. 2; *Bul. Agr. [Brussels]*, 18 (1902), No. 2, pp. 256-263, figs. 2).—A comparative study was made of 2 types of milk, one showing

a rapid and one a slow rising of the cream. The fat globules were measured and the milk and butter analyzed as a basis for further study. As regards composition the 2 types of milk were normal. The rapid creaming milk showed the presence of numerous large fat globules, often in clumps, while in the other type the grouping of globules was rare, and the larger ones were more or less irregular in outline. Centrifugal separation of the slow creaming milk was less complete.

The influence of creaming on the distribution of the principal constituents of milk, F. BORDAS and S. DE RACZKOWSKI (*Compt. Rend. Acad. Sci. Paris*, 135 (1902), No. 7, pp. 354, 355).—This study was made with particular reference to phosphoric acid and lecithin. From 3,200 cc. of whole milk submitted to centrifugal separation 2,800 cc. of skim milk and 370 cc. of cream were obtained. The whole milk, skim milk, and cream contained, respectively, 0.176, 0.184, and 0.096 per cent of total phosphoric acid and 0.058, 0.018, and 0.334 per cent of lecithin, showing that about 69 per cent of the lecithin was removed with the cream.

Study of pasteurization of cream in dairying, L. MARCAS and M. HENSEVAL (*Rev. Gén. Lait*, 1 (1902), Nos. 17, pp. 387-395; 18, pp. 413-423).—Three series of experiments are reported in detail in which butter was made under similar conditions from cream pasteurized at temperatures ranging from 70 to 90° C. Pasteurization increased slightly the yield of butter in all cases, though the difference was too small to be considered of practical importance. The butter from pasteurized cream had a higher water content, which accounted for the increase in yield. As judged by 2 experts, the pasteurized butter was superior in quality.

The influence of food on the quantity of volatile fatty acids in butter, H. WEIGMANN and O. HENZOLD (*Rev. Gén. Lait*, 1 (1902), Nos. 7, pp. 145-149; 8, pp. 173-180; 9, pp. 196-202).—Four series of experiments are reported. Different rations were found to influence the content of volatile fatty acids in butter. When this influence was unfavorable it was apparent, usually, immediately following a change of rations rather than after several days; but when favorable the increase in the content of volatile fatty acids followed slowly. The cause of this variation is attributed to the nature of the food rather than to a change in nutrition, although in certain cases a change of rations in itself appears to exert a similar influence.

Fluorids as butter preservatives, with observations on their influence on artificial digestion, O. and C. W. HEHNER (*Analyst*, 27 (1902), No. 315, pp. 173-179).—The presence of fluorids was detected in 20 samples of French butter, the amount present being estimated at from 1 to 4 grains of sodium fluorid per pound of butter. In artificial-digestion experiments the presence of 0.04 per cent of sodium fluorid or its equivalent in ammonium fluorid inhibited the action of ptyalin and pepsin and to a less extent that of diastase. The action of rennet was prevented when fluorids were added in excess of the amount precipitable by the calcium salts in the milk.

The Institute of Butter Control in Friesland, M. BEAU (*Jour. Agr. Prat.*, n. ser., 4 (1902), No. 39, pp. 408-411).—A summarized account is given of the results of the examination of butter in Friesland from May, 1901, to April, 1902. During the year 1,341 samples of butter were analyzed. The average Reichert-Wollny number was 28.69, corresponding to a percentage of volatile fatty acids of 5.71. During the summer months, however, 44 per cent of the samples showed a Reichert-Wollny number less than 27.63, which corresponds to the standard of 5.5 per cent for volatile fatty acids. During the winter months 29 per cent of the samples were below this standard.

Characteristics of butter from human milk, SAUVATRE (*Abs. in Ann. Chim. Analyt.*, 7 (1902), No. 4, pp. 143-145).—In general the physical and chemical properties of butter from human milk corresponded closely to those of butter from cow's milk. In human butter, however, the Reichert number was only 15.8.

Estimation of the quantity of casein precipitable by rennet, L. LINDET (*Rev. Gén. Lait*, 1 (1902), No. 12, pp. 265-268).—From determinations of the specific gravity

and fat content of the milk, the specific gravity of the milk less the fat is calculated, a formula and a table being given for this purpose. A sample of milk is curdled with rennet under the ordinary conditions of cheese making and the specific gravity of the whey is determined. A lactometer graduated from 1,025 to 1,035 is used, each difference of 1 between the reading for the whey and the calculated reading for the skim milk being estimated as equivalent to 3.5 gm. of casein per liter of milk coagulable by rennet.

Influence of low temperatures on the ripening of cheese, E. VON FREUDENREICH (*Rev. Gén. Lait*, 1 (1902), No. 21, pp. 481-485).—Four Emmenthaler cheeses were each made from 15 liters of milk, artificial rennet being used. Cheeses 1 and 2 were inoculated with liquefying micrococci and lactic acid bacteria, while cheeses 3 and 4 were made without the addition of cultures. Cheeses 1 and 3 were placed at once in cold storage. Cheeses 2 and 4 were kept at about 20° C. for 24 hours and then placed in cold storage. After remaining for 5 months at temperatures below 10° the 4 cheeses were subjected to chemical and bacteriological examinations. In percentages of total nitrogen the 4 cheeses, in numerical order, showed 10.53, 20.50, 10.19, and 10.64 per cent of soluble nitrogen, and 0.35, 0.64, 1.70, and 1.66 per cent of nitrogen of the products of decomposition. The greater amount of soluble nitrogen in No. 2 was attributed to the development of the micrococci during the first 24 hours before this cheese was placed in cold storage. The numbers of bacteria per gram in the 4 cheeses were about 600, 560, 200, and 146 million. A considerable increase in the number of lactic acid bacteria was apparent. As judged by taste, it is stated that cheeses 1 and 3 showed no ripening, while cheeses 2 and 4 showed ripening to a slight degree, cheese 2, however, being somewhat bitter. The author concludes that normal ripening apparently did not take place under the conditions of the experiment.

Edam cheese, M. BEAU (*Jour. Agr. Prod., n. ser., 4* (1902), Nos. 34, pp. 246-248; 35, pp. 274, 275).—An account of this industry in Holland.

Summary of the proceedings of the Second National Congress of Dairying, M. HENSEVAL, (*Rev. Gén. Lait*, 1 (1902), Nos. 15, pp. 346-355; 16, pp. 374-378; 17, pp. 397-402).—The congress was held at Brussels, Belgium, in April, 1902. Reports along the following lines were presented and discussed: The influence of pasteurization upon the quality and yield of butter, pasteurization of the by-products of the dairy, inspection of dairies, commercial treaties and uniform legislation relating to dairying, and supervision of the butter trade.

Examination of apparatus for determining butter fat in milk and cream, A. L. WINTON (*Connecticut State Sta. Rpt. 1901, pt. 4, pp. 279-283*).—During the few months in which the State law concerning the purchase of milk and cream has been in operation the station has tested 222 pipettes, 463 milk test-bottles, and 1,810 cream test-bottles, of which 58 pieces were found inaccurate. The methods employed in testing are stated.

VETERINARY SCIENCE AND PRACTICE.

Proceedings of the American Veterinary Medical Association for 1901 (*St. Paul: Webb Pub. Co., 1902, pp. 408, figs. 17*).—The thirty-eighth annual meeting of the Association was held at Atlantic City, N. J., September 3 to 6, 1901. The address of the president, T. W. Butler, contained a brief review of progress in veterinary medicine and various suggestions concerning the code of ethics for the regulation of veterinarians.

The subject of tuberculosis received an extended discussion, and a resolution was finally adopted declaring, among other things, "that the evidence of accidental inoculations and clinical observations apparently demonstrate that bovine tuberculosis may be communicated to man; . . . that experiments showing the difficulty or the

impossibility of transmitting human tuberculosis in a fatal form to cattle can not be accepted as evidence that the bovine bacillus, which is far more virulent and fatal to many animals, can not infect man; . . . that if it is admitted that human tuberculosis is not communicable to cattle under ordinary conditions, this should be a great encouragement for the eradication of bovine tuberculosis, since it would prove that the danger often feared that cattle, if freed from the disease, would be immediately reinfected from mankind, does not exist in fact and need not be considered." A resolution was also adopted instructing the committee on diseases to investigate the subject of anthrax and make a report at the next meeting of the association.

V. A. Moore reported some preliminary observations on skin disinfection and wound infection. The 3 species of bacteria found to be of special interest in this connection are an undetermined species of streptococcus, an undetermined species of micrococcus, and *M. pyogenes aureus*. Numerous experiments were made in the disinfection of the skin, the disinfectants being carbolic acid, potassium permanganate, lysol, Sanitas, and corrosive sublimate in various strengths. The only disinfectant which thoroughly sterilized the skin in any case was corrosive sublimate in a 0.1 or 0.2 per cent solution.

W. H. Dalrymple gave a general account of the prevalence of anthrax in Louisiana, the spread of which he stated to be largely due to carelessness in allowing the carcasses of animals dead of anthrax to remain upon the ground. As the result of this, the disease may be rapidly carried from one place to another by the various insects which visit such carcasses, especially species of the family Tabanidae. Various birds and mammals are also instrumental in spreading the disease.

Some obstructions to efficient meat and milk inspection were discussed by C. A. Cary; and G. R. White presented an account of municipal meat inspection legislation, with special reference to the law and the rules and regulations of the board of health of the city of Nashville. The difficulties encountered by the live-stock inspectors in large stock yards were briefly considered by S. G. Hendren.

J. J. Repp read a paper on the Transmission of Tuberculosis through Meat and Milk. The literature of the subject was critically reviewed, and the practical conclusion drawn that meat and milk from highly tuberculous animals are unfit for food. A paper on the Attitude of the Farmer toward the Tuberculin Test was presented by C. W. Gay. Attention was called to the objections raised by the farmers to the application of the tuberculin test. These objections are said to be due principally to the fear of having apparently healthy cattle condemned, and to the lively discussion of the subject of tuberculosis which has appeared in all periodicals, including farm journals, since the publication of Koch's address.

J. C. Roberts discussed the Texas-fever problem in the South, arguing that immunity to Texas fever is not hereditary but must be acquired anew by every animal; that nonimmune cattle of all ages are subject to the disease, and that southern cattle, when raised free of ticks, are as susceptible as northern cattle. In a paper on Texas fever in native South Carolina cattle, G. E. Nesom stated that the annual loss from this disease in that State is about \$50,000. It was recommended that the upper portion of the State should be freed from ticks and that the lower portion be rigidly quarantined.

The desirability of appointing veterinarians on State boards of health was discussed by S. B. Nelson, who regarded such appointments as necessary on account of the many outbreaks of diseases which are common to man and domesticated animals. J. B. Paige presented an elaborate discussion on the subject of stable ventilation. He recommended the adoption of some form of ventilating device by means of which the greatest possible amount of air can be secured without reducing the temperature too greatly in cold weather.

Lameness in horses was discussed by W. C. Fair, who stated that during a practice of 30 years, 25 per cent of his cases have been lameness. Various directions were given

to make possible a short and rapid diagnosis of the cause of lameness. In a paper on radical operations for bursal enlargements, C. C. Lyford considered a seton almost indispensable for keeping open the operation wounds in enlarged bursae and thus making possible a thorough washing with antiseptic solutions. A paper on the value of a few common operations on the horse by L. A. Merillat gave brief notes on various forms of neurectomy, tenotomy, and the use of the actual cautery.

L. Van Es discussed the subject of colleges and associations as guardians of the standing of veterinarians among the profession, and the relation of the veterinarian to his profession and the public was discussed by W. Shaw. A paper on the pathological anatomy and microscopical diagnosis of rabies was read by A. Eichhorn. The author stated that the plexiform ganglion shows greater or less changes in all stages of rabies, and that a positive diagnosis can be made most easily from an examination of this ganglion. W. McEachran discussed the symptoms, diagnosis, pathological changes, and treatment of distemper in a dog.

In discussing the diagnosis of glanders by the Strauss method, L. Frothingham reported an extensive series of experiments on guinea pigs inoculated with material obtained from cases of glanders in horse and man. While a certain percentage of these experiments gave negative results, the author believes that this method for diagnosis of glanders is the most valuable one which can be used.

Notes are given on the proceedings of the fifth annual meeting of the Association of Experiment Station Veterinarians of the United States, which was held in connection with the above meeting.

The address of the president, R. R. Dinwiddie, is reported, together with a paper by C. A. Cary on the preparation of bouillon, gelatin, and agar-agar, and one by M. Jacobs on the subject of nodular disease in sheep.

The duration of the life of pathogenic bacteria in minute particles of water and on dust particles, F. KIRSTEIN (*Ztschr. Hyg. u. Infektionskrankh.*, 39 (1902), No. 1, pp. 93-170).—The purpose of the experiments which are reported in this article was primarily to determine the length of time during which pathogenic bacteria which are associated with particles of dust or minute drops of moisture may remain alive in rooms subjected to ordinary illumination with diffuse sunlight. Experiments with the tubercle bacillus showed that this organism preserved its vitality when thrown out in moisture in the form of the finest possible particles for at least 4 days. Tubercle bacilli which had been thrown out in a spray in that manner and collected 8 days after the spraying were found to have lost their virulence. The period at which the tubercle bacilli die under conditions mentioned is, therefore, between 4 and 8 days. The experiments of other authors along this line with the tubercle bacillus are discussed in this connection. It was argued that the great variation in results obtained by different authors is due largely to the fact that the tubercle bacilli were encased in drops of moisture or sputum of very different size in different experiments. The author found that where tubercle bacilli were protected from the action of diffuse sunlight and desiccation in particles of sputum of considerable size, the organisms preserved their vitality for a period of 3 months or more.

In similar experiments with the organism of fowl cholera it was found that these bacilli lost their vitality after a period of 17 hours. Similar experiments were also made with a number of staphylococci and streptococci and similar results were obtained. In all cases it was found that when the organisms were not protected by a thick film or other substance from the action of the light and air, their vitality disappeared within a few days at most and usually within a few hours.

The properties and nature of mixtures of toxins and their antitoxins, J. DANYSZ (*Ann. Inst. Pasteur*, 16 (1902), No. 5, pp. 331-345).—The experiments reported in this article by the author were confined largely to a study of the properties of mixtures of ricin and antiricin. A solution of ricin was made in the usual manner and of such a strength that 1 cc. of the solution of ricin contained enough for 1,000 lethal doses

for rabbits. Antiricin serum was obtained by immunizing a goat. After one series of injections with the solution of ricin 1 cc. of the serum of this goat was sufficient to neutralize the action of 0.5 cc. Later, after another series of injections, 1 cc. of the serum neutralized 1 cc. of the ricin and still later 2 cc. An extensive series of experiments was made in which various mixtures of these 2 substances were used. During these experiments it was found that the formation of precipitates in the mixtures in different proportions of ricin and antiricin, as well as the variable properties of the mixtures containing identical quantities of toxin and antitoxin, and finally the at once antitoxic and toxic properties of these mixtures in any proportion proved beyond question that these 2 substances fix or impregnate each other reciprocally in variable proportions. When mixed together, toxins and antitoxins do not form a simple compound but rather a series of compounds in which one of the substances is more or less impregnated by the other. The mixtures are therefore more or less active.

Agglutination in cases of mixed infection and the diagnosis of these infections, A. CASTELLANI (*Ztschr. Hyg. u. Infektionskrankh.*, 40 (1902), No. 1, pp. 1-20).—A brief review is given of the literature relating to this subject. The author's experiments included a study of mixed infections produced by simultaneous injection of different micro-organisms, the agglutination which occurs when a secondary infection is added to an already existing primary one, agglutination in mixed infection in man, and the diagnosis of mixed infections with the aid of the agglutination test. The results of these experiments indicate that in cases of experimental mixed infections which are produced simultaneously, the blood serum acquires an agglutinating power toward all micro-organisms with which the animal is inoculated. The beginning, the intensity, and the duration of the agglutination for each kind of organism are the same as in animals inoculated with but one species alone. When a secondary infection is added to a primary one near the beginning or toward the end of the latter the blood acquires an agglutinating power for the organisms of both infections, and this power does not differ from that which is manifested in case of simultaneous mixed infection.

Tuberculosis, E. VON BEHRING, P. RÖMER, and W. G. RUPPEL (*Beitr. Exper. Ther.*, 1902, No. 5, pp. 90, figs. 42).—The experiments for the purpose of perfecting a method of immunizing cattle against tuberculosis have been carried on at the Institute for Hygiene and Experimental Therapy of the University of Marburg for a number of years, and have led to results of great importance from a practical as well as a scientific standpoint. The most important conclusions which are drawn from these investigations are that cattle can be perfectly immunized against tuberculosis; that tuberculosis of man and cattle is one and the same disease; that the agglutination method for recognizing tuberculosis, as proposed by Arloing and as modified by von Behring, is unsatisfactory; and that mammals upon which experiments have been made may be arranged with regard to their susceptibility to tuberculosis in the following order, beginning with the most susceptible: Guinea pigs, rabbits, dogs, goats, cattle, horses, sheep, and white mice. During the experiments which are described in the present report, and which extended over a period of more than 5 years, an exceedingly virulent form of tubercle culture was produced which killed cattle within 2 or 3 weeks, under symptoms of milary tuberculosis. This culture was used for testing the degree of immunity of animals which had been treated, and also for testing the susceptibility of the control animals. It was found possible to secure cultures of tubercle bacilli of almost any origin sufficiently attenuated to produce a mild form of the disease in cattle, and thus to confer upon them a lasting immunity. All cultures of bacilli of different origin are, however, not equally well suited for use in immunizing cattle. For practical purposes the authors recommend that neither tubercle bacilli of bovine origin nor those from human patients which have been increased in virulence by passage through cattle or goats should be used in attempts

to immunize cattle. The best results were obtained from the use of bacilli of human origin which have been cultivated on artificial media for about 6 years. As a rule young cattle, from 5 to 7 months old, were selected for the experiments. Each animal received intravenously 1 mg. of a serum culture 4 to 6 weeks old; after 4 weeks the animal received 25 mg. of the same culture. The effect of the first inoculation was usually noticed in an elevation of temperature, slight loss of flesh, coughing in some instances, and a susceptibility to tuberculin reaction. The animals, however, recovered usually within a week or 10 days and did not react to tuberculin thereafter. The second inoculation produced milder symptoms and the reaction persisted for a shorter time. After this treatment, which in some cases was repeated a larger number of times, the animals proved to be immune to inoculation with virulent cultures which were sufficient to kill the control animals within a few weeks. The immunized animals also proved resistant to infection by natural methods, as shown by exposure to cattle suffering from advanced tuberculosis.

The authors consider their method of immunization to be strictly analogous to vaccination in man for smallpox. The term, however, was rejected on account of its association with smallpox and on account of the derivation of the word. The term "jennerization" is chosen for the method adopted by the authors for immunizing cattle. The process which takes place in the jennerization of cattle is therefore considered as an isopathic autoimmunization.

Many of the animals which have been immunized at the Marburg institute have been exposed for a number of years to natural infection, and have all shown perfect resistance to the disease. It is considered, however, that the method has not been tested sufficiently to determine with certainty whether immunization against artificial infection is an easier or more difficult matter than immunization against natural infection. This question will be tested more extensively in future experiments. In a number of experimental cattle which had been jennerized evidence of apparent infection was obtained upon post-mortem examination, but this apparent infection persisted for a short time only, when the attenuated bacilli died or became encapsuled. In the cases in which small tuberculous foci were produced in the lungs as the result of jennerization the authors used much more virulent cultures than were actually required for producing immunity. This was done in order to gain some knowledge of the limits of virulence of cultures which could safely be used. The authors believe that young cattle may be immunized against tuberculosis by the use of cultures of tubercle bacilli, which will not produce any bad effects in the animals. It is the intention of the authors to conduct further experiments for the purpose of determining whether inoculation of fresh cultures of human origin may not be preceded by inoculation with tubercle bacilli cultivated in vacuum, with bacilli attenuated according to Arloing's method, or even with tubercle bacilli from fowls. Subsequent experiments must also determine whether the dose of 25 mg. is sufficient in all cases to produce a permanent immunity, and whether any danger would attend the use of larger doses.

The comparative virulence of the tubercle bacillus from human and bovine sources, M. P. RAVENEL (*Pennsylvania Dept. Agr. Rpt. 1901, pt. 1, pp. 286-324; Jour. Com. Med. and Vet. Arch., 23 (1902), Nos. 2, pp. 65-81; 3, pp. 138-156*).—The experiments which are reported in this paper involved 2 lines of work, the isolation and study of pure cultures of tubercle bacilli from various sources in man and cattle, and the testing of the pathogenic power of tubercles of human and bovine origin. A considerable variety of animals was employed in these experiments for testing the virulence of pure culture and tuberculous material. The experimental animals included guinea pigs, rabbits, dogs, cats, horses, goats, calves, sheep, and pigs. Detailed notes are given on the technical methods employed in securing pure cultures of the tubercle bacillus from bovine tubercles and from human sputum. The conditions surrounding the various inoculation experiments and the subsequent fate of all such experi-

mental cases are carefully described. The number of experiments conducted was sufficient to justify the drawing of quite comprehensive conclusions. The author's general conclusions may be summarized as follows:

The tubercle bacillus of bovine origin exhibits quite constant and persistent peculiarities of growth and morphology, by means of which it may be differentiated from the form of tubercle bacillus commonly found in man. Pure cultures of bacilli from the 2 sources differ decidedly in pathogenic power, and this property affords another means of differentiating the 2 forms. The bovine tubercle bacillus is much more pathogenic than that of human origin for all species of experimental animals which were tested, with the possible exception of hogs, which appeared to be very susceptible to both forms of the bacillus. Tuberculous material from cattle and from man corresponds closely to pure cultures of tubercle bacillus from the 2 sources in regard to its comparative pathogenic power for all animals which were tested. The author believes that he is justified from evidence at hand in assuming that the bovine tubercle bacillus possesses a higher degree of pathogenic power than the human bacillus for man as well as the domesticated animals which have been tested.

Detailed notes on the numerous experimental cases are presented in tabular form. From these tables it is seen that in general the infection of experimental animals from tubercle bacillus of human origin was only slight or took place after a longer incubation period than in the case of infection from the bovine tubercle bacillus. In many cases, it should also be observed, no infection whatever took place.

The average life of guinea pigs inoculated with human tubercle bacillus was more than twice that of those which were infected with bovine bacilli. The rabbits which were inoculated with human tubercle bacilli gained in weight and had to be killed in order to conduct the post-mortem examination, while extensive infection was produced in other rabbits from inoculation of bovine tubercle material.

Influence of the toxons of tuberculin upon the development of experimental tuberculosis, S. ARLOING and DESCOS (*Compt. Rend. Soc. Biol. Paris*, 54 (1902), No. 2, pp. 52, 53).—The authors had already demonstrated that it was possible to destroy a considerable part of the toxon of tuberculin by the addition of a definite quantity of antituberculin serum and that the persistent toxicity was due to the presence of toxon. Further experiments were conducted on rabbits and guinea pigs. The experimental animals were divided into 3 lots, and all were inoculated with tuberculosis at the same time. The first lot had received preventive inoculations of tuberculin and serum previous to the inoculation of tuberculosis; the third lot received curative inoculations of the same mixture, after inoculation with tuberculosis; while the second lot was simply inoculated with the tubercle bacilli, and served as a check upon the other lots. As the result of these experiments the authors conclude that tuberculin neutralized by serum and reduced in its content of toxons does not give better results in combating tuberculosis than tuberculin or antituberculin serum used separately. Inoculation for the purpose of prevention or cure appeared to favor the development of tubercular lesions and to augment their extension. When employed for curative purposes the method seemed to hasten death, if the tuberculin was not sufficiently neutralized. It was concluded, therefore, that the toxons of tuberculin possess a certain amount of toxicity, and also the property of favoring the development of experimental tuberculosis.

Chemotactic properties of various tuberculous sera, F. ARLOING (*Compt. Rend. Soc. Biol. Paris*, 54 (1902), No. 17, pp. 556-558).—The author studied the serum of normal cows, of cows inoculated hypodermically with tuberculous cultures, cows affected with spontaneous tuberculosis of a generalized form, and goats inoculated with a fluid obtained by filtering tuberculous material. It was found as a result of these experiments that antituberculous serum is endowed with a positive chemotactic action which is not possessed by the serum of healthy cows or that of cows in advanced stages of tuberculosis. In experiments on goats it was found that repeated

injections of the fluid obtained by filtering tuberculous material conferred a more pronounced chemotactic action upon the serum of experimental goats, rendering it more decidedly antituberculous.

Contagion and tuberculosis in man and beast, G. F. KEENE (*Rhode Island State Bd. Agr. Rpt. 1901*, pp. 82-93).—This article is of a controversial nature and contains a brief summary of evidence which indicates the possibility of transmission of tuberculosis from animals to man.

Further contribution to the possibility of transmission of tuberculosis from man to hogs, M. TEMPEL (*Ztschr. Fleisch u. Milchhyg.*, 12 (1902), No. 8, pp. 231, 322).—The author had previously suspected the possibility of transmission of tuberculosis from tuberculous attendants to hogs. A number of cases of tuberculosis in hogs have been observed in which the disease appeared to have gained entrance through the wound in the scrotum in consequence of the operation of emasculation. Further observation on this point indicated that such cases are rather frequent. In one instance 4 hogs were apparently infected in that manner by an operator who was suffering from tuberculosis of the larynx and who had the habit of holding his knife between his teeth.

Is tuberculosis hereditary? A. VAN LEEUWEN (*Tijdschr. Veeartsenijk. Maanblad*, 29 (1902), No. 5, pp. 197-201).—This article is of a controversial nature, and in it the author makes the assertion that even if tuberculosis is not strictly hereditary, it may nevertheless be congenital or may take its origin during the development of the fetus. It is also argued that evidence exists for the assumption of predisposition to tuberculosis in the offspring of tuberculous animals.

The tuberculin test for tuberculosis, D. E. SALMON (*U. S. Dept. Agr. Yearbook 1901*, pp. 581-592).—The author presents a brief review of the opinions of various European and American investigators as to the efficacy and effect of the tuberculin test. It is concluded that the test is exceedingly accurate, that by its use tuberculosis in its incipient stage may be detected, and that no injurious effects are produced by tuberculin in healthy cattle.

A report on the proceedings of the British Congress on Tuberculosis, held in London, July, 1901, M. P. RAVENEL (*Pennsylvania Dept. Agr. Rpt. 1901*, pt. 1, pp. 447-488).

Diagnosis of anthrax, J. BONGERT (*Ztschr. Fleisch u. Milchhyg.*, 12 (1902), No. 7, pp. 199-202, figs. 8).—The objects of the experiments reported in this paper were to determine how long after death the anthrax bacillus could be demonstrated in material from the dead body by one or another of the staining methods of Johné, Klett, and Olt, and also to determine the best and surest method for identifying the anthrax bacillus in such material. During these experiments it was found that the demonstration of anthrax bacilli by streak cultures frequently failed. The causes of these failures were found in the changes in form that the anthrax bacillus undergoes in consequence of the action of putrefactive bacteria and in the fact that anthrax bacilli are frequently not present in the blood in sufficient numbers to enable their ready identification by streak cultures. As a result of the experiments the author concludes that the morphological demonstration of anthrax bacillus in streak culture does not offer a certain means of determining whether a given animal died of anthrax or not. The best and most certain method of bacteriological diagnosis of anthrax is found in plate cultures. The most suitable method for preserving anthrax material which is to be studied later or shipped some distance is by slow drying of the virulent matter in a thick layer upon glass slides or on the inside of glass tubes.

The disinfection of animal hair by means of steam, PROSKAUER and CONRADI (*Ztschr. Hyg. u. Infektionskrank.*, 40 (1901), No. 1, pp. 134-140).—Experiments were made for the purpose of determining the effectiveness of different methods in killing anthrax spores on animal hair. Three forms of steam sterilizing apparatus were used, and it was found impossible to obtain the same results by the 3 forms of appa-

ratus. It is concluded from these experiments that the differences in results which have thus far been recorded are due to slight differences in the operation of the sterilizing apparatus.

Tick fever or murrain in southern cattle, J. C. ROBERT (*Mississippi Sta. Bul.* 73, pp. 24, figs. 2).—In this bulletin the author presents a general account of Texas fever. Notes are given on the effect of water on the hatching of the eggs; the effect of light and cold upon incubation; the effect of water, cold, and rainfall upon the ticks; the length of life of the ticks; the effect of small numbers and large numbers of ticks upon calves; the effect of a few ticks on cattle more than 12 months old, and the effect of large numbers of ticks on cattle past the age of 12 or 18 months; symptoms of Texas fever; post-mortem findings; relation of seasons of the year to the disease; occurrence of Texas fever among southern cattle; method of vaccination against Texas fever; curative treatment; and immunization by infestation of young animals with ticks. The longest period in which the author has kept ticks alive without food is 3 months. It is stated that there are many farms throughout Mississippi on which no ticks occur, that ticks are never found in cultivated fields, in pastures and woods that have not been occupied by infested cattle for 12 months, or on land which is annually washed by an overflow of water. A number of observations are recorded which show that immunity to Texas fever is not inherited, and that consequently the calves of immune cattle must themselves be immunized in order to acquire protection. Since it is considered an exceedingly difficult matter to eradicate the cattle tick from the whole State, it is suggested that attention should be given to infesting all young calves with a few ticks so as to render them immune and thus to protect the owner against subsequent loss from infection with Texas fever.

Clinical notes on cases of azoturia, hæmoglobinuria, and acorn poisoning, E. J. THORBURN (*Vet. Jour., n. ser., 5* (1902), No. 26, pp. 102-106).—With regard to azoturia the author argues that much doubt still remains concerning the cause of the disease, the usual symptoms, and most effective treatment. In cases observed by the author no change had recently been made in the feed, no period of rest preceded the attacks, and the distance which the horses had traveled before acute symptoms developed were 10 to 18 miles rather than 1 or 2 miles, which is mentioned as the usual distance in text-book treatment of this disease. While full doses of aloes are usually given in treating azoturia, the author reports bad results from too large or too frequent doses, and advises that some care be taken in administering this remedy.

Notes are also given on a number of cases of hæmoglobinuria, with details on the conditions under which the disease occurred and the usual symptoms. In treating this disease it was recommended that animals first be removed from the place where they became infected, and either put on different pasture or in the stable, according to the time of year. Full doses of purgatives should be administered, together with quinin and nux vomica in cases where loss of appetite is observed.

An unusual number of cases of acorn poisoning in cattle is reported. The symptoms are loss of appetite, grunting, prostration, and rapid emaciation, with a high temperature. In treating these cases of poisoning it is recommended that purgatives be first administered, followed by stimulants and digestive tonics.

On the actinomycosis-like development of some of the acid-resisting bacilli, A. C. ABBOTT and N. GILDERSLEEVE (*Centbl. Bakt. u. Par., 1. Abt., 31* (1902), No. 12, Orig., pp. 547-550, pl. 1).—The observations of the authors are considered as affording additional evidence in support of the belief that actinomycetes, the tubercle bacillus, and certain of the acid-resisting bacilli are closely related botanically and should therefore be classified together from a morphological standpoint. The present paper is of a preliminary nature, and all the results of the authors' investigations are not stated. The organisms which were studied included the grass bacillus, timothy hay bacillus, and butter bacillus, as well as actinomycetes and the

tubercle bacillus. The authors accept the proposition made by Metschnikoff in 1898, that the bacillus of tuberculosis represents merely a phase in the development of a more complex parasite, and it is believed that the same view is equally applicable to the organisms belonging to the acid-resisting bacilli, and the authors suggest that they be all grouped together with the actinomyces or streptothrices.

Intravenous injections and the treatment of aphthous fever, E. NOCARD (*Jour. Agric. [Paris]*, 13 (1902), No. 146, pp. 91-93).—The method of Baccelli for treating aphthous fever is discussed by the author in a critical manner. Baccelli reported success in every case with a large number of animals in treating them for aphthous fever by intravenous injections with corrosive sublimate. The author reports that a commission has been established for the purpose of investigating the value of this method. The results thus far obtained by the commission have indicated no difference in the progress of the disease in animals which have received injections of corrosive sublimate and in those which have not.

Interim report upon cattle disease in Southern Rhodesia, W. ROBERTSON (*Agr. Jour. Cape Good Hope*, 20 (1902), No. 13, pp. 754-763).—A report is made upon an outbreak of so-called redwater in Southern Rhodesia. The clinical symptoms and post-mortem appearance of the animals are critically described, and the disease is said to be identical with Texas fever. The usual treatment is recommended.

Distomatosis—"The cattle scourge of Connaught," J. WATSON (*Vet. Jour., n. ser.*, 5 (1902), No. 27, pp. 145-151).—An account is given of the local conditions in the County of Connaught, which appeared to favor the continual infestation by liver flukes. Cattle and sheep are extensively affected by liver rot, and the losses are heavy. The County of Connaught possesses a large number of small lakes and ponds, and the rainfall is comparatively heavy. The difficulties in the way of preventing multiplication of the larval forms of the liver fluke are therefore very great.

Sarcoptic mange of the ox, H. TAYLOR (*Vet. Jour., n. ser.*, 5 (1902), No. 27, pp. 134-136, fig. 1).—The author briefly notes the rare cases which have been observed of sarcoptic mange in cattle. Recently 2 cases were observed by the author, each in a dairy near Edinburgh. The question as to whether the mite which causes this disease is identical with that on the horse is left undetermined.

Algerian sheep in France, and sheep pox, TRABUT (*Bul. Agr. Algérie et Tunisie*, 8 (1902), No. 12, pp. 306-308).—In this article the author defends the position of the French Government with regard to the regulations issued for the purpose of preventing the introduction of sheep pox from Algeria into France. Many objections have been raised against the regulations, and it has been argued that the latter were calculated to introduce rather than prevent the introduction of sheep pox. These arguments are declared to be without foundation.

Demonstration of virulence of blood in sheep affected with pox, F. J. BOSC (*Compt. Rend. Soc. Biol. Paris*, 54 (1902), No. 4, pp. 112-114).—The experiments conducted by the author on this subject indicate that the blood of sheep affected with this disease is virulent during the period immediately preceding eruption, as well as during the eruptive period. The blood of such animals, when inoculated in a pure condition, produces a fatal development of sheep pox in experimental sheep, with the usual symptoms.

The virulence of the lymphatic glands in sheep pox, F. J. BOSC (*Compt. Rend. Soc. Biol. Paris*, 54 (1902), No. 14, pp. 462, 463).—Experiments made on young lambs indicate that the material of the lymphatic glands of sheep affected with pox is virulent and capable of causing subcutaneous tumors with local eruption, but not a generalized eruption over the surface of the body.

External parasites of sheep, F. E. EMERY (*Wyoming Sta. Rpt. 1902*, pp. 42-45).—Brief notes are given on the animal parasites which are most frequently observed on sheep, and directions are presented for preparing and applying sheep dips for the destruction of these parasites.

Hog cholera, J. J. WESTER (*Tijdschr. Veeartsenijk. Maandblad*, 29 (1902), No. 4, pp. 147-174).—The author outlines in general terms the various forms of hog cholera which occur, classifying these forms according to the organs which are chiefly affected. Notes are given by way of differential diagnosis between hog cholera and swine plague, and the effectiveness of various forms of serum treatment which have been recommended is discussed.

Combating infectious diseases of pigs, A. VAN LEEUWEN (*Tijdschr. Veeartsenijk. Maandblad*, 29 (1902), No. 6, pp. 249-254).—Attention is called to the difficulties in the way of a thorough and effective disinfection of premises after the prevalence of infectious swine diseases. The governmental regulations may require certain methods to be applied and remedies to be used in a given manner, but experience has shown that even the most thorough application of the best disinfecting methods known is not sufficient to destroy all the organisms which may be found in the buildings and yards occupied by hogs, except when the work is done in the most scrupulous manner.

Conference of government veterinarians on inspection of pigs and pig products, W. C. QUINNELL ET AL (*Jour. Dept. Agr. Victoria*, 1 (1902), No. 3, pp. 251-255).—During this conference resolutions were passed for the purpose of regulating the action of inspectors with regard to tuberculosis, actinomycosis, parasitic diseases, and post-mortem changes in pigs. It is recommended that in pig carcasses affected with localized tuberculosis the affected parts only be removed, and the rest of the pork be admitted for sale. It is further recommended that pigs affected with the following diseases in any stage be condemned: Anthrax, hog cholera, septicæmia, and pyæmia.

The method of treating hogs affected with the diamond skin disease in abattoirs, LEVY (*Ztschr. Fleisch u. Milchhyg.*, 12 (1902), No. 8, pp. 234-237).—The author gives a critical review of the opinions of different authors regarding the nature of the diamond skin disease and its connection with swine erysipelas. It is frequently observed that hogs which have been affected with the diamond skin disease are immune to swine erysipelas and vice versa. The diamond skin disease is usually of a light form, while swine erysipelas is fatal in a large proportion of cases. Both are known to be caused by the same bacillus. The author believes that on account of the frequent occurrence of this bacillus in the intestines of healthy hogs the present methods of combating the disease are inefficient.

Combating glanders in the horse, V. BABES (*Ztschr. Hyg. u. Infektionskrank.*, 39 (1902), No. 2, pp. 217-232, pls. 2).—The author made an extensive series of experiments which involved the consideration of all the various problems connected with this disease, including the nature of mallein, the mallein reaction, behavior of evidently glanderous horses toward mallein, mallein injections in horses which do not react in a typical manner, glanderous tubercles, the significance of the cessation of mallein reaction, the reaction of horses which are affected with other diseases than glanders, and the influence of mallein upon the glanderous process and upon the organism of the horse.

The results of these experiments may be stated as follows: The toxic substances which are obtained by filtration and precipitation from pure cultures of glanders bacillus in a manner similar to that of the preparation of tuberculin cause a specific reaction in glanderous horses. More than 90 per cent of the 7,000 evidently glanderous horses, more than 30 per cent of the horses which had been in contact with glanderous horses, and only 1 to 2 per cent of horses in herds which were not infected reacted. The specific action of mallein appears with certainty, however, only in rested, well-fed animals without fever. Low fever temperature occurring just previous to the injection or previous reactions do not interfere with the results of later injections, provided that an interval of 8 days occurs between the two injections. The failure of reaction after frequent injections does not indicate a cure of the disease

in all cases, since the reaction frequently begins again after a long interval or the disease may break out anew. In animals which react in a typical manner subsequent examination shows either that the animals are manifestly glanderous or that glanderous tubercles are present in the lungs, liver, or spleen. According to the author's investigations these tubercles are usually due to the entrance of the glanders bacillus into the respiratory passages. Miliary or larger tubercles may thus arise in the smallest bronchia and later the intestines may become infected, usually through the medium of the lymphatic glands.

In an infected stable the author found in addition to 1 or 2 manifestly glanderous horses, and about the same number with suspicious symptoms, from 20 to 30 per cent apparently healthy horses which reacted in a typical manner.

On the basis of the author's investigations it is recommended that all manifestly glanderous horses be destroyed; that 2 mallein injections be made with intervals of 1 to 2 weeks; that all horses which have reacted once in a typical manner should be isolated; that the stalls should be thoroughly disinfected, as well as all drinking troughs or vessels or other utensils which could have become infected. It is also recommended that in an infected herd all horses or animals which do not react or which react in a typical manner should be subjected to systematic mallein injections with increasing doses for the period of 2 months. After the lapse of the second month 2 mallein injections of the ordinary size should be given. Horses which still react in a typical manner should either be killed or, if too numerous or valuable, may be further treated, and after the lapse of another month may be tested again, at which time, if a reaction takes place, they should be destroyed.

Mal de Caderas, O. Voges (*Ztschr. Hyg. u. Infektionskrankh.*, 39 (1902), No. 3, pp. 323-372, pl. 1).—The term Mal de Caderas is applied in South America to a disease of horses closely related to the tsetse-fly disease. It is produced by a blood parasite known as *Tripanosoma equina*. The most conspicuous symptom is a lameness of the posterior extremities, but this symptom is not always present, and the simplest and surest method of diagnosing suspected cases is by inoculation of experimental animals with the blood of suspected horses. The percentage of mortality from this disease is very high, reaching 100 per cent in some herds of horses.

The blood parasite to which the disease is due is described in considerable detail. Inoculation experiments with this parasite show that rats, rabbits, dogs, sheep, goats, guinea pigs, and poultry are susceptible to the disease, while cattle appear to be completely resistant. It is suspected that the blood parasite is carried by a biting insect, probably *Musca brava*, which is said to resemble in appearance the tsetse fly.

Report on a parasitic disease in horses, mules, and carabao in the Philippine Islands, J. J. CARTER (*Vet. Jour., n. ser.*, 5 (1902), No. 29, pp. 292-294).—An investigation of a parasitic disease which affects the carabao in the Philippine Islands disclosed the fact that the blood parasite found in these animals is identical with that reported as occurring in horses and mules and is apparently the surra parasite. Experiments have been instituted by the author, and while final results have not been reached, it appears that the disease may be readily transmitted from horses and mules to carabao or vice versa, and that the agent of transmission of the blood parasite is a biting fly closely resembling the tsetse fly. Good evidence was obtained that pastures may become infested from the presence of one diseased animal and that the disease may thus be transmitted to other animals which are allowed in the pasture soon afterwards.

Pink eye, S. WHARAM (*Vet. Jour., n. ser.*, 5 (1902), No. 28, pp. 210-215).—This disease is believed by the author to be a form of influenza due to a micro-organism which has not yet been isolated. Among the predisposing causes of the disease, mention is made of low temperature, damp atmosphere, insanitary surroundings, and improper or insufficient food, together with exhaustion from overwork. Notes are given on the symptoms, post-mortem appearances, and usual methods of prevent-

ing and treating the disease. Careful and frequent disinfection of the stables is indicated for the purpose of preventing outbreaks of this disease as far as possible.

Tetanus in dogs, DUCOURNEAU and P. JAYLES (*Rev. Vet. Toulouse*, 27 (1902), No. 1, pp. 1-5, fig. 1).—The authors present notes on the subject of tetanus in dogs. It is stated that this disease is probably more frequent in dogs than is usually suspected. In one case a dog affected with tetanus received 200 cc. of artificial serum and a few hours later 5 cc. of antitetanus serum. In this case recovery ultimately took place, although the course of the disease was not rapid and was not immediately affected by the serum treatment.

The treatment of tetanus, TENNETT (*Ztschr. Veterinärk.*, 14 (1902), No. 1, pp. 24, 25).—On account of the apparent immunity of dogs to tetanus an experiment was made in treating a case of tetanus in a horse by injections of carbolized serum from a dog. This treatment, however, gave negative results.

Malaria of dogs, NOCARD and MOTAS (*Ann. Inst. Pasteur*, 16 (1902), No. 4, pp. 257-290, pls. 2).—A general account is given of the symptoms, etiology, and treatment of this disease. Two clinical forms are distinguished; an acute form, which is almost always followed by death within a few days, and a chronic form, which may be followed after several days by recovery. The symptoms of both forms are described in detail. An elaborate description of the blood parasite is given. A number of these organisms were found within the red blood corpuscles, but the larger number are free. The organism, from a morphological standpoint, can hardly be distinguished from that of Texas fever, but it is physiologically distinguished by the fact that apparently it will not develop in any other animal than the dog. All dogs which recover from the natural attacks of the disease or from artificial inoculation are perfectly immune to further attacks. A number of experiments were made in the use of serum obtained from animals which were naturally immune or which had been hyperimmunized. It was found that the serum obtained from such immune animals exercises a destructive effect upon the organisms in the blood. Virulent blood heated to a temperature of 45° C., or more, completely loses its virulence. When heated to a temperature of 44° for periods of 1 hour no effect was apparently produced upon the vitality or virulence of the organism. The same temperature maintained for a period of 1½ hours, however, destroyed the virulence of the blood parasite.

Rabies, M. P. RAVENEL (*Pennsylvania Dept. Agr. Rpt. 1901*, pt. 1, pp. 511-532, figs. 4).—The author presents a general account of this disease, including its history, distribution, cause, method of invasion, resisting power of the virus, period of incubation, symptoms, means of diagnosis, and treatment. Statistics are presented showing the results obtained from the application of the Pasteur preventive treatment on 55,000 persons who had been bitten by mad dogs or dogs supposed to be mad.

Distribution of rabies and an experiment in combating it in the government of Moscow, A. STEPANOV (*Arch. Vet. Nauk, St. Petersburg*, 32 (1902), No. 2, pp. 156-178).—Statistics are presented showing the distribution of rabies in various domesticated animals and in man in different parts of Russia, and other countries, from 1883 to the present time. The attempt to eradicate the disease in the government of Moscow was only moderately successful, and this result is attributed by the author to the ignorance of the people with regard to the etiology and pathogenesis of this disease.

The reaction of neuroglia to the presence of rabies virus in dogs, ANGLADE and CHOCREAU (*Compt. Rend. Soc. Biol. Paris*, 54 (1902), No. 18, pp. 575-577).—As the result of numerous microscopic examinations for the purpose of determining any constant lesions which might be considered the result of rabies, the authors conclude that the reaction of neuroglia is less rapid in all other diseases than in rabies. In the latter disease the changes in the nervous elements take place very early and are of an acute and generalized nature.

Blackhead in turkeys, C. CURTICE (*Rhode Island State Bd. Agr. Rpt. 1901, pp. 287-296, pl. 1*).—The author presents a history of the discovery and investigations concerning the nature of this disease. No satisfactory treatment is known for the disease, and prompt and thorough isolation of all diseased birds is therefore necessary. In cases of extensive outbreaks or persistent occurrence of the disease the author recommends setting turkey eggs under hens, the latter fowls being unsusceptible to the disease.

Notes on the biology of the organism of cyanolophia of domestic fowls, A. LOVE (*Centbl. Bakt. u. Par., 1. Abt., 31 (1902), No. 10, Orig., pp. 448-451*).—In the author's previous investigations on this subject it was found impossible to isolate any organism from diseased fluids or tissues of affected fowls. Further experiments were made for the purpose of determining the reaction of the virus of the disease to various chemical and physical agents. It was found that sulphuric acid in a 1 per cent solution was sufficient to sterilize the virus within 10 minutes. Sterilization was also accomplished in the same time by a 2 per cent solution of potash lye, and by chlorid of lime in a 3 per cent solution in 50 per cent alcohol. While the coarser Chamberland and Berkefeld filters did not prevent the passage of the organism, it was found that the filtrate from the finer filters became sterile after allowing it to stand for a week or 10 days. Virus in which other micro-organisms or fungi were allowed to grow, rapidly lost its virulence.

Diphtheria of fowls; vaccination; serotherapy, C. GUÉRIN (*Rev. Vet. Toulouse, 27 (1902), No. 2, pp. 84-97*).—Notes are given on the symptoms of the disease and on the nature and development of the pathogenic organism. A number of experiments were tried in devising a satisfactory treatment for this disease. During these experiments it was found that pigeons were most susceptible of all domesticated birds to the disease. In pigeons the virulence of the organism was increased by successive passages. It was found to be a simple matter to transmit avian diphtheria experimentally to pigeons, either by inoculation of pure cultures, or of diphtheritic material. It was found possible also to produce a complete and lasting immunity by means of injections of attenuated virus into the peritoneum.

Yellow liver, or congenital functional debility in ostrich chicks, D. HUTCHESON (*Agr. Jour. Cape Good Hope, 20 (1902), No. 13, pp. 765-768*).—This disease occurs in the form of atrophy of the liver, with fatty degeneration of the liver cells. The abdominal and thoracic cavities usually contain a clear fluid, the musculature is pale, and the cardiac blood appears to be of lighter color and more fluid than usual. The yellow color of the liver appears to be due not to a primary disease of the liver, but to incomplete absorption of the yolk sac at the time of hatching. For preventing this disease the author recommends more careful attention to the kind and quantity of food, and regularity in feeding, together with plenty of exercise and laxative feeding during the first few days after hatching.

A pigeon epizootic caused by an invasion of *Heterakis perspicillum*, T. KAŠPAREK (*Centbl. Bakt. u. Par., 1. Abt., 31 (1902), No. 6, Orig., pp. 245-247*).—A pigeon raiser imported a pair of birds from England, which later showed signs of a wasting disease, and died. Subsequently, several other birds fell sick, and the most of them also died. An examination of some of these cases showed the presence of large numbers of *H. perspicillum*, which appeared to have been the cause of the disease. This parasite did not infect any other domesticated animal, but was, so far as observations were made, strictly confined to pigeons.

What ails the chickens? F. E. EMERY (*Wyoming Sta. Rpt. 1902, pp. 37-39*).—For destroying chicken lice it is recommended that fowls be dipped in a solution of some sheep dip, chloro-naphtholeum, or similar insecticide. It is estimated that from 10 to 12½ gals. will be sufficient for 30 to 50 fowls. The plumage should be thoroughly soaked, while care should be exercised to prevent the solution from gaining entrance to the lungs of the birds. The yards and buildings may be sprayed with

the same material, and the whole process should be repeated after 6 or 8 days. Poultry raisers are advised to give a little extra feed at molting time in order to hasten the growth of the new feathers.

Insects as carriers and spreaders of disease, L. O. HOWARD (*U. S. Dept. Agr. Yearbook 1901*, pp. 177-192, figs. 16).—A brief account is given of the agency of mosquitoes, flies, and other insects and related animals in transmitting malaria, typhoid fever, yellow fever, and other diseases. Attention is called to the difficulties met with in combating these diseases in country localities where the breeding places for flies and mosquitoes are especially favorable. Notes are given on the best measures to be adopted in destroying flies and mosquitoes in various stages, and thus preventing any opportunity of spreading malaria and typhoid.

Insects as factors in the transmission of disease, H. SKINNER (*Pennsylvania Dept. Agr. Rpt. 1901*, pt. 1, pp. 329-333).—This paper contains a brief popular account of the agency of insects, particularly mosquitoes and flies, in the transmission of malaria, yellow fever, and typhoid fever.

AGRICULTURAL ENGINEERING.

Utilizing our water supply, A. J. McCLATCHIE (*Arizona Sta. Bul. 43*, pp. 59-141, figs. 9).—This is a discussion of the best means of utilizing the water supply of Arizona, especially that of the Salt River Valley, based largely on investigations at the station (E. S. R., 14, p. 195) on "the amount of water needed by various crops, the returns per acre of land and per acre-foot of water, from the application of a given amount of water, and the best methods of irrigating various crops." The sources, fluctuation, and total and available amounts of the water supply; appropriation, distribution, and duty of the water supply; and means of increasing the available amount and duty of the supply, are discussed.

The watershed of the Salt River covers an area of 12,000 square miles. Its topography and climate are such as to cause great variations in the flow of the streams that drain it, but the average flow of Salt River below the mouth of its largest tributary, the Verde, has been approximately 1,200,000 acre-feet per year during the past 41 years. There are 275,000 acres of land under canal in Salt River Valley. This is more than the total water supply will irrigate. The amount of water actually used for irrigation is less than one-half of the total supply. It is estimated that the water supply at present available would properly irrigate 110,000 acres, which might be safely increased to 160,000 or 180,000 acres by the construction of the proposed Tonto reservoir.

Development and application of water near San Bernardino, Colton, and Riverside, Cal., J. B. LIPPINCOTT (*Water Supply and Irrig. Papers, U. S. Geol. Survey, Nos. 59, 60*, pp. 141, pls. 11, figs. 14).—These papers describe the general conditions of water supply in this important and densely populated region, where the value of water for irrigation is very high. The topics discussed are general location and topography, soil, climate, crops, and water supply. Descriptions are given of the streams tributary to the region, the irrigation systems, artesian wells, and pumping plants. "The data are of particular interest because of the developments made during the dry years which culminated in 1890. Every possible expedient was resorted to for economizing or increasing the supply of water; tunnels were driven into the hills, dams were built to bed rock in the canyons, and wells were dug or drilled throughout the valleys. Almost every conceivable device for pumping water has been employed and great ingenuity displayed in bringing water to the orchards and more valuable crops. The details of some of the works and wells have been brought together by Mr. Lippincott, and form an exhibit of results accomplished under conditions where water has great value."

Fourth report of an investigation of the rivers of Ohio as sources of public water supplies, 1901 (*Columbus: Ohio State Board of Health, 1902, pp. 220, charts 57*).—This is reprinted from the fifteenth annual report of the Ohio State Board of Health, pp. 379-603.

Hydrography of the Southern Appalachian Mountain region, H. A. PRESSEY (*Water Supply and Irrig. Papers, U. S. Geol. Survey, Nos. 62, 63, pp. 190, pls. 44*).—This report "is the outcome of systematic measurements of the water supply from this area and of special investigations made in connection with a general inquiry as to the importance of the streams in the development of the country." It contains a discussion of the general features of the region, the drainage basins, and the flow of the various streams of the region.

Some typical reservoirs in the Rocky Mountain States, E. MEAD (*U. S. Dept. Agr. Yearbook 1901, pp. 415-430, pls. 7*).—Accounts are given of a number of typical reservoirs in Colorado and Utah, with special reference to cost of construction and the benefits derived from the use of the stored waters.

The Nile reservoir dam at Assuân, and after, W. WILLCOCKS (*Jour. Khediv. Agr. Soc. and School Agr., 4 (1902), No. 4, pp. 136-160*).

A practical irrigating system, H. M. ALBAGH (*Ohio Farmer, 101 (1902), No. 22, p. 485, fig. 1*).—A brief account of irrigation plants of S. Preslan and C. H. Thompson used in growing garden truck for the Cleveland market.

Supplementary report on irrigation in Natal, F. V. CORBETT (*Agr. Jour. and Min. Rec., 5 (1902), No. 10, pp. 309-312*).

How to build small irrigation ditches, C. T. JOHNSTON and J. D. STANNARD (*U. S. Dept. Agr., Farmers' Bul. 158, pp. 28, figs. 9*).—A reprint of an article originally published in the Yearbook of this Department for 1900 (*E. S. R., 13, p. 289*).

The measurement of water for irrigation, B. P. FLEMING (*Wyoming Sta. Bul. 53, pp. 58-117, figs. 8*).—A nontechnical discussion of the principles of measurement of water and the construction and use of cheap and efficient measuring devices prepared with a view to meeting the numerous requests for information on the subject and to supplement the reports of the station investigations on the duty of water and the moisture requirements of different crops. A digest of the water laws of Wyoming is also given.

Accuracy of stream measurements, E. C. MURPHY (*Water Supply and Irrig. Papers, U. S. Geol. Survey, No. 64, pp. 99, pls. 4, figs. 30*).—This paper gives the results of investigations into the accuracy of stream measurements as ordinarily conducted by the hydrographers of the U. S. Geological Survey, with special reference to the instruments commonly employed.

Floods and flood warnings, H. C. FRANKENFIELD (*U. S. Dept. Agr. Yearbook 1901, pp. 477-486*).—This is a brief discussion of the factors determining the volume, extent, and duration of floods, the characteristics of the river systems of the Atlantic Coast and the Mississippi Valley with reference to floods, and the government work in forecasting river stages.

Preliminary list of deep borings in the United States. Part II, Nebraska and Wyoming, N. H. DARTON (*Water Supply and Irrig. Papers, U. S. Geol. Survey, No. 61, pp. 67*).—An account of a continuation of investigations noted elsewhere (*E. S. R., 13, p. 1103*).

American farm implements, P. McCONNELL (*Jour. Bath and West. and South. Counties Soc. [England], 4. ser., 12 (1901-2), pp. 18-35, figs. 6*).—A brief account of the principles of construction and use, and the merits of some American (including Canada and the United States) makes of hay rakes, reaping and mowing machines, thrashing machines, chaff cutters, plows, cultivators, seeders, manure spreaders, wagons, horsepowers, and windmills. The author concludes that a large proportion of American implements are "too slim and easily broken" for use in Great Britain,

where the crops, the climate, and the soil are very different from those of America, but that the principles of these implements are capable of adoption in that country and often even the implements themselves, with very slight modifications. He urges the importance of wider use of such labor-saving implements.

The American plow for the Russian trade (*Amer. Inventor*, 9 (1902), No. 14, pp. 214, 215, figs. 8).—Illustrated descriptions of the kinds of plows used by Russian farmers.

Hay or straw baling presses, A. J. PERKINS (*Jour. Agr. and Ind. South Australia*, 6 (1902), No. 2, pp. 91-96, figs. 7).—A brief discussion of the work of certain recently introduced continuous baling presses.

Horsepower as indicating work of steam and oil engines, W. R. JAMIESON (*Jour. Agr. and Ind. South Australia*, 6 (1902), No. 2, pp. 106, 107).—A brief explanation of the terms brake horsepower, indicated horsepower, and normal horsepower. The first is said to represent "the useful power of which an engine is capable." The indicated horsepower is about 10 per cent higher, while the normal horsepower is about two-fifths of the brake horsepower.

The modern harvest field (*Country Life* [London], 12 (1902), No. 296, pp. 318, 319, figs. 2).—Mainly a discussion of the use of motors for driving harvesters, plowing the stubble, and other purposes, with brief reference to a petroleum motor recently tried for these purposes in Lincolnshire, England.

On injection motors, L. LECORNU (*Compt. Rend. Acad. Sci. Paris*, 134 (1902), No. 26, pp. 1566-1568).

Proceedings of the Third Annual Good Roads Convention of the Boards of Supervisors of the State of New York (*U. S. Dept. Agr., Public Road Inquiries Bul.* 22, pp. 63, pls. 13).—Proceedings and papers of the convention held at Albany, N. Y., January 28 and 29, 1902. The information contained in this bulletin relates especially to the advantages of the State-aid plan as practiced in New York. Among the papers presented were *A Few Practical Suggestions on Road Building*, by C. W. Ross; *The League of American Wheelmen and the 'Good Roads' Law*, by L. H. Washburn; *Wide Tires*, by F. M. Power; *The Press and Good Roads*, by A. H. Battey; *Relation Between Macadam Roads and Electric Street Railways*, by E. P. North, and *The Relation of Common Roads to Railroads*, by L. M. Haupt.

Pennsylvania's road system, J. HAMILTON (*Pennsylvania Dept. Agr. Rpt.* 1901, pt. 1, pp. 554-558).—A brief account of the improvements that have been made and of the needs of the system.

City roads and pavements suited to cities of moderate size, W. P. JUDSON (*New York: The Engineering News Pub. Co.*, 1902, pp. 195, figs. 67).—This is the second revised and enlarged edition of a work first issued several years ago. In this revision special effort has been made to incorporate the latest information with reference particularly to concrete base, block stone, wood, vitrified brick, asphalt, and bituminous pavements, and broken-stone roads.

New covering for roads (*Tradesman*, 48 (1902), No. 4, p. 71).—A brief reference to a report by the United States consul at Rouen calling attention to the use in France of a mixture of blast-furnace slag and tar as a covering for roads. It is claimed by the inventor, who is an Englishman, that when carefully pressed down with heavy rollers the covering renders the surface of the road impervious to water and free from dust.

Road making from the engineer's standpoint, A. W. CAMPBELL (*Pennsylvania Dept. Agr. Rpt.* 1901, pt. 1, pp. 428-436).—A general discussion of this subject.

Road building with convict labor in the Southern States, J. A. HOLMES (*U. S. Dept. Agr. Yearbook* 1901, pp. 319-332, pls. 5).

Government cooperation in object-lesson road work, M. DODGE (*U. S. Dept. Agr. Yearbook* 1901, pp. 409-414, pls. 2).

Mountain roads as a source of revenue. J. W. ABBOTT (*U. S. Dept. Agr. Year-book 1901*, pp. 527-540, pls. 7).—The advantages of the construction of good roads through scenic regions are discussed.

The new farm buildings. F. B. LINFIELD (*Utah Sta. Rpt. 1901*, pp. XLII-XLVI, pls. 4, fig. 1).—The location and construction of a \$10,000 cattle barn and a \$2,000 sheep barn recently built at the station are briefly described. Other buildings, including a piggery and poultry house, are to be added in time. "In planning the buildings, their arrangement, and location, the aim was to provide a separate building for each class of live stock, with ample storage for all the feed required during the winter season. They were located to give a maximum of sunlight, yet to have them as close together as possible and conveniently grouped."

The pressure of stored grain on the sides of the receptacles containing it. D. N. GOLOVIN (*Izv. Moscow Selsk. Khoz. Inst. [Ann. Inst. Agron. Moscou]*, 8 (1902), No. 2, pp. 168-208).—Investigation of the laws of the pressure of grain on the sides and bottom of the vessels containing it was begun only recently, but a number of publications have appeared on the subject. A summary of their contents is given in the present article.—P. FIREMAN.

Refrigerating machinery; its principles and management. A. R. LEASK (*London: Simpkin, Marshall & Co., Ltd., 1901*, 2. ed., pp. IX+296, figs. 74).

Refrigerating and ice-making machinery. A. J. WALLIS-TAYLER (*London: Crosby Lockwood & Son, 1902*, 3. ed. ent., pp. XVIII+376, pls. 2, figs. 103).

Refrigeration, cold storage, and ice making. A. J. WALLIS-TAYLER (*London: Crosby Lockwood & Son; New York: D. Van Nostrand Co., 1902*, pp. XXXI+654, figs. 361).

Materials of construction—a treatise for engineers on the strength of engineering materials. J. B. JOHNSON (*New York: John Wiley & Sons, 1902*, 4. ed. ent., pp. 795, ill.).

MISCELLANEOUS.

Bulletins and annual reports of Arizona Station. H. J. HALL (*Arizona Sta. Index to Vol. I, Buls. 1-25, and Ann. Rpts. 1890-1897*, pp. III+16; *Vol. II, Buls. 26-32, and Ann. Rpts. 1898-99*, pp. 293-306).—A general index.

Twenty-fifth Annual Report of Connecticut State Station, 1901 (*Connecticut State Sta. Rpt. 1901*, pp. XVI).—These pages accompany Part IV of the report and contain the organization list of the station, a report on the work of the station during the year, and a financial statement for the year ended September 30, 1901.

General index to reports and bulletins, volumes 1 to 20, 1882 to 1901 (*Ohio Sta. Bul. 128, Index Sup.*, pp. 247-292).

Eleventh Annual Report of Oklahoma Station, 1902 (*Oklahoma Sta. Rpt. 1902*, pp. 14-79).—This includes a report of the director on the work of the station during the year, a meteorological summary, a financial statement for the fiscal year ended June 30, 1902, and reprints of press bulletins, as follows: Wheat experiments; pasturing wheat; selection of cotton seed; broom corn; Bermuda grass; rape for early spring feed; alfalfa in Oklahoma; feeding wheat; stock feeding; wheat meal, bran, and shorts; rations for fattening steers; feeding cotton-seed products to steers; feeding cotton-seed meal to hogs; a good pear; a good grape; fruit trees; spray apple trees; cultivate trees; fall planting of trees; plant trees and care for them; blackberries in Oklahoma; potato growing; animal parasites; vaccination to prevent blackleg; loco investigations; woolly aphis; borers in soft maples; and protection against plant diseases and insects.

Fourteenth Annual Report of Oregon Station, 1902 (*Oregon Sta. Rpt. 1902*, pp. 12, 46-80).—This includes a financial statement for the fiscal year ended June 30, 1902, a report of the director reviewing the different lines of station work, and departmental reports, parts of which are noted elsewhere.

Twelfth Annual Report of Utah Station, 1901 (*Utah Sta. Rpt. 1901*, pp. *LIV*).—This contains the organization list of the station, a report of the director reviewing the work of the station during the year and outlining proposed work, departmental reports, a list of bulletins issued by the station, acknowledgments, and a financial statement for the fiscal year ended June 30, 1901. The report of the agronomist reviews the work done during the year, especially in irrigation, culture experiments, and the destruction of dodder. The report of the horticulturist gives a detailed outline of experiments in progress. The report of the irrigation engineer contains observations on seepage and evaporation.

Twelfth Annual Report of Wyoming Station, 1902 (*Wyoming Sta. Rpt. 1902*, pp. 63).—This includes the organization list of the station, a report of the director, abstracts of Bulletins 50-53 of the station issued during the year, reprints of press bulletins noted elsewhere, a list of acknowledgments, a financial statement for the fiscal year ended June 30, 1902, and reports of the heads of departments.

Crop Reporter (*U. S. Dept. Agr., Division of Statistics Crop Reporter*, 4 (1902), Nos. 4-6, pp. 8 each).—These numbers contain reports upon the condition of crops in the different States and Territories on August 1, September 1, and October 1, 1902, and information of a statistical nature concerning particular crops in the United States and crop conditions in foreign countries.

Yearbook of the Department of Agriculture, 1901 (*U. S. Dept. Agr. Yearbook 1901*, pp. 846, pls. 90, figs. 52).—The Yearbook for 1901 has been prepared on the same general plan as in the past. It includes a report of the Secretary, giving a general review of the operations of the Department during the year, 33 miscellaneous articles noted elsewhere, and an appendix containing the usual statistical matter and other information of interest to farmers.

Agriculture in the tropical islands of the United States, O. F. COOK (*U. S. Dept. Agr. Yearbook 1901*, pp. 349-368, pls. 6).—The more important crops that can be successfully grown in the Tropics are mentioned and briefly described, suggestions being given as to their nature, the regions where they are most likely to be successful, and the possibility of their commercial success.

Agricultural investigations in the island possessions of the United States, W. H. EVANS (*U. S. Dept. Agr. Yearbook 1901*, pp. 503-520).—A historical review is given of the various attempts that have been made in promoting agricultural investigations and agricultural instruction in Porto Rico, Hawaii, and the Philippine Islands.

The future demand for American cotton, J. L. WATKINS (*U. S. Dept. Agr. Yearbook 1901*, pp. 193-206).—The comparative use of cotton, wool, flax, and silk is discussed, and statistics are given on the production and consumption of cotton in different countries.

The cotton-seed industry, C. M. DAUGHERTY (*U. S. Dept. Agr. Yearbook 1901*, pp. 285-298).—This is an account of the growth and present status of the cotton-seed industry in the United States.

Wheat ports of the Pacific Coast, E. S. HOLMES (*U. S. Dept. Agr. Yearbook 1901*, pp. 567-580, pls. 5).—The author describes the ports of San Francisco, Portland, Seattle, and Tacoma, and also the grain fleet of the Pacific Coast, and gives statistics on the exports of wheat and flour and on ocean freight rates.

Some problems in the rural common school, A. C. TRUE (*U. S. Dept. Agr. Yearbook 1901*, pp. 133-154, pl. 1, figs. 4).—The author points out some of the weaknesses of the rural common schools in our present system of education and shows how some of these defects are being overcome in a number of States by erecting or utilizing central schools and bringing the children in public conveyances to them, grading up the central school and introducing studies in the curriculum more closely related to the practical business of the farm, securing teachers in sympathy with farm life, making the schools more largely the center of the intellectual life of the community, and by the cooperation of the farmer and his family with the teachers and pupils through institutes and like agencies.

List by titles of publications of the United States Department of Agriculture from 1840 to June, 1901, inclusive, R. B. HANDY and MINNA A. CANNON (*U. S. Dept. Agr., Division of Publications Bul. 6, pp. 216*).

Nature study and life, C. F. HODGE (*London and Boston: Ginn & Co., 1902, pp. 514, pl. 1, figs. 196*).—This is a practical treatise on nature study, the subject being treated from the standpoint of living things. It contains a vast amount of suggestive and useful information regarding domestic animals and native plants, insects, birds, and lower forms of animal life. Much of it has an agricultural and economic bearing. Thus, detailed directions are given for the growing of an apple tree, peach tree, grapevine, etc., from the planting of the seed to the grafting or budding of the plants, and the after treatment as fruit trees. A chapter on our common birds is considered from the standpoint of what birds do, and their value in the community and to farm life is clearly brought out. Most of the insects treated are those directly related to our orchard, garden, and field crops, and to the household. A chapter is given on elemental forestry, and another on flowerless plants, like ferns, mosses, and mushrooms. A final chapter contains suggestions for lessons with plants and animals, suited to the different grades in the school.

NOTES.

CALIFORNIA UNIVERSITY AND STATION.—Among some of the most imperative needs of the university, as set forth by President Wheeler in a recent number of *Sunset*, are the establishment of a school of forestry and a university farm, "with full equipment to illustrate all the usual agricultural processes." E. W. Major, a graduate of the University of Minnesota and for several years an assistant in the dairy department of the station, has been appointed instructor in dairy husbandry in the university, and has entered upon his duties. His first task was the organization of the ten weeks' course in dairying, upon which 26 students have entered. W. A. Setchell, professor of botany in the university and botanist to the station, has been granted his sabbatical leave of absence for one year from July 1, 1903. Through a misunderstanding, it was announced in the October number of the *Record* that J. Burt Davy had resigned his position in the university and station to accept a position in the Bureau of Plant Industry of this Department. It is now learned that Mr. Davy will retain his position of instructor in the university and assistant botanist to the station, but has been granted leave of absence for one year, during which he will carry on studies in economic botany in this Department, with the title of assistant curator.

COLORADO COLLEGE AND STATION.—S. Arthur Johnson, a graduate of Rutgers College, has been appointed assistant entomologist, vice E. D. Ball, who, as previously noted, has gone to Utah.

CONNECTICUT STORRS STATION.—The headquarters of the station have recently been moved from Middletown to Storrs, and hereafter the business of the station will be conducted at the latter place. Its work will be broadened somewhat and developed along the lines of poultry investigations, horticulture, dairying, and soil tillage. E. R. Bennett, a graduate of the Michigan Agricultural College and deputy inspector of orchards in Michigan, has been appointed assistant horticulturist of the station. He will devote his entire time to experiment station work, and will investigate especially matters concerning small fruits and truck gardening. A bacteriological laboratory is being fitted up at Storrs, where investigations will be conducted in dairy and soil bacteriology under the supervision of Dr. H. W. Conn. The staff of the station as at present organized is as follows: L. A. Clinton, acting director and agriculturist; A. G. Guley, horticulturist; W. O. Atwater, supervisor, nutrition investigations; H. W. Conn, supervisor, dairy bacteriology; C. L. Beach, dairy husbandman; W. A. Stocking, jr., assistant bacteriologist; F. H. Stoneburn, poultryman; E. R. Bennett, assistant horticulturist; H. L. Garrigus, assistant, field experiments; W. M. Esten, laboratory assistant; B. F. Koons, consulting entomologist; C. A. Meserve, consulting chemist; E. H. Lehnert, consulting veterinarian; E. A. White, consulting botanist.

IOWA STATION.—C. E. Gray, assistant chemist of the station, has resigned to accept the position of chemist of the Continental Creamery Company, Topeka, Kans.

MINNESOTA STATION.—A. G. Ruggles has been appointed assistant entomologist of the station.

List by titles of publications of the United States Department of Agriculture from 1840 to June, 1901, inclusive, R. B. HANDY and MINNA A. CANNON (*U. S. Dept. Agr., Division of Publications Bul. 6, pp. 216*).

Nature study and life, C. F. HODGE (*London and Boston: Ginn & Co., 1902, pp. 514, pl. 1, figs. 196*).—This is a practical treatise on nature study, the subject being treated from the standpoint of living things. It contains a vast amount of suggestive and useful information regarding domestic animals and native plants, insects, birds, and lower forms of animal life. Much of it has an agricultural and economic bearing. Thus, detailed directions are given for the growing of an apple tree, peach tree, grapevine, etc., from the planting of the seed to the grafting or budding of the plants, and the after treatment as fruit trees. A chapter on our common birds is considered from the standpoint of what birds do, and their value in the community and to farm life is clearly brought out. Most of the insects treated are those directly related to our orchard, garden, and field crops, and to the household. A chapter is given on elemental forestry, and another on flowerless plants, like ferns, mosses, and mushrooms. A final chapter contains suggestions for lessons with plants and animals, suited to the different grades in the school.

NOTES.

CALIFORNIA UNIVERSITY AND STATION.—Among some of the most imperative needs of the university, as set forth by President Wheeler in a recent number of *Sunset*, are the establishment of a school of forestry and a university farm, "with full equipment to illustrate all the usual agricultural processes." E. W. Major, a graduate of the University of Minnesota and for several years an assistant in the dairy department of the station, has been appointed instructor in dairy husbandry in the university, and has entered upon his duties. His first task was the organization of the ten weeks' course in dairying, upon which 26 students have entered. W. A. Setchell, professor of botany in the university and botanist to the station, has been granted his sabbatical leave of absence for one year from July 1, 1903. Through a misunderstanding, it was announced in the October number of the *Record* that J. Burt Davy had resigned his position in the university and station to accept a position in the Bureau of Plant Industry of this Department. It is now learned that Mr. Davy will retain his position of instructor in the university and assistant botanist to the station, but has been granted leave of absence for one year, during which he will carry on studies in economic botany in this Department, with the title of assistant curator.

COLORADO COLLEGE AND STATION.—S. Arthur Johnson, a graduate of Rutgers College, has been appointed assistant entomologist, vice E. D. Ball, who, as previously noted, has gone to Utah.

CONNECTICUT STORRS STATION.—The headquarters of the station have recently been moved from Middletown to Storrs, and hereafter the business of the station will be conducted at the latter place. Its work will be broadened somewhat and developed along the lines of poultry investigations, horticulture, dairying, and soil tillage. E. R. Bennett, a graduate of the Michigan Agricultural College and deputy inspector of orchards in Michigan, has been appointed assistant horticulturist of the station. He will devote his entire time to experiment station work, and will investigate especially matters concerning small fruits and truck gardening. A bacteriological laboratory is being fitted up at Storrs, where investigations will be conducted in dairy and soil bacteriology under the supervision of Dr. H. W. Conn. The staff of the station as at present organized is as follows: L. A. Clinton, acting director and agriculturist; A. G. Gulley, horticulturist; W. O. Atwater, supervisor, nutrition investigations; H. W. Conn, supervisor, dairy bacteriology; C. L. Beach, dairy husbandman; W. A. Stocking, jr., assistant bacteriologist; F. H. Stoneburn, poultryman; E. R. Bennett, assistant horticulturist; H. L. Garrigus, assistant, field experiments; W. M. Esten, laboratory assistant; B. F. Koons, consulting entomologist; C. A. Meserve, consulting chemist; E. H. Lehnert, consulting veterinarian; E. A. White, consulting botanist.

IOWA STATION.—C. E. Gray, assistant chemist of the station, has resigned to accept the position of chemist of the Continental Creamery Company, Topeka, Kans.

MINNESOTA STATION.—A. G. Ruggles has been appointed assistant entomologist of the station.

NEW YORK CORNELL STATION.—A live-stock judging pavilion is now under construction. The judging room will be 26 by 36 ft., and will greatly facilitate the practical work with animals, and incidentally the building will be available for other uses.

NORTH CAROLINA STATION.—Franklin Sherman, jr., who for some time has been employed as entomologist to the State department of agriculture, has been placed upon the station staff as entomologist. Nineteen head of thoroughbred Aberdeen Angus cattle were purchased in the vicinity of Columbus, Ohio, during the past summer and are now being inoculated by the veterinarian of the station, preparatory to sending out to farmers in different parts of the State for whom the purchases were made. Thirty-nine head of the same breed of cattle were purchased in Missouri the past winter and inoculated against Texas fever. A portion of these animals were also obtained for farmers, the rest being purchased for the use of the station and the State department of agriculture.

PENNSYLVANIA STATION.—Thorpe M. Carpenter, recently of the Massachusetts Station, Leonard R. Cook, of Purdue University, and H. L. Wilson, of the University of Virginia, have been appointed assistant chemists of the station, vice M. S. McDowell, C. W. Norris, and N. W. Buckhout, whose resignations have been previously noted.

TENNESSEE STATION.—A new two-story barn, 20 by 48 ft., has just been completed at a cost of about \$400. This barn is intended for cattle feeding under the conditions prevailing on farms in Tennessee, and is designed especially for experiments with stock cattle to be fed on cheap rough fodder and a light grain ration, and finished on grass the following summer. The barn contains 4 pens, 12 by 14 ft., calculated to accommodate 4 lots of 4 cattle each, and has ample storage space above for the rough fodders. The pens connect with an open air yard so that the cattle can be turned out in good weather. In a barn previously erected 16 head of cattle will be fed on a heavy grain and silage ration during this winter and finished for the April market. The object of this experiment, and those provided for in the new barn, is to determine whether the farmers of Tennessee should winter feed their cattle and finish them for the spring market, or carry them through the winter on a cheap ration and finish on grass for the autumn market. During the present winter the station will have more than 100 head of beef and dairy cattle, horses, mules, sheep, and swine, on feeding experiments.

U. S. DEPARTMENT OF AGRICULTURE.—A. S. Hitchcock, of the Bureau of Plant Industry, has been spending some time in Europe, studying especially the sand-binding grasses and their management in Holland, Belgium, France, and Germany. He will return about January 1. A. D. Hopkins has returned from an extended trip to Arizona, southern California, northern Idaho, the Puget Sound country, and the Black Hills, where he has been studying the damage done to timber by insects.

MISCELLANEOUS.—During the past season the North Carolina State board of agriculture has continued field experiments at two substations or test farms in the two ends of the coastal-plain section of the State, the tests being with fertilizers, culture methods, rotations, and varieties of corn, cotton, and peanuts; fertilizer tests with bright tobacco, and an experiment in growing Cuban tobacco on bright tobacco soils. Some cooperative work has also been done in testing varieties of corn and cotton which have been found by previous experiments at these farms to give good results, and the work at the farms has been supplemented by laboratory work. A third farm has been established on the red clay land in the Piedmont section, and experimental work will be taken up on this farm next spring. These farms are maintained exclusively with the funds of the State board of agriculture.

H. M. Cottrell, formerly of the Kansas College and Station, is now professor of agriculture in Ruskin College, located at Trenton, Mo. Ruskin College is the central institution of a number of cooperative associations of which Walter Vrooman is the

leading spirit. Thomas E. Will, formerly president of the Kansas College, is professor of social science in the same institution.

The annual report of the board of agriculture of Great Britain for 1901-2, just received, shows that the total amount of grants by the board for agricultural education and research was £7,950 (about \$38,700). The report indicates that the board of agriculture is being brought into closer touch with the educational work in charge of the county councils. These councils are "evinced an increasing desire to avail themselves of the assistance of the board, in its advisory capacity, in the development of their educational schemes so far as these bear upon agriculture or rural science." The need of such central coordinating influence has been quite apparent. Most of the county councils have now settled down to elaborate the details of the educational schemes which they have initiated. The board has also been associated with the board of education in the preparation of syllabi for use in rural schools and classes. Continuing the policy of the board to establish and develop collegiate centers, a movement is on foot to secure such an agricultural collegiate center for the southwest of England, although it has not yet taken definite form. The expansion of systematic horticultural instruction by the various collegiate centers is mentioned as a prominent feature of the work. This appears to be largely extension work in the form of lectures and demonstrations, visits to gardens, and the furnishing of advice. In the counties of Cumberland and Northumberland fruit stations have also been established which are thought to promise much success. During the year a fine group of educational buildings was completed at the Yorkshire farm of Garforth, and very extensive additions were made to the class rooms, laboratories, and dormitories of the Southeastern Agricultural College at Wye. It is mentioned that in both cases these additional facilities were the result of a demand rather than an anticipated growth. The college at Wye has been formally affiliated with the University of London.

Science states that in consequence of the removal of Prof. D. A. Gilchrist, the head of the agricultural department at Reading College, to a similar position at Durham College, Newcastle, the department has been reorganized, and the following appointments made: To be lecturer in agricultural botany and director of the agricultural department, John Percival, vice principal of the Southeastern Agricultural College at Wye; to be lecturer in the practice of agriculture, J. O. Peet; to be lecturer in dairy farming and dairy bacteriology, C. W. Walker-Tisdale; to be director of the horticultural department, Frederick Keeble, lecturer in botany at University College, Reading; to be lecturer in horticulture and keeper of the gardens, William H. Patterson.

The report of the Nova Scotia School for Horticulture for the year 1901 has just been received. This school is located at Wolfville, and is in charge of Prof. F. C. Sears, formerly connected with the Kansas and Utah stations. The year is reported as in many respects the most successful in the history of the institution. The total attendance of the school was 68 students, 58 of whom were from Nova Scotia, 7 from New Brunswick, and 3 from Prince Edward Island. The school year opens November 1 and closes May 1, and the course covers two years. The work of the school has been encouraged through the passage by the provincial legislature of "an act to encourage horticulture," appropriating \$1,000 a year for the establishment in each county of one or more model orchards, with an experimental plat in connection with the School of Horticulture. The execution of this act is in the hands of the provincial secretary of agriculture and the director of the School of Horticulture. Two of the model orchards were established during the year, and the experimental plat at the school was started. "The plan for the model orchards is to make them as far as possible what their name implies, models that may be followed with profit by all growers in the sections where they are established. To this end the most up-to-date methods will be followed in caring for the land, fertilizing, spraying, and pruning.

But besides being models as to methods, it is hoped to make them of use experimentally, and therefore a few trees each of a number of new varieties of fruits will be included in each orchard. Each plantation will include apples, pears, plums, cherries, peaches, apricots, quinces, crab apples, and all kinds of small fruits." On the experimental plat of the school varieties of most of these fruits were set out, together with a long list of ornamental trees and shrubs; and experiments were made in growing a variety of cover crops for orchards. The work of holding "agricultural meetings" has been continued, the report mentioning 23 such meetings during the year which were attended by the principal of the school.

Under the direction of the board of advisers of the faculty and alumni of the New York State College of Forestry, a periodical publication, known as the *Forestry Quarterly*, has appeared. The objects to which this journal is devoted are to aid in the establishment of rational forest management, to offer an organ for the publication of technical papers of interest to professional foresters in America, and, by means of abstracts, to keep the profession in touch with the current literature and forestry movement in the United States.

A new journal on moor culture, entitled *Hedeselskabets Tidsskrift*, has appeared. The journal is to be published monthly by the Moor Society of Aarhus, and is devoted to a discussion of the usual problems met with in the cultivation of swampy areas, including particularly the culture of grasses and other crops which can be raised in such conditions, and reports of fertilizer experiments.

A note in *Nature* states that Lord Curzon, the viceroy of India, has ordered the heads of the veterinary, survey, forest, meteorological, geological, agricultural, and botanical departments of India to form a board of economic inquiry, which shall meet twice annually to formulate a programme and to review past work. The board is also to act as an advisory committee to the Government.

In order to encourage the cultivation of plants grown by children attending the elementary schools, the education board at Barbados, British West Indies, has issued a list of 50 prizes, varying in value from \$2 to 25 cents each, to be offered by the Imperial Department of Agriculture at an exhibition to be held at Dodd's Plantation, January 13, 1903. The plants exhibited must be grown and cared for by the exhibitor. As a further means of promoting this work the Imperial Department of Agriculture distributes small packages of vegetable seeds to the different schools.

EXPERIMENT STATION RECORD.

VOL. XIV.

JANUARY, 1902.

NO. 5

As the representatives of this Office have visited the experiment stations in different parts of the country during the past year they have been deeply impressed with the fact that many of our most successful station officers are being overworked. This is chiefly due to the great variety of services which they are called upon to perform. Teaching, lecturing at farmers' institutes and elsewhere, writing books, compiling bulletins and newspaper articles, corresponding with a large number of persons on a great variety of subjects, attending meetings of associations, agricultural fairs, etc., absorb a large amount of time and energy; and when to these things is added the earnest pursuit of new knowledge by night and by day, with perhaps very little vacation from year to year, the worker either breaks down prematurely or else, as most frequently happens, the character of his work increasingly approximates the level of mediocrity.

A part of the blame for this unfortunate state of things is undoubtedly to be laid to the charge of the workers themselves. Success in one line often tempts men to broaden their operations to cover lines of effort for which they have no special fitness. An itching for popular applause or the fascinations of administrative functions seduce many investigators to neglect their laboratories for the office and the lecture platform. The notion that a man is great according to the multiplicity of his works, rather than their permanent value, is widespread among us. The vast and complicated operations of the leaders of our industrial system are too often taken as a model to be followed as far as possible in our educational and scientific institutions.

To have one's ear constantly to the telephone, to dictate rapidly to a stenographer, to be ever on the move in a limited express train—the American scientist seems often to think he is deprived of his rightful privileges if he can not do all these things. To sit down quietly to plan a thorough investigation of a particular problem, and to pursue details of that plan month after month until the solution is gained, is one of the most difficult things to do amid the feverish activity of our modern world.

NOTE.—These notes are from the Annual Report of the Office of Experiment Stations for 1902.

Many men attribute their failure to achieve success as investigators to their environment, when the trouble is really in themselves. Complaints about lack of time and funds and opportunities count for very little when they come from men who are evidently spreading the scope of their operations beyond a reasonable limit, or who can not produce well-conceived and carefully thought out plans of research. When a station worker tells us in one breath that he can not investigate because he is overloaded with teaching, and in the next informs us that his spare time is occupied in the private management of a large farm, or that he is on the lookout for an opening as college president, we can hardly be expected to sympathize with him if he proves a failure as an investigator.

But on the other hand the failure of station officers to reach their highest efficiency as investigators must in very many cases be attributed to the conditions under which they are compelled to work. Without doubt many advantages have accrued to our stations from their union with colleges, but many evils have also befallen them because of the crude condition of these educational institutions.

Too many of our agricultural colleges are even yet in the high-school stage, and the number of class-room periods required of members of their faculties is reckoned on that basis. This condition is aggravated by the recent popularity of these colleges, which has swelled the number of their students beyond their capacity to accommodate, and has thus materially increased the labors of the teaching staff. When to this is added the success of our experiment stations to such an extent that their correspondence and outside calls for assistance have swelled to vast proportions, and the success of the farmers' institutes and other forms of college extension work among farmers, the demands upon many of our station workers have exceeded their powers of physical and mental endurance.

The recent splendid liberality of many of our State legislatures toward the agricultural colleges in provisions for their equipment with buildings and apparatus is most praiseworthy, but even this has, at least temporarily, laid heavier and most distracting burdens on our station workers. Enlarged material equipment and increased numbers of students are, without doubt, putting heavy burdens upon college presidents and boards of management, who must care for these things and provide teachers for the daily routine of college courses. Their task is a most difficult one, and the public needs to have a more intelligent appreciation of its requirements.

It is nevertheless very important that the just claims of the experiment stations to the best services of able investigators should be duly considered and adequately met.

The value of experiment stations as agencies for the improvement of farm practice, and as instruments for the enlargement of the science of agriculture on which the courses in our agricultural schools and colleges are based, is becoming more apparent with each passing year. Theoretically this is more generally acknowledged by the managers of our colleges; but many of them are still urging what they consider valid reasons for refusing to transmute this theory into practice. And our observations of the past year convince us that there has never been a time when it was more necessary to plead on behalf of our successful station workers that they be relieved from onerous and multifold routine duties, in order that their vigor may be long maintained and their best energies be given to experimental research on behalf of agriculture.

More attention should, in our judgment, be given by the managers of our stations to the hours of labor required of, and the seasons of rest afforded and even enforced upon, our successful station workers. After proper training for research has been acquired, the length of the period during which sustained efforts of the highest order are successfully made is a most important factor in the success of the agricultural investigator. What a waste and loss when the man whose early career gives promise of much fruit of research breaks down in middle life, and either dies or lives on in the shadows of mediocrity. Good investigators are exceedingly rare, and it is really the duty of boards of control and college presidents to seek out such men and to guard them carefully against overwork and dissipation of energy.

We plead, therefore, for a broader and deeper study of the human side of our institutions of agricultural research, in order that there may be a richer and more continuous return for the great outlay which our people are making in the hope of benefiting agriculture, and that there may be a greater enriching of the intellectual side of our agricultural colleges, the permanent success of which depends after all very largely on the work of their research departments.

In former reports it has been urged that it is unwise for stations with limited funds to maintain so many different departments that the funds available for the expenses of experiments other than salaries are very small. This we would continue to urge, at the same time recognizing that under existing conditions it is practically essential that even stations having only the Hatch fund for their maintenance shall be divided into several departments. It is therefore all the more desirable that in some way additional funds shall be obtained to enable the stations to conduct their operations on a larger scale.

More funds are also required to enable the stations to engage in experimental inquiries in lines which they have hitherto neglected.

In the important field of agricultural engineering, with the exception of the work done in irrigation in Colorado and in a more limited way in a few other States, the stations have thus far done almost nothing. Though the farmers of the United States are by far the largest users of agricultural machinery of those in any country, the experiment stations have not undertaken any serious studies of such machinery.

When the Hatch Act was passed fifteen years ago it was estimated that the annual value of agricultural products in the United States was three billion dollars, and that thus the annual expenditures for the stations organized under that act would not amount to more than a tax of twenty-five cents on every thousand dollars' worth of agricultural product. The census of 1900 shows that the annual output of our farms now amounts to five billion dollars. It is believed that the experiment stations have had much to do with this increased agricultural production. The funds expended in their maintenance have thus proved to be highly remunerative investments.

Experience has demonstrated that it is a wise policy to invoke the aid of science and expert skill for the extension and improvement of our agriculture. It would be well, therefore, for our people to consider seriously the extension of the operations of the stations on a scale which it is believed would secure wider and more permanent results.

RECENT WORK IN AGRICULTURAL SCIENCE.

CHEMISTRY.

The determination of sulphur and phosphorus in plant substances, C. P. BEISTLE (*Jour. Amer. Chem. Soc.*, 24 (1902), No. 11, pp. 1093-1100).—Comparative tests of 8 different methods on cotton-seed meal, timothy hay, and egg albumen are reported. The results show that the fusion method with potassium hydroxid and potassium nitrate gave the highest results for sulphur in all three of the substances examined. "The amount of sulphur in the ash of the various samples is so low that it gives no indication of the total amount of sulphur present, showing that the greater portion is driven off by ignition. The sulphur obtained by boiling with potassium hydroxid solution, with subsequent oxidation with chlorin, gave only half the sulphur found by the fusion method. The sulphur found by ignition in the bomb calorimeter is about the same in amount as that found by combustion in a stream of oxygen and absorption of the products of combustion in a hydrochloric acid solution of bromin, but is still considerably less than is obtained by fusion." It was found that special precautions were necessary in order to secure the complete oxidation of the sulphur.

"The fusion method gave slightly more phosphoric acid than the ash in the case of the cotton-seed meal, but practically the same for the timothy hay and egg albumen. This would indicate that in the substances examined, the phosphoric acid was volatile to a very slight extent, if at all. Boiling with potassium hydroxid solution and treating with chlorin gave results so low that this method may be discarded for the analysis of this class of bodies. The phosphoric acid found by ignition in the bomb calorimeter was slightly less than by fusion, and this difference was probably due to mechanical loss of the smaller particles of the glassy slag which contained almost all the phosphoric acid. The amount of phosphoric acid obtained from the hay by boiling with nitrohydrochloric acid was practically the same as found by fusion or incineration. When the cotton-seed meal was treated in this way only about half of the phosphoric acid present was obtained."

Investigations are reported which indicate that this latter fact is possibly due to the phosphoric acid being in organic combination, which is not broken down by boiling with strong nitrohydrochloric acid.

The determination of sulphur and phosphorus in organic materials, H. C. SHERMAN (*Jour. Amer. Chem. Soc.*, 24 (1902), No. 11, pp. 1100-1109).—Comparisons of the bomb calorimeter and nitric acid methods (with compressed oxygen), sodium peroxid-hydroxid, for sulphur and the calorimeter, sodium carbonate, and sulphuric acid ammonium nitrate methods for phosphorus, on dried lean beef, milk curd, coagulated white and yolk of eggs, wheat bran, and dried beans are reported. The conclusions reached were as follows:

"For the determination of sulphur the method of combustion in compressed oxygen is preferred. Equally good results were obtained by the hydroxid-peroxid method, but the manipulation is less convenient. The nitric acid method as used gave low results."

"In the determination of phosphorus practically identical results were obtained whether the material was oxidized by combustion in oxygen, by heating with carbonate and nitrate, or by boiling with sulphuric acid and ammonium nitrate. For the analysis of food materials and physiological products the last-mentioned method will probably be found most convenient, especially in laboratories where the Kjeldahl method for nitrogen is largely used.

"In analyzing animal and vegetable materials there is very much greater danger of loss by volatilization of sulphur than of phosphorus."

The estimation of soil acidity and the lime requirements of soils, F. P. VEITCH (*Jour. Amer. Chem. Soc.*, 24 (1902), No. 11, pp. 1120-1128).—The method proposed is as follows:

"For the preliminary test, to 3 portions of 10 gm. each of the soil in platinum dishes add 50 to 60 cc. of distilled water, and different amounts of standard limewater. For example, to the first 10 cc., to the second 20 cc., and to the third 30 cc. of limewater are added. Dry down at once on the steam bath, transfer to a stoppered Jena flask with 100 cc. of distilled water, allow to stand overnight, with occasional shaking, filter (the filtrate should be clear or but faintly turbid), take 50 cc. in a Jena beaker, add a few drops of phenolphthalein solution, and boil until the appearance of the pink color or, in the case where no color is developed, to a volume of about 5 cc. Then with the 2 portions of treated soil, one of which has been rendered alkaline by the added limewater and the other of which is still acid, as guides, prepare 3 fresh portions of 10 gm. each, and add limewater as before, except that the amount added to a dish differs from that added to another, by only 1 or 2 cc. Dry, allow to stand, filter, and treat exactly as before. The smallest amount of limewater which gives the characteristic pink with phenolphthalein is taken as the acidity equivalent of the soil. From the data thus obtained, the acidity and lime requirements of the soil may be calculated."

The results obtained with this method on a number of samples of soils from different localities are compared with those obtained by Wheeler in field and laboratory experiments on the same soils, but no very definite relation is shown between the lime requirements as indicated by the proposed method and the productive capacity of the soils. The relations of soil acidity to the productive power are discussed, the need of further study of the subject being pointed out.

Tacke's method for determining acidity in peat soils as applied to other soils, M. GRATCHEV (*Zhur. Opušn. Agron. [Jour. Expt. Landw.]*, 3 (1902), No. 3, pp. 355-365).—This method (E. S. R., 9., p. 32) is not considered applicable to soils in general.

A short method of determining potash, B. SJOLLEMA (*Chem. Ztg.*, 26 (1902), No. 85, pp. 1014, 1015).—The use of barium carbonate and magnesium chlorid to replace barium chlorid in the precipitation of sulphates in case of potash salts is proposed. The carbonate (stirred up in water) is used at the rate of 10 gm. of carbonate to 5 gm. of the potash salt. In case of salts containing considerable amounts of chlorids the use of magnesium chlorid is unnecessary.

The volumetric determination of lime in the presence of salts of iron, aluminum, manganese, magnesium, phosphoric acid, and sulphuric acid, N. STEPANOV (*Zhur. Opušn. Agron. [Jour. Expt. Landw.]*, 3 (1902), No. 2, pp. 190-200).—In the method proposed the lime in 50 cc. of the solution to be examined, corresponding to 2.5 gm. of substance, is precipitated by adding ammonium oxalate in presence of a slight excess of oxalic acid. The precipitate is washed free from oxalic acid, dissolved in 10 per cent hydrochloric acid, and titrated with potassium permanganate solution.

The separation of iron, aluminum, and phosphoric acid from lime, N. STEPANOV (*Zhur. Opušn. Agron. [Jour. Expt. Landw.]*, 3 (1902), No. 2, pp. 201-203).—The results reported show that 2 precipitations with ammonia in presence of acetic acid are not sufficient to entirely free the precipitate from lime.

The precipitation of solid particles in solutions and the mechanical analysis of soils. G. NEFEDOFF (*Zhur. Opytu. Agron. [Jour. Expt. Landbr.], 3 (1902), No. 4, pp. 421-430, figs. 7*).—To secure a rapid and satisfactory separation of the different grades of soil particles in mechanical analysis of soils, the author recommends rubbing up the sample with water in a porcelain mortar with a rubber-covered pestle, stirring the thin paste so obtained in water, and measuring the amount of material falling to the bottom of a long narrow cylinder during successive intervals of time. An apparatus by means of which the successive precipitates may be removed and weighed is described.

On the combustion of nitrogen. R. SALVADORI (*Gaz. Chim. Ital., 30 (1900), II, pp. 389-404; abs. in Bul. Soc. Chim. Paris, 3. ser., 28 (1902), No. 18-19, p. 770*).—Experiments on the oxidation of nitrogen by burning in a mixture of oxygen and hydrogen are reported, which show among other things that within certain limits an increase of pressure and of the proportion of nitrogen in the gaseous mixture increases the production of nitric acid. A high temperature of the gas at the beginning of the operation and a notable excess of oxygen retard the combustion of nitrogen.

The artificial production of nitrates. MAIZIÈRES (*L'Engrais, 17 (1902), Nos. 41, pp. 975, 976; 42, pp. 999, 1000*).—A discussion of this subject apropos of the announcement of the formation of a company to utilize power from Niagara Falls in the production of nitrates from atmospheric nitrogen by the Bradley and Lovejoy process (*E. S. R., 14, p. 119*).

Determination of lactose in milk. DEGREZ (*Rev. Gén. Lait, 1 (1902), No. 20, pp. 469-474*).—Comparative tests of several methods are reported.

A method for the quantitative estimation of ergot in flour. W. MITLACHER (*Ztschr. Allg. Oesterr. Apoth. Ver., 1902, No. 5, pp. 115-126; abs. in Bot. Centbl., 83 (1902), No. 14, pp. 411, 412*).—Criticises the method of Max Gruber and describes a means for estimation that is claimed to give results less liable to error.

On the cause of the injury of platinum crucibles in analysis of phosphates. W. C. HERAEUS (*Ztschr. Angew. Chem., 15 (1902), No. 37, pp. 917-921*).—Investigations are reported which indicate that in the process of igniting precipitates in platinum crucibles a certain amount of phosphorus may be set free, which then combines with the platinum, to the injury of the crucibles.

Laboratory work. P. BONAME (*Rap. An. Sta. Agron. [Mauritius], 1901, pp. 9-24*).—A brief summary of the chemical work of the Agronomic Station of Mauritius on fertilizers, soils, sugar cane and its products, and miscellaneous materials.

Directions for laboratory work in physiological chemistry. H. C. JACKSON (*New York: John Wiley & Sons; London: Chapman & Hall, Ltd., 1902, pp. 1-62*).—According to the author, this book was specially designed as a laboratory guide for students in physiological chemistry, especially the medical students in the University and Bellevue Hospital Medical College, New York. The chemical bodies most important from a physiological point are discussed, and a number of experiments are described in considerable detail.

Proceedings of the eighteenth annual convention of the Association of Official Agricultural Chemists (*U. S. Dept. Agr., Bureau of Chemistry Bul. 67, pp. 184*).—This is a detailed report of the proceedings, edited by H. W. Wiley, a summarized account of which has appeared (*E. S. R., 13, p. 406*).

BOTANY.

Report of the consulting botanist. W. CARRUTHERS (*Jour. Bath and West and Southern Counties Soc. [England], 4. ser., 12 (1901-2), p. 208*).—A brief report is given on several inquiries which were made by the consulting botanist at the request of members of the society. A seed mixture for permanent pasture was prepared, which consisted of timothy, rough-stalked meadow grass, orchard grass, meadow fescue, meadow foxtail, white clover, and yarrow. A number of weeds are reported

as overrunning pasture fields, one of the most troublesome of which proved to be a species of *Crepis*. The spreading habit of the plant prevents the growth of more valuable species, and by its abundant fruit multiplies quite rapidly. It is suggested that its spread may be prevented by cutting when in flower, but where very abundant the pasture should be abandoned and cultivated crops grown for a few years. A brief report is also made of the occurrence of soft brome grass in a wheat field. For some reason the wheat had been crowded out, and four-fifths of the crop is said to be made up of this weed. Since the soft brome grass is an annual, it could be easily eradicated if careful attention be given the subject.

Report of the section of botany, A. LÖFGREN (*Extr. from Relat. Com. Geogr. e Geol. São Paulo, 1901, pp. 127*).—In addition to the routine report, in which the investigations during the year are briefly described, an appendix is added in which the different varieties of fruit occurring in the botanic garden are enumerated, and an account given of the seed-testing investigations, and descriptions of camphor, esparto grass, ipecac, cassava, jute, perfume plants, and certain species of *Acacia* and *Eucalyptus*.

Report of the government botanist, J. H. MAIDEN (*Agr. Gaz. New South Wales, 13 (1902), No. 5, pp. 499-501*).—A brief report is given of the various investigations undertaken by the author during the year.

Flora of the Galapagos Islands, B. L. ROBINSON (*Proc. Amer. Acad. Arts and Sci., 38 (1902), No. 4, pp. 77-270, pls. 2*).—A list is given with description of new species of the flora of the Galapagos Islands, the study being based upon the collection secured by the Hopkins-Stanford expedition to those islands. In addition an attempt has been made to summarize all the available information regarding the flora of these islands, and a bibliography of the subject is appended.

The phylogeny of the cotyledon, H. L. LYON (*Postelsia, the Yearbook of the Minnesota Seaside Station, 1901. St. Paul, 1902, pp. 55-86*).—According to the author, the typical embryo of ferns and angiosperms is differentiated into 3 primary members—the cotyledon, stem, and root. Cotyledons are not arrested leaves, but are primarily haustorial organs. The monocotyledonous condition is the primitive one and prevails in the mosses, ferns, monocotyledons, and some gymnosperms. The 2 or more cotyledons of dicotyledonous plants are jointly the homologue of the single cotyledon of the monocotyledonous plant. The cotyledon always occurs at the base of the primary stem. The hypocotyl is a structure peculiar to the angiosperms, being differentiated between the primary stem and root. The so-called cotyledons of the pteridophytes and gymnosperms, with the possible exception of ginkgo and the Cycads, are true foliage leaves.

Some neglected factors in discussions of heredity, G. J. PERCE (*Abs. in Science, n. ser., 16 (1902), No. 395, p. 137*).—In discussing heredity the author claims that organisms are exposed to certain influences which are constant in their variation and intensity. Among these influences are atmosphere, the earth, water, gravity, etc. These influences can not be escaped nor have they been eliminated in any experiments so far as known, and their importance can only be guessed. The reaction of living organisms to these influences should be considered in all discussions of heredity.

Soil temperatures and vegetation, D. T. MACDOUGAL (*Abs. in Science, n. ser., 16 (1902), No. 395, p. 137*).—A description is given of a method of making observations on soil temperatures by means of the newly designed Hallock thermograph, and the influence of temperatures of soil and air on plant growth was commented upon.

On the distribution of acids in stems, leaves, and flowers, A. ASTRUC (*Compt. Rend. Acad. Sci. Paris, 133 (1901), No. 13, pp. 491-493; abs. in Bot. Centbl., 89 (1902), No. 16, p. 462*).—An investigation is reported of a score or more genera of plants for the distribution of free or combined acids which exist quite commonly in plants.

The acidity of the stems was found to be diminished from the summit downwards. The acidity of the leaves, which is much greater than that of the stem, is in inverse proportion to the age of the leaves, young leaves being the more acid. Within a given leaf the acidity is greatest near the zone of growth. In the flowers the acidity decreases from the bud to the fully expanded flower. In all the investigations the younger parts were found to possess the greatest acidity.

A simple method for demonstrating the translocation of starch, S. M. BAIN (*Univ. Tennessee Record*, 5 (1902), No. 4, pp. 259-262, figs. 3).—While engaged in studies on the effect of fungicides on the foliage of peach, plum, etc., the author found that by placing a number of small drops of a 3 per cent solution of copper sulphate upon the mature leaves of plums or peaches, if the leaves are allowed to remain attached to the stem until the dead areas begin to drop out, the translocation of the starch may be shown. The specimens should be put into alcohol on successive days from the time of the application until the dead areas are conspicuous, and examined in cross section under the microscope, using Schulze's solution for staining. It will be noticed that rapid cell division has occurred at the healed margin, and by the application of iodine distinct zones of starch accumulation will be readily discovered.

Testing for mannose, F. H. STORER (*Bul. Bussey Inst.*, 3 (1902), II, pp. 13-45).—The author reports the presence of mannan in the trunk of sugar maple trees, especially in the wood of trees which were felled during the winter months. After the formation of the leaves has begun the amount of mannan present rapidly diminishes to a minimum. It is evident from the investigations reported that mannan is stored as a reserve food in the wood of the sugar maple. Negative results were obtained in testing the wood of the gray birch, poplar, and willow for this substance. It was found present in the orange peel, but not in the seeds, and occurs in a small quantity in the tuberous roots of the Jerusalem artichoke in connection with inulin. Mannan was found present as an adjunct to starch in the seeds of the horse chestnut and also in the storage roots of chicory, dandelion, and asparagus. Although the wood of the white pine and Norway spruce contain mannan in abundance, it was almost totally absent from the seeds of these trees. The author believes that in regard to wood of trees, other substances will be found comparable to starch and mannan which serve as reserve food for the production of leaves and new wood in the spring. Detailed directions are given for the testing and identification of this substance.

The effect of acetylene gaslight on plant growth, F. W. RANE (*Abs. in Science*, n. ser., 16 (1902), No. 395, p. 137).—According to the author, acetylene gaslight has a marked effect upon plant growth, especially upon plants grown under glass during the winter months. Experiments showed that some plants were more influenced than others by the stimulation of the light.

Concerning the specific individuality of the root-tubercle bacteria of leguminous plants and the agricultural significance of the question, H. BUEHLER (*Fühling's Landw. Ztg.*, 51 (1902), Nos. 11, pp. 385-391; 12, pp. 417-427).—An account is given of experiments in which peas and beans were inoculated with organisms taken from tubercles found on the roots of peas, beans, horse beans, and *Acaia speciosa*. The seeds were sterilized in 0.2 per cent solution of corrosive sublimate and grown in sterilized quartz sand, watered with distilled water, and fertilized with phosphoric acid, kainit, and lime. All the organisms were cultivated in pure cultures which served for inoculation material. The author concludes that all the organisms are forms of *Bacillus radicicola*. The bacteria best adapted to a given species of leguminous plant are those naturally found upon that plant. Inoculation with bacteria is possible within certain limits, and while pure cultures are desirable, yet, on account of the difficulties connected with the obtaining and use of such materials, it will generally be found best in agricultural practice to depend upon soil inoculation.

The fixation of nitrogen by leguminous plants, T. REMY (*Chem. Ztg.*, 26 (1902), No. 80, pp. 945, 946).—A brief discussion of some of the principal results of recent investigations on this subject.

Nitrogen assimilation and proteid formation of plants. T. CZAPEK (*Beitr. Chem. Physiol. u. Pathol. Ztschr. Biochem.*, 1 (1902), pp. 538-560; *abs. in Bot. Centbl.*, 89 (1902), No. 18, p. 518).—Cultures were made with *Aspergillus niger* in solutions containing different forms of nitrogen. The cultures were divided into series in order to compare derivatives of different organic acids, such as the ammoniacal salt, amid, nitril, monamid acid and corresponding amid, the oxyacid ammoniacal salt and its corresponding amid, etc. Sugar was added as required to supply the necessary carbohydrates for the plant. The results obtained showed in each series, as the acetic, propionic, tartaric, etc.; the amid acid was the most favorable source of nitrogen, followed by the oxyacid ammoniacal salt, while the nitril and monocarbonic acid salt of ammonia were always the poorest. In the albuminoid synthesis of the mold studied the amid acids furnished the best sources of supply. This was best secured when the amount of nitrogen offered corresponded with the percentage found in the albuminoids of the plant.

The germinative power of the conidia of *Aspergillus oryzae*. MARY F. HILLER (*Proc. Indiana Acad. Sci.*, 1901, pp. 272-275).—A series of experiments is reported upon in which the germination of the conidia of *Aspergillus oryzae* in different media was tested. It appears that the germinative power of the conidia of this mold is dependent upon the medium upon which the inoculating material is grown. In the experiments conducted the inoculating material varied from 2 years to 4 years and 7 months, and from the results obtained the germinative power seemed to diminish with increased age. Some media were found to be decidedly favorable to the germination of the fungus while others were detrimental. Alcohol was found not to have any stimulating effect upon the conidia. A brief bibliography completes the paper.

The stimulating action of soluble salts of copper on *Penicillium glaucum*. LE RENARD (*Jour. Bot. [Paris]*, 16 (1902), No. 3, pp. 97-107; *abs. in Bot. Centbl.*, 89 (1902), No. 24, p. 693).—The salts of copper in small quantity in certain plant nutrients acts as a stimulus to the growth of some organisms. The stimulative action does not proceed regularly with the increase of the chemical, but is apparently controlled by the media used in the cultures. The stimulating effect is greatest in those media which are the most readily assimilable. Glucose is the medium admitting the greatest excitive action, followed by levulose and gelose. Saccharose, which is ordinarily readily assimilable by the mold experimented with, seems to check the action of the copper salts. The sulphate, chlorid, and nitrate of copper stimulated growth under the conditions of the experiment, but copper acetate was without appreciable effect, the acetate being reduced in the presence of glucose. Copper salts retard germination instead of stimulating it, as in the case of the growth of the mycelium of the fungus.

The resistance of some molds to metallic poisons. C. PULST (*Jahrb. Wiss. Bot. [Pringsheim]*, 37 (1902), No. 2, pp. 205-263, figs. 2; *abs. in Bot. Centbl.*, 89 (1902), No. 24, p. 684).—The concentration of metallic salts which molds can withstand when the poisonous compound is added to nutrient media in which the molds are grown varies widely with different organisms. *Mucor mucedo*, *Aspergillus niger*, and *Botrytis cinerea* are capable of enduring only weak solutions, while *Penicillium glaucum* is very resistant. The effect of a salt depends upon the physiological effect of the undissociated part and the concerted action of the kations.

The effect of copper upon *Penicillium glaucum* was so slight as to be unimportant and the fungus underwent such changes in its development that the filaments in contact with the poison were uninjured, although a poisonous quantity was present.

Preliminary notes on some new species of fungi. G. F. ATKINSON (*Jour. Mycol.*, 8 (1902), No. 63, pp. 110-119).—Descriptions are given of about 25 new species of basidiomycetous fungi.

The physiology of sea water, R. H. TRUE (*Science*, n. ser., 16 (1902), No. 402, p. 433).—In experiments made under the author's direction at the Woods Hole Marine Biological Laboratory it appeared that a synthetic solution prepared in such a manner as to contain the 6 chief substances present in sea water in the proportion represented differed very markedly in its physiological properties from sea water. Subsequent studies failed to sustain the experiments, and it is clearly indicated that through some error, perhaps due to the insufficient allowance for water present in the salts used, less of these substances was introduced than necessary for making up the solution. Since this correction has been made it has been possible to make synthetically an artificial sea water in which certain marine algae can develop, and also many very sensitive marine animals may be kept for a considerable time, often carrying out a large part of their development in the artificial mixture.

Catalogue of publications relating to botany in the library of the U. S. Department of Agriculture (*U. S. Dept. Agr., Library Bul. 42*, pp. 242).—An author list and subject index is given to the various books and pamphlets relating to botany in the library of this Department, together with a list of the serial botanical publications.

WATER—SOILS.

A new process for purifying potable water, P. GUICHARD (*Bul. Soc. Chim. Paris*, 3. ser., 27 (1902), No. 18-19, pp. 941-943).—In the method proposed a slight excess of calcium permanganate is added to the water, and after a sufficient length of time the excess is removed by the addition of iron, the insoluble oxides of iron and manganese formed being removed by filtration. The latter is accomplished by means of a simple form of filter press in which 2 thicknesses of sterilized paper are used.

On the determination of the reducing capacity of natural waters, L. W. WINKLER (*Ztschr. Analyt. Chem.*, 41 (1902), pp. 419-426; *abs. in Chem. Centbl.*, 1902, II, No. 15, p. 958).—The author reports determinations of the reducing capacity of a large number of samples of water as measured by means of permanganate solution made with a view to determining the limits of reduction for normal waters.

The river irrigating waters of Arizona—their character and effects, R. H. FORBES (*Arizona Sta. Bul. 44*, pp. 145-214, figs. 12).—This bulletin records the results of a systematic study begun in 1899 of the water of the three principal irrigating streams of the Territory—the Salt, the Gila, and the Colorado rivers—and of sundry samples from less important sources.

“With reference to the quality of their waters for irrigation, the rivers of Arizona are very changeable in character, varying in silt and salt content with the nature and condition of the watershed, with the amount and location of rainfall, with climatic effects such as evaporation and temperature, and under the influence of up-river seepage. With reference to the general character of their drainage waters, the watersheds of the Salt, the Gila, and the Colorado rivers may be divided into (1) the mountainous, more forested portions with greater rainfall and better drainage; and (2) the more level, desert portions, receiving less rainfall, and less perfectly drained. . . .

“The mountain flood waters in these rivers are less saline and usually contain less silt than the desert flood waters, which, resulting as a rule from torrential downpours, sweep immense quantities of alkaline salts and erosion sediments into the drainage.

“Low waters in all cases contain higher than the average proportions of salts, partly, especially in summer, because of concentration by evaporation, and largely because of the predominance at such times in these streams of seepage waters, both natural and, in some cases, from up-river irrigation. The amount of sediment in low waters is very small. . . .

"As suggested by the maximum percentages of sediment, the silting up of reservoirs and ditches would be greatest under the Gila River, next greatest under the Colorado, and least under the Salt River, for the years of observation."

The percentages by weight of sediment in the total run-off of the 3 rivers for the year periods of observation were, approximately, in the Gila, 2 per cent; in the Colorado, 0.30 per cent; and in the Salt River, 0.21 per cent; but the sediments in Salt River for this time were much less than normal.

"The sediments of the Colorado are probably in larger part directly erosive in character, coming mainly from the canyon and bad-lands country. The excessive sediments of the Gila are in large part the sweepings from overstocked grazing ranges, and the detritus from valleys whose erosion is the result of overgrazing. The comparatively small amounts of sediments observed in Salt River are in part due to the reservations which protect the upper Salt River watershed. The color, specific gravity, fineness, flocculence, and mineral nature of river sediments are all traceable to watershed conditions. The Colorado is notable (part of the year) for its dense, highly colored sediments and the Gila for its flocculent, more usually black sediments, sometimes exceedingly rich in organic matter. The Salt River sediments more nearly resemble those of the Gila in physical character, but are perceptibly coarser.

"The specific gravities of solid sediments were observed to vary in Salt River from 2.249 to 2.703, averaging 2.604; in the Gila River from 2.580 to 2.766, averaging 2.672; and in the Colorado River from 2.581 to 2.694, averaging 2.652.

"The bulk of mud in flood waters, as compared with that of solid sediments, was observed to vary, after from 10 to 30 days' settling, in Salt River from 5.6 to 7.5 times as great, averaging 6.2 times; in the Gila River from 5 to 8.3 times as great, averaging 6.7 times; and in the Colorado River from 4.5 to 9.5 times as great, averaging 6.2 times. These mud volumes are subject to slow contraction, during long periods of time, amounting to 20 per cent and upward.

"The fertilizing value of these sediments mainly depends upon the nitrogen and organic matter they contain. Potash and phosphoric acid were also estimated, the former being already abundant in our desert soils, and the latter being in slowly available, insoluble form in the river waters. All fertilizing materials are most abundant in time of flood, greatly decreasing at time of low water. . . .

"Under the agricultural conditions which obtain in southern Arizona, it is judged that 100 parts of salts in 100,000 of water, or about 2,700 lbs. per acre-foot, is an objectionable but manageable degree of salinity in an irrigating water. On this basis," Salt River, during 369 days, was above the limit 302 days, below 67; the Gila, during 187 days, was 138 days above, 59 days below; the Colorado River, during 380 days, was 50 days above, 330 days below.

"The character of the soluble salts of the Salt, Gila, and Colorado rivers is usually 'white alkaline' in excess, consisting mainly of chlorides and sulphates of sodium and calcium. The Salt and Gila rivers only, during some but not all floods, have been observed to contain an excess of sodium carbonate, or black alkali, evidently swept into the drainage from overlying watersheds."

The conditions favoring the accumulation of alkali in the surface soil and the control of the rise of alkali and the distribution of the alkaline accumulation by flooding, drainage, and deep and thorough cultivation are briefly explained.

A soil study. IV, The ground water, W. P. HEADDEN (*Colorado Sta. Bul. 72, pp. 47*).—In continuation of previous investigations (E. S. R., 13, p. 830) the author studied the ground water with special reference to soluble salts. Summarizing his results he says that "alkalization in Colorado resolves itself into a question of drainage" and is aggravated by overirrigation.

"Crops growing on alkaliized soil with the water table quite near the surface were sensitive to droughty conditions. . . .

"The height of the water plane often changes without sensible cause, probably due to atmospheric conditions, pressure, temperature, etc. Light rains during dry periods produce, as a rule, comparatively great increases in the height of the water plane, probably due to modification of the capillary conditions. Light rains during an interval of abundant moisture when the soil is wet do not produce an increase in the height of the water plane. Moderate rains were sometimes accompanied by temporary depression of the water plane. This was accounted for by the rate of rainfall, character of soil, and the air contained therein. The effect of an irrigating ditch running past the east end of the plat was to raise the height of the water plane by 0.3 ft. at a distance of 142 ft. from the center of the ditch. This rise was apparently produced by the causing of a backward pressure and not by direct infiltration of water. When the water plane rose due to changes in capillary conditions caused by light rainfalls it usually fell to its former level in about 3 days, but when it rose after an irrigation it required from 10 to 13 days for its fall.

"The total solids, salts held in solution in the different well waters, varied both in quantity and in the ratio of the different salts present. Their amount and character depended upon the conditions obtaining in the immediate vicinity of the well. The total solids rose and fell with the water plane, passing into the water as it rose, and remaining in the soil when it fell. . . . The increase in the amount of total solids in a well water is not always the greatest in those wells which show the greatest rise in the water plane, nor in those which usually show the greatest quantities of total solids. The increase in the total solids due to the rise of the water plane seems to be partly dependent upon the rate of diffusion through the soil. . . . The total solids in the well waters were less than in the water in the soil. This difference was not due to a mixture of water entering the wells from different sources, but was seemingly due to the modification of the laws of diffusion and solubility by the soil itself. . . .

"The chlorin, or its corresponding salt, sodium chlorid, was at no time very abundant in the ground water and bore no definite relation to the total solids, as the sodium chlorid ranged from 5 to a little more than 14 per cent of their total weight. The increase or decrease of sodium chlorid, common salt, was not proportional to the increase or decrease of the total solids, and did not serve as an index of either the amount of total solids present or of their variation, except within very wide limits. The chlorin may not always be present in the form of sodium chlorid. . . . Analytical results indicate that it may sometimes be present as magnesium chlorid, and the irregular deportment of chlorin in the waters may be due to such causes, i. e., differences in the manner of its combination. The chlorin present in the ground waters and its variations in quantity throw but little or no light upon the movement of the alkali salts within this soil.

"The term 'total solids' is equivalent to the salts constituting the free solution in the soil. The term represents a different mixture of salts than is found in the incrustations forming on the surface of the soil, or obtained by evaporating an aqueous extract of the soil to dryness. The total solids in the ground water varied greatly in the different wells, and also from time to time, in regard to their quantity, but only to a limited extent in their chemical composition. The difference in the latter respect was almost exclusively confined to the relative quantities of the respective salts. . . .

"The alkali incrustations from this plat consist essentially of sodium and magnesium sulphate in the ratio of two to one. They together constitute 80 per cent of the mass. Calcium sulphate is subordinate in quantity, with sodium chlorid and carbonate still more so.

"The salts dissolved in the ground water, the total solids, consist much more largely of calcium sulphate than of sodium sulphate, and contain about the same amount of magnesium sulphate as the incrustation from this plat. The ratio of cal-

cium sulphate to the magnesium and sodium sulphates in the total solids is approximately $2:1\frac{1}{2}:1$. The salts extracted from the first 2 in. of the soil by continued treatment with water consisted of the same salts. They made up nearly 80 per cent of the total, but the ratio was approximately $4:2:1$. The aqueous extract of the second 2 in. of soil contained very little magnesium sulphate, no sodium sulphate, and almost 51 per cent of calcium sulphate. This extract showed a large amount of soluble silicic acid, corresponding to 14.5 per cent of sodium silicate calculated on the dried residue. The upper portions of the ground water are richer in total solids than the successively deeper portions, and the salts in solution differ, especially in their relative quantities.

"There seemed to be an abundant formation of nitric acid in the upper portions of the soil, even in portions of the plat where the alkali salts were abundant. Nitric acid occurred so generally in the ground waters and its variations were so dependent upon other conditions that we can not judge of the effect of the alkalis present nor of that of the mechanical conditions. There was no relation between the amount of total solids and that of the nitric acid present. There was no relation between different wells in regard to the quantity of nitric acid present or its variations. Irrigating the ground increased the nitric acid in the well waters; so did even light rainfalls, probably due to increase of capillary exchange of the nitrates between the upper portions of the soil and the ground water. The ground water from this plat is richer in nitrates than that from neighboring land which is in better condition.

"The nitrites in the ground water are relatively high and are increased by irrigation. This is probably due to the biological conditions of the soil and the deportment of solutions of nitrites toward the soil, especially in regard to the readiness with which they will pass through it.

"The free ammonia and ammonia salts were not especially abundant in the ground water, either before or after irrigation, though more abundant after than before. The ground water was slightly richer in free ammonia than the drain water from this plat. The albuminoid ammonia in the ground water was not excessively high, but it was materially increased by irrigation. The albuminoid ammonia did not appear to pass freely into the drain water.

"The amount of nitrates removed by off-flow water is probably quite limited, as their quantity in the off-flow diminished rapidly."

Alkali. J. D. TINSLEY (*New Mexico Sta. Bul. 42, pp. 31*).—A general discussion of this subject, based on compiled information and on laboratory and field investigations by the author extending over several years. The topics discussed are: Kinds of alkali; composition of alkali in the Pecos Valley; reactions between some of the constituents of alkali; origin of soils and alkali; soil texture, percolation, and capillarity; accumulation of alkali; prevention of the accumulation of alkali; relations of manure to alkali; removal of alkali from the soil; amount of alkali injurious; and summary of conditions in the Roswell and Carlsbad, N. Mex., and Barstow, Tex., districts.

Drainage and flooding for the removal of alkali. J. D. TINSLEY (*New Mexico Sta. Bul. 43, pp. 29, pls. 2*).—About 20 acres of Hondo bottom land near Roswell, N. Mex., was used in these experiments. The soil was very variable, ranging from sandy loam to clay, and consisting largely of sediment deposited by the Hondo River in time of flood. The soil contained so much alkali, almost entirely of the "white" type, that it was suited only to alkali-resistant crops such as saltbushes.

"The drainage system consisted of a main central drain 610 ft. long running from the foot of the slope to the Hondo . . . laid on a grade of 4 in. to the hundred feet. The first 100 ft. from the Hondo is open, the next 270 ft. is laid with 8 in. tile, and the upper 240 ft. with 6 in. tile. . . .

"On the east side of the center there are 12 lateral drains making an angle of about 18 degrees with the main drain, parallel to each other and 155 ft. long. The first 8,

from the south, are 30 ft. apart, and laid with 3 in. tile at depths between 2 and $3\frac{1}{2}$ ft.; the next 3 are 40 ft. apart, laid with 4 in. tile, and their depths are from $2\frac{1}{2}$ to 4 $\frac{1}{2}$ ft., their greatest depth being where they join the main and the least at their east ends, due both to their grade and the slope of the land toward the east. The twelfth drain is 100 ft. from the eleventh, is laid with 5 in. tile and has a mean depth of about 4 $\frac{1}{2}$ ft.

"On the west side of the main there are 7 drains, each 155 ft. long, and these also make an angle of about 18 degrees with the main. The first 4 are laid with 3 in. tile at a depth of from 3 to $3\frac{1}{2}$ ft., and 60 ft. apart; the next 2 are laid with 4 in. tile at a depth of from $3\frac{1}{2}$ to 4 ft., and 60 ft. apart. The seventh is laid with 5 in. tile at a depth of about 4 $\frac{3}{4}$ ft., and is 100 ft. from the sixth. The end of the main drain, where it empties into the river, is about 6 $\frac{1}{2}$ ft. deep.

"The slope of the land was such as to allow the east end of some of the drains to come within 2 ft. of the surface, while the greatest average depth of any of them was about 5 ft. This gave an opportunity for studying the effect of various depths of water table on the rate of removal of alkali and on the growth of crops."

Observations on the fluctuations in the water table, the discharge of the drains, and alkali content of the soil and drainage water are recorded.

"Where the water table was within 6 in. or less of the surface the amount of alkali was low.

"The maximum effect of capillarity in Hondo meadows soil was found where the water table was about 2 ft. below the surface of the ground, as was shown by the maximum accumulation of alkali.

"Drains less than 3 ft. deep were not effective.

"Ten floodings applied to the natural salt grass-covered surface removed about one-seventh of the total alkali from the first 2 ft. of soil, and carried a large amount of that formerly in the first foot down into the second.

"Seepage water should be cut off by deep drains placed on the side of the land from which it comes.

"Combined open and tile drains will cost from \$20 to \$30 per acre."

The rôle of the plant in dissolving the plant food of the soil, P. KOSSOVICH (*Zhur. Opitn. Agron. [Jour. Expt. Landw.]*, 3 (1902), No. 2, pp. 145-180, pls. 4, figs. 2).—Pot experiments with mustard, peas, and flax are reported in detail (both in Russian and in German). The results show that plants play an important part in dissolving plant food of the soil through acid secreted by their roots.

On the influence of calcium carbonate on the progress of decomposition of organic matter, P. KOSSOVICH and I. TRETYAKOV (*Zhur. Opitn. Agron. [Jour. Expt. Landw.]*, 3 (1902), No. 4, pp. 450-484, fig. 1).—The literature of the subject is reviewed and experiments in small glass lysimeters are reported which show that the addition of calcium carbonate retarded the decomposition of organic matter (hay and oak leaves). This is stated to be in agreement with the general conclusions of other investigators and with what occurs in nature in the case of chernozem soils on limestone formations. Such soils are rich in humus, while other soils poor in lime do not accumulate large amounts of humus even under forest growth. The close relation between humus and lime content in soils has been pointed out by Hilgard.

The changes in soils which render them productive, A. KRAINSKY (*Zhur. Opitn. Agron. [Jour. Expt. Landw.]*, 3 (1902), No. 2, pp. 181-189).—A study of the influence of the addition of various substances to soils on the processes which go on in them—solution of constituents, nitrification, etc.—is briefly reported.

Denitrification in cultivated soil, G. AMPOLA and C. ULPIANI (*Gaz. Chim. Ital.*, 31 (1900), 1, pp. 185-220; abs. in *Bul. Soc. Chim. Paris*, 3. ser., 28 (1902), No. 18-19, p. 815).—Observations on the rate of denitrification in 4 kg. lots of soil containing 30 gm. of nitrate of soda each and inoculated with 10 liters of cultures of denitrifying organisms are reported. After 4 months practically all of the nitrate nitrogen had

been set free. It was further observed that calcium nitrate was more resistant to the denitrifying process than potassium and sodium nitrates.

Comparative experiments on the denitrifying organisms of manure, straw, soil, etc., C. HÖFELICH (*Centbl. Bakt. u. Par., 2. Abt., 8 (1902), Nos. 8, pp. 245-248; 9, pp. 273-278; 10, pp. 305-308; 11, pp. 336-339; 12, pp. 361-367; 13, pp. 398-406*).—Culture studies are reported, from which the more important conclusions are that horse manure always contains denitrifying organisms and cow manure generally contains them, the organisms being the same in each manure; the same organisms are found very abundantly in straw; the soil always contains denitrifying organisms of the same kind as are found in manure.

On denitrification, H. WEISSENBERG (*Centbl. Bakt. u. Par., 2. Abt., 8 (1902), No. 6, pp. 166-170*).—A study of the denitrifying action of *Bacterium pyocyaneum* in culture media under various conditions.

Soil bacteria and the nitrogen question, A. KOCH (*Chem. Ztg., 26 (1902), No. 80, p. 945*).—A brief discussion of some of the principal results of recent investigations on this subject.

On the presence of lime as dolomite in certain cultivated soils, T. L. PIMPSON (*Chem. News, 86 (1902), No. 2234, p. 148*).—Analyses of a number of soils from Argentina are reported which show the presence of about an equal proportion of calcium and magnesium, namely, 1 per cent.

Glacial formations and drainage features of the Erie and Ohio basins, F. LEVERETT (*U. S. Geol. Survey Monographs, 41 (1902), pp. 802, pls. 26, figs. 8*).—The feature of this exhaustive report of special agricultural interest is the chapter on soils, which discusses the sources of the soil material and classifies and describes the typical soils of the region. These include residuary soils, stony-clay soils, gravelly or stony soils, sandy soils, silty soils, and peaty or organic soils.

The geology of Louisiana, G. D. HARRIS, A. C. VEATCH, and J. A. A. PACHECO (*Louisiana Stat. Spec. Rpt. Geol. and Agr., pt. 6, pp. 171 + 288, pls. 44, figs. 27*).—This is a collection of special papers based on the work of 3 field seasons, 1900-1902, continuing that of previous years (*E. S. R., 12, p. 221*). The subjects reported on are the tertiary geology of the Mississippi embayment, the salines of North Louisiana, the geography and geology of the Sabine River, notes on the geology along the Ouachita, improvements in Louisiana cartography, the subterranean waters of Louisiana, the tides in the Rigolets (by R. A. Harris), and oil in Louisiana. The reports on subterranean waters and on oil are of special interest at this time, the first because of the growth of the rice industry and the consequent increased demand for water for irrigation. The work reported is almost exclusively stratigraphic in character, observations on topography, drainage, soils, etc., not being attempted on account of limited funds.

Science in agriculture (*Farmers' Gaz., 61 (1902), Nos. 1, p. 5; 2, pp. 20, 21*).—A brief review of the work done in different countries in studying and mapping soils.

FERTILIZERS.

The value of barnyard manure, C. E. THORNE and J. F. HICKMAN (*Ohio Sta. Bul. 134, pp. 89-101*).—The results of tests, on the plan described in a previous bulletin (*E. S. R., 12, p. 127*), of open yard and stall manure on rotations of corn, oats, wheat, and mixed clover and timothy, and on corn, oats, and wheat grown continuously, are reported. The yard manure "is taken from flat, open yards, where it has accumulated for several months during the fall and winter, and has been subjected to the conditions which affect the ordinary open-yard manure of the average Ohio farm, conditions which involve very considerable losses. For both corn and wheat the manure is applied to the surface as a top-dressing. It is put on with the

manure spreader." This manure was used at rates of 4 and 8 tons per acre on each crop in the rotations and 2½ and 5 tons in case of the continuous grain cropping.

In another series of experiments comparative tests were made of open-yard manure treated with fine-ground phosphatic rock, acid phosphate, kainit, and gypsum at the rate of 40 lbs. per ton of manure, and of manure similarly treated, which was "taken from box stalls, where it had accumulated under the feet of animals which were kept continuously in their stalls, being given sufficient bedding to keep them clean without cleaning out the stalls."

The results show in general "that it will pay well to give more attention than is done on the average farm to the preservation of barnyard manure, first, by guarding it from the sources of loss which occur in the ordinary, open barnyard, and, second, by treating it with materials calculated to reduce the losses from escaping ammonia on the one hand and to increase its content of phosphoric acid on the other.

"To accomplish this purpose, acid phosphate appears to be the material producing the largest and most profitable immediate increase in effectiveness of the manure, but the experiments strongly suggest the possibility that the finely ground, phosphatic rock from which acid phosphate is made may be found an economical substitute for the latter by using it as an absorbent in the stables and thus securing an intimate mixture with the manure in its fresh condition."

Aerobic fermentation of barnyard manure, C. DUPONT (*Ann. Agron.*, 28 (1902), No. 6, pp. 289-317).—Studies of the behavior in different media of *Bacillus mesentericus ruber* and *B. thermophilus grignoni* are reported. These organisms produced carbon dioxide in large quantities and traces of volatile acids. The first is very active above 55° C. and can be cultivated in all media even in absence of nitrogen. It attacks sugar and starch and rapidly breaks down protein with the production of ammonia and the liberation of some free nitrogen. The second can withstand relatively very high temperatures. In its oxidizing action it resembles *B. mesentericus ruber*, but rarely produces ammonia from protein. Barnyard manure is very favorable to the growth of *B. mesentericus ruber*, and at the lower temperatures it soon becomes the predominating organism. When the temperature rises, however, its activity diminishes and it is replaced by *B. thermophilus grignoni*, which will live at a temperature of 70°.

Experiments on the treatment of barnyard manure with lime, O. REITMAIR (*Ztschr. Landw. Versuchsw. Oesterr.*, 5 (1902), No. 10, pp. 1107-1140).—The results of the experiments reported indicate that with manure of the kind used in these experiments (mixed solid and liquid manure, with litter, containing 75 per cent of moisture) calcium carbonate is of no value as a preservative.

Field experiments with a fertilizer made from beet-sugar factory refuse, H. SVOBODA (*Ztschr. Landw. Versuchsw. Oesterr.*, 5 (1902), No. 9, pp. 1036-1052).—Experiments on a variety of crops during 1900 and 1901 are reported with this fertilizer which is prepared by a patented process consisting essentially of concentrating the diffusion residue to 78 to 80° Brix (1.4 sp. gr.), mixing with powdered calcium carbonate and crude sulphuric acid, and drying. The material is variable in composition, but contains on an average 14 to 15 per cent of lime almost entirely in the form of sulphate, 10 to 14 per cent of potash, 3 to 4½ per cent of nitrogen, and a very small amount of phosphoric acid (about 0.16 per cent).

Chemical-agricultural investigations on "ligara," F. GABRIELLI (*Staz. Sper. Agr. Ital.*, 35 (1902), No. 8, pp. 642-653).—The fertilizing value of this material, which is apparently a kind of peat, is discussed.

Contribution to the knowledge of the green manuring of heavy soils, F. HANUSCH (*Ztschr. Landw. Versuchsw. Oesterr.*, 5 (1902), No. 9, pp. 1063-1066).—The effect of green manuring with a number of different kinds of plants in comparison with fallow is reported. The results were irregular and did not denote any advantage for the green manuring as regards total crop of oats.

Clover as a fertilizer, W. SAUNDERS (*Canada Cent. Expt. Farm Bul.* 40, pp. 23, pls. 2).—Green manuring with clover as a means of improving soils is discussed.

A study of the cultural value of fertilizers, E. RABATÉ (*Jour. Agr. Prat., n. ser.*, 4 (1902), No. 42, pp. 497-501).—The author discusses a number of different ways of estimating the cultural value of fertilizers, and concludes that the simplest and most satisfactory criterion for such estimates is the net profit obtained per unit of area.

The solvent power of different plants for mineral phosphates (*Rev. Gén. Agron.* [Lourain], 11 (1902), No. 7-8, pp. 337-341).—Attention is called to experiments reported by C. Schreiber in 1897, in which this subject was studied with a number of different kinds of plants—11 Gramineæ, 9 Leguminosæ, 3 Crucifere, and 8 miscellaneous plants—the solvent power of the plants being distinguished from that of the soil by growing the plants in a soil which was shown to have no solvent power of itself for the phosphates. The Gramineæ showed little solvent power, the greatest being in case of corn; the Leguminosæ utilized the mineral phosphates to a considerable extent; the same was true of the Crucifere and buckwheat. The solvent power was very small in case of tobacco and flax, and especially carrots and asparagus; it was slightly greater, but still very small, in case of potatoes and beets. The recent investigations of Prianshnikov (*E. S. R.*, 13, p. 934) are referred to as confirming Schreiber's conclusions, although apparently no account is taken by this investigator of the earlier work.

The phosphate rocks of Arkansas, J. C. BRANNER and J. F. NEWSOM (*Arkansas Sta. Bul.* 74, pp. 59-123, figs. 24).—This is a bulletin of information to encourage the development of the phosphate deposits of Arkansas which occur probably in 3 different regions of the State. The first, and probably the most important, lies in north-central Arkansas, north of Boston Mountains and west of Black River, and includes parts of the counties of Independence, Stone, Izard, Searey, Marion, Baxter, and Newton; "the second is in the cretaceous area of the southwestern part of the State. It is possible that there is a third north and west of the city of Hot Springs."

The deposits of the first region are being worked by one company for use in the manufacture of acid phosphate, and 2 railway companies are building roads into the region. The phosphate which is now being used "is soft and easily crushed, and in appearance is identical with some of the Tennessee phosphate rocks," and "works up into a dry, friable acid phosphate." The various localities where phosphate has been discovered are described in detail and analyses of 85 samples are reported. The latter show that the phosphates contain a large amount of iron and alumina, the better class containing from 3.08 to 9.01 per cent. The tricalcium phosphate in the better grade of phosphate varies from 49.38 to 76.62 per cent. In the majority of cases the percentage of iron and alumina is too high for the manufacture of high-grade superphosphates. The phosphates are, however, recommended for direct use as a fertilizer in fine-ground condition.

Investigations on the conditions of formation of oceanic salt deposits, especially the Stassfurt salt beds. XXVII, The artificial preparation of Pinnoit, J. H. VAN'T HOFF and G. BRUNI (*Sitzber. Kgl. Preuss. Akad. Wiss. Berlin*, 1902, No. 35, pp. 805-807).—Pinnoit ($MgO.B_2O_3.3H_2O$) which is found in nature as a transformation product of boracite may be prepared artificially by saturating a solution of boric acid (1 part in 10 of water) with magnesium oxid or carbonate in the warm, filtering, and evaporating slowly at 60 to 70° C.

Fertilizer experiments on moor soils in Sweden (*Deut. Landw. Presse*, 29 (1902), Nos. 48, p. 413, figs. 2; 49, pp. 420, 421).—The results of fertilizer experiments on moor soils in progress for 13 years are reviewed.

The after-effect of commercial fertilizers, BACHMANN (*Deut. Landw. Presse*, 29 (1902), No. 84, p. 683).—Experiments are reported in which better returns were obtained from the use of a complete fertilizer each year than when only nitrogen

was added the second year and the accumulations of potash and phosphoric acid from previous manurings were depended upon to furnish the required amounts of those constituents.

Analyses of commercial fertilizers, H. J. WHEELER ET AL. (*Rhode Island Sta. Bul. 85*, pp. 179-188).—This bulletin includes 44 analyses of tankage, bone, fish, and complete fertilizers designed for potatoes and vegetables.

FIELD CROPS.

Silage studies, F. W. MORSE (*New Hampshire Sta. Bul. 92*, pp. 49-62).—Experiments in progress since 1891 and comprising studies on the composition of corn at different stages of growth and from different quantities of seed per acre, the comparison of varieties for silage and their effect on milk production, and the changes in composition taking place in the silo, are reported and discussed. The results are in some instances compared with those obtained at other stations. The analytical data are given in tables.

It is concluded that the corn plant has reached its maximum food production when it is nearly matured, with the ears fully formed and well filled, and that at this stage it is best suited for silage. The Leaming dent corn was found the most desirable silage variety; and for those portions of the State with too short a season for this variety to reach the proper stage the Sanford flint corn is recommended.

In a feeding test silage made from Sanford, Leaming and Mosby Prolific was compared. Two groups of cows in 1896 and 4 groups in 1897 were fed the different kinds of silage in successive periods of about 3 weeks each. The groups included from 3 to 9 cows each. Judging from the average shrinkage in the yield in milk in passing from one period to another, the results on the whole would seem to place Sanford silage highest and Mosby Prolific lowest in feeding value.

A chemical study of the silage shows that "the sugar in the green fodder is practically all destroyed in the silo, and since it is most abundant in the corn plant in the early stages of ear development, it is an additional argument for postponing cutting until the grain is full size and the sugars have changed largely to starch." The amount of seed per acre affected the yield of green fodder and its composition. The use of 2 bu. of seed produced fodder lacking in protein and containing an increased proportion of fiber. A bushel of seed per acre produced fodder a little inferior in composition to that obtained from the use of $\frac{1}{2}$ bu., but the yield was nearly 50 per cent greater and the total yield of protein and carbohydrates was also increased.

Culture experiments in 1900-1901, A. DAMSEAUX (*Bul. Agr. [Brussels]*, 18 (1902), No. 1, pp. 9-22).—The average results of observations made during 16 years show that winter wheat grown after beets yielded 470 kg. of grain and 300 kg. of straw more per hectare than when grown after clover. A comparison of spring and winter wheat for this same period showed that the average yield of winter wheat per hectare was greater by 710 kg. of grain and 830 kg. of straw.

Oats sown broadcast at the rate of 100 kg. per hectare yielded 3,350 kg. of grain and 7,200 kg. of straw as compared with 3,520 kg. of grain and 6,700 kg. of straw per hectare when sown at the rate of 150 kg. Sowing 100 kg. per hectare in drills resulted in a yield of 3,600 kg. of grain and 7,700 kg. of straw, and sowing at the rate of 150 kg. per hectare gave a yield of 4,050 kg. of grain and 6,050 kg. of straw.

The seed of several early varieties of field and sweet corn was obtained from Canada and planted in May. In spite of an unfavorable summer, the grain ripened in September.

Sugar beets grown after clover produced, on an average, for 14 years 312 kg. of sugar more per hectare than where the crop followed winter wheat. The results of variety

tests with sugar beets are reported and a rotation and fertilizer application for sugar-beet culture suggested.

The results obtained in fertilizer and culture tests with field beets, abutilon, colza, lupines, and grass are briefly noted.

Influence of the size of seed grains on the yield of grain and straw. F. LUBANSKI (*Selsk. Khoz. i Lyeson.*, 200 (1901), Mar., pp. 611-617).—Experiments were conducted with winter wheat, barley, oats, and sugar beets. The results show that the influence on the yield, and even to some extent on the quality of the crop, was in favor of large seed.—P. FIREMAN.

Results on the experimental fields of Haute Marne (*Semaine Agr.*, 22 (1902), No. 1080, pp. 28, 29).—The results of variety and fertilizer tests with wheat, oats, and potatoes are briefly noted, and the management of natural meadows is discussed.

Report of the Agricultural Chemical Experiment Station at Vienna in 1901 (*Ztschr. Landw. Versuchs. Oesterr.*, 5 (1902), No. 3, pp. 415-440).—Brief notes on fertilizer experiments with wheat, rye, potatoes, and field beets are included in the report.

Report of the Moor Culture Station at Karlshuld, T. MAYER (*Vrtljschr. Bayer. Landw. Rath.*, 7 (1902), No. 1, pp. 28-43).—A brief report on the work of the station in 1901, which consisted mainly of culture and variety tests with cereal, root, and forage crops grown on moor soil.

Economic notes on some of the grasses in southwest Missouri, S. A. HOOVER (*Missouri State Bd. Agr. Rpt.* 1902, pp. 449-456).—The section of the State is briefly described and short notes on a large number of wild and cultivated grasses are given.

Forage conditions of central Montana, F. A. SPRAGG (*Montana Sta. Bul.* 36, pp. 40, figs. 23).—This bulletin discusses the geology and physiography of central Montana and describes the natural plant formations in the region, i. e., those localities which through difference of soil moisture and situation produce grasses adapted to the conditions. These localities are known as the bad lands, alkali flats, prairie benches, wet meadows, foothills, and mountain parks. The most common grasses occurring in each region are briefly enumerated. A generic key to the grasses, rushes, and sedges of Montana is published, and an annotated list of the grasses of central Montana, including 76 species, is given.

A preliminary report on the summer ranges of western Nevada sheep, P. B. KENNEDY and S. B. DOTEN (*Nevada Sta. Bul.* 51, pp. 57, pls. 26, map 1).—This bulletin is a report on an investigation of the sheep ranges of the Sierra Nevada within the State. The plants upon which sheep feed, including many grasses and legumes, were collected, and each species is briefly described. The depletion of the ranges for cattle and sheep is considered and methods for range improvement are suggested. The character of the grazing lands is described and notes on the methods of herding sheep and the control of the ranges are given.

Grasses and legumes, C. S. PHELPS (*Rhode Island Bd. Agr. Rpt.* 1901, pp. 232-254).—An article treating briefly of the culture and uses of a number of grasses and legumes. The composition and digestibility of the most common hays are discussed and some fertilizer experiments with grasses and legumes are reviewed.

Forage and pasture plants of Iceland, S. STEFÁNSSON and H. G. SÖDERBAUM (*Medd. K. Landt. Akad. Eeptfält.* No. 74, pp. 50, fig. 1).—After discussing the soil, climate, and flora of Iceland, the following plants are described with reference to their growth, value, and distribution on the island, and their chemical composition: *Aira caespitosa*, *Festuca rubra*, *Poa pratensis*, *P. glauca*, *Agrostis vulgaris*, *Alopecurus geniculatus*, *Carex cryptocarpa*, *C. rostrata*, *C. goodenoughii*, *Elyna bellardi*, *Eriophorum polystachium*, *Scirpus palustris*, *C. caespitosus*, *Juncus filiformis*, *Triglochin palustre*, *Salix lanata*, *Equisetum palustre*, and *E. limosum*.

Cooperative fertilizer tests with grasses and field crops (*Reading Col., Agr. Dept. Rpt.* 1901, pp. 1-23, 30, 51-58).—Tabulated results of fertilizer experiments on

hay and pasture lands and with cereal and root crops are reported, with brief comments. Notes on manures and manuring are given.

Grass mixtures for hay and pasture (*Reading Col., Agr. Dept. Rpt. 1901*, pp. 23-26).—The results with 7 different grass mixtures are reported, with brief comments.

Some Australian vegetable fibers, J. H. MAIDEN (*Agr. Gaz. New South Wales, 13* (1902), No. 2, pp. 167-182).—A list of indigenous Australian fiber plants is given, together with short descriptions of the different species.

Alfalfa, R. L. BENNETT (*Arkansas Sta. Bul. 75*, pp. 125-129, fig. 1).—Brief popular directions for the culture of alfalfa in Arkansas are given.

Alfalfa for Maryland, W. T. L. TALIAFERRO (*Maryland Sta. Bul. 85*, pp. 14).—This bulletin is a brief popular treatise on the culture and uses of alfalfa. Results of culture and feeding tests with alfalfa made at different experiment stations are reviewed in the text. The culture of alfalfa in Maryland is given special consideration, and the regions presenting the necessary soil requirements for the successful culture of the crop are pointed out.

Alfalfa, TRABUT (*Bul. Agr. Algérie et Tunisie, 8* (1902), No. 8, pp. 185-195).—This article is a concise discussion of alfalfa culture in its different phases, together with a brief history of the plant as a cultivated forage crop.

Experiments with barley in 1902, L. GRANDEAU (*Jour. Agr. Prat., n. ser., 4* (1902), No. 41, pp. 467-471, figs. 2).—These experiments, conducted on the experimental fields of the Parc des Princes, consisted of a test of 3 varieties—Hanna, Chevalier-Richardson, and Champagne—and the comparison of 4 different phosphates as fertilizers for barley. Thomas slag was the most effective phosphatic fertilizer and Hanna the most productive variety.

Tests with malting barley (*Reading Col., Agr. Dept. Rpt. 1901*, pp. 31-35).—The results with 6 varieties indicate that some varieties are better adapted to certain localities than others. Five of the varieties were tested simultaneously in different localities. The results are tabulated and briefly discussed.

Buckwheat culture at high altitudes, H. P. WEBER (*Amer. Agr. (ind. ed.), 69* (1902), No. 22, p. 724).—A brief note on the culture of buckwheat in Maryland at an elevation of 1,800 feet above sea level.

Carrots as a forage crop, F. LUBANSKI (*Selsk. Khoz. i Lyesev., 202* (1901), Sept., pp. 663-672).—A general article on the best methods of growing carrots for forage purposes.—P. FIREMAN.

Red and striped maize, H. STEWART (*Country Gent., 67* (1902), No. 2559, p. 129).—This article discusses color variation in the grains of corn. The continuous appearance of red ears, although they are practically never used for seed, is considered as evidence of the natural force of reversion.

Cotton culture in Senegal, PONTY (*Agr. Prat. Pays Chauds, 2* (1902), No. 7, pp. 16, 17).—A general note on cotton culture in that country. A description of the cotton produced is given.

Cotton culture in Asia Minor, Y. HENRY (*Agr. Prat. Pays Chauds, 2* (1902), No. 7, pp. 124, 125).—Brief notes on cotton culture in Asia Minor, including statements as to soil, climate, varieties, and quality of product.

The cultivation of flax on the Dugin estate (*Selsk. Khoz. i Lyesev., 202* (1901), July, pp. 173-207).—The estate is situated in the Syckevski district of the Smolensk government, where the cultivation of flax for seed and fiber is comparatively recent. The feature which distinguishes the methods of manipulation of the crop on this estate from those practiced in other parts of the government is careful water retting according to the prevailing systems of Belgium and France. The financial returns are estimated at about \$17.50 per acre.—P. FIREMAN.

Experiments with lupines, vetches, and peas for green manuring, O. PRSCH (*Organ Ver. Oudleer. Rijks. Landbouwschool, 13* (1901), No. 151, pp. 29-33).—The

experiments were conducted on fertile sandy soil for 2 years. Each year stems, leaves and fruits, and roots were weighed and analyzed. Tables are given showing the weight of dry matter for yellow, white, and blue lupines and for vetches and peas. The results show that the blue lupine gave a greater yield of dry matter and nitrogen than either the white or the yellow. The lupines produced a larger amount of nitrogen and dry matter in the roots and a smaller amount in the stems and leaves than the peas and vetches.—H. M. PIETERS.

Increasing the yield of mangels, A. ARNSTAUT (*Hessische Landw. Ztschr.*, 72 (1902), No. 2, pp. 12, 13).—The results of fertilizer experiments are reported, and the culture of the crop with special reference to increasing the yield is discussed. A number of the best varieties of mangels are briefly described.

Marram grass (*Queensland Agr. Jour.*, 10 (1902), No. 3, pp. 205, 206).—A brief note on marram grass as a sand binder.

Marram grass, A. MOLINEUX (*Jour. Agr. and Ind., South Australia*, 5 (1902), No. 7, pp. 604-607, figs. 2).—This article discusses results obtained with marram grass as a sand binder.

Experiments with oats in 1902, L. GRANDEAU (*Jour. Agr. Prat., n. ser.*, 4 (1902), No. 39, pp. 403-407, figs. 2).—The results for 1902 of culture and fertilizer experiments with oats in progress on the experiment fields of the Parc des Princes since 1891 are reported. Phosphoric acid was applied in 4 different forms and all produced a large increase in yield, Thomas slag being the most effective. The different varieties grown in this test were Kirsche, Mesdag, and Beseler, yielding 20.86, 20.40, and 16.82 quintals of grain and 47.68, 50.54, and 53.65 quintals of straw per hectare, respectively. The differences in yield due to the fertilizer applications were greater than the differences in yield between the varieties.

Experiments with different phosphates for oats, H. G. SÖDERBAUM (*Medd. K. Landt. Akad. Exptlfält.*, No. 67, pp. 15, pl. 1).—Calcium phosphate, Thomas slag, and superphosphate were compared in pot experiments. The results were largely in favor of Thomas slag and superphosphate and about equal for these 2 substances.

The influence of different temperatures on the growth of roots, A. TOLSKY (*Zhur. Opitn. Agron. [Jour. Expt. Landw.]*, 2 (1901), No. 6, pp. 733-744).—For the purpose of this study oats were grown in soil kept artificially at temperatures of 25 and 8° C., respectively, and compared with plants grown in soil at the natural temperature. In part of the experiment the artificial temperatures were kept up until the first leaves began to unfold, and in the other part until the plants began to tiller. The high temperature caused a quicker germination and growth than the lower temperatures, but produced a small root system. The soil kept at a high temperature produced long and thin roots with few branches, while with the lower temperatures short and thick roots with many branches near the surface of the soil were obtained. From these results the author concludes that for sowing oats a cool soil is preferable to a warm one.

Methods of plant breeding, A. KIRSCHKE (*Deut. Landw. Presse*, 29 (1902), No. 3, pp. 18, 19, figs. 3).—An account is given of results in plant selection with oats.

Relation of the chemical composition and anatomical character to the value of potato tubers, F. WATERSTADT and M. WILLNER (*Bl. Gersten-, Hopfen- u. Kartoffelbau*, 1901, No. 9, p. 293; *abs. in Centbl. Agr. Chem.*, 31 (1902), No. 5, pp. 329-331).—The content of starch, crude fiber, and generally of proteids is considerably higher in the outer layer of fresh potatoes than in the marc, but the content of nonprotein nitrogen is smaller, and the total nitrogen is also usually less. The amounts of protein nitrogen and starch in the dry matter of both these parts of the tuber do not differ much, but as a rule the marc contains rather more proteids.

The tubers of heavy yielding varieties contain relatively more marc tissues than the tubers of less productive sorts. No relation seems to exist between the feeding

value of potatoes and their content of dry matter, starch, and nitrogen, but in the better varieties the relation between starch and total nitrogen is found to be narrow.

Electro-culture of crops (*Agr. Jour. Cape Good Hope*, 20 (1902), No. 12, pp. 666, 667).—The results of experiments in electro-culture with potatoes are reported.

Experiments in storing potatoes, O. APPEL (*Arb. K. Gesundheitsamte, Biol. Abt.*, 2 (1902), No. 3, p. 373; *abs. in Centbl. Bakt. u. Par.*, 2. Abt., 8 (1902), No. 21, pp. 683, 684).—Cooperative experiments on storing potatoes by burying them in the ground were made and the results are here summarized. The methods of covering the potatoes are described and the results compared. The development of bacteria on the stored potatoes in some cases killed the eyes or buds.

Report on ramie, E. DAZEY (*Jour. Agr. Trop.*, 2 (1902), No. 11, pp. 148, 149).—A brief description of a cheap process of decorticating ramie.

Rice cleaning and polishing, D. C. ROPER (*Twelfth Census United States, Census Bul.* 201, pp. 14).—This is a report on rice cleaning and polishing in the United States and the Hawaiian Islands during 1900. The information presented is largely statistical. Historical and descriptive notes on rice culture are also given.

Rational fertilization of soil seeded to winter rye, S. BOGDANOV (*Selsk. Khoz. i Lyesor.*, 201 (1901), Apr., pp. 96-116).—After a survey of the literature on the subject and a discussion of the experimental work of various investigators, the author lays down a plan for the fertilization of soil seeded to rye. If the soil still contains a certain degree of fertility, it is considered unnecessary for the satisfactory development of winter rye to fertilize before winter; but if not fertile enough, a small quantity of a readily assimilable nitrogenous fertilizer should be applied. On light, sandy soils all the necessary fertilizers may be applied in the spring. If the soil is not a sandy one and also when the fertility of the soil is very low so that fertilizer is required before winter, it is recommended to apply the potash and phosphoric acid and only a part of the nitrogen in a slowly assimilable form before sowing. The remainder and larger portion of the nitrogen is to be given in 1 or 2 applications in the spring.—P. FIREMAN.

Notes on sugar-beet culture (*Amer. Agr. (mid. ed.)*, 69 (1902), No. 10, p. 350).—An article giving complete details of the production of a prize crop yielding 74,306 lbs. of beets per acre with an average sugar content of 16.1 per cent and a purity of 82.3. The yield of sugar per acre was 11,963 lbs.

Sugar cane report, season 1901, H. J. BLYTH (*Dalsing Serai, India: Indigo Improvements Syndicate*, 1902, pp. 3).—Notes and analyses of different varieties of sugar cane grown in 1901 at the Dalsing Serai Experimental Farm, in the Province of Behar, India.

Sweet potato experiments, C. L. NEWMAN (*Arkansas Sta. Bul.* 72, pp. 33-43).—The results of variety tests with sweet potatoes for the years 1898-1901, inclusive, are given in a table. Of the varieties under test for 4 years, Providence, Southern Queen, Notch Leaf Bunch Yam, Polo, Nancy Hall, Jersey Yellow, and General Grant, given in the order of productiveness, yielded on an average over 200 bu. per acre. Pumpkin, Florida Yam, General Grant, and Southern Queen showed the best keeping qualities. Pumpkin, Vestal New Arkansas Yellow Yam, Florida Yam, General Grant, Nancy Hall, and Tennessee are recommended for their superior table qualities.

Small, medium, and large seed was planted in beds and an equal number of slips from each lot planted on equal areas for comparison. The slips from the large seed yielded 4.8 bu. per acre more than those from the small seed, but the yield of merchantable potatoes was 9.8 bu. greater. "While the results of this test show but a small increased yield from slips from large seed as compared with slips from small seed, it is probable that the progenitors for a number of generations were all small

and that the growing of but one crop from large seed went but a short way toward counteracting the influence of heredity."

A comparison for 2 years of vine cuttings and slips for propagation resulted in an average increase of 7.9 bu. of merchantable potatoes and of 4.5 bu. per acre of total yield in favor of vine cuttings. Cuttings 2 ft. long and slips gave practically the same yield, while cuttings 1 ft. long yielded 16.9 bu. of merchantable potatoes and 12.1 bu. of total crop more, and 4.8 bu. of culls less per acre than slips. The results of a test of moving and pruning sweet potato vines to facilitate late cultivation indicate that "any treatment that disturbed the vines, whether by moving, pruning, or lifting, to a more or less extent decreased the merchantable yield, and the time and labor spent in thus manipulating the vines was uselessly employed and probably detrimental to the crop."

For 2 years planting on a level was compared with planting on ridges 3, 6, and 9 in. high. "The highest total yield and the highest yield of merchantable potatoes were secured from the plats with ridges raised 3 in. high. These also gave the smallest number of culls. The next best yield in both merchantable and total product was from the level plats. Ridges 9 in. high gave 28.7 bu. per acre less than the level plats and 33 bu. per acre less than the plat with ridges 3 in. high."

Several lots of sweet potatoes were selected immediately after digging and treated in various ways for the purpose of checking or preventing decay. The percentage of sound potatoes after 10 weeks of storage ranged from 14 to 72. Attempts to store the potatoes within 3 to 5 days after digging or before they were thoroughly dried were all unsuccessful. Sweet potatoes heated for 8 days in a well-ventilated room at a temperature varying from 100 to 130° F. were quite successfully stored in a cellar with the other lots treated in different ways, and the percentage of sound potatoes after 10 weeks of storage ranged from 94 to 98.

Fertilizers for tobacco, B. W. KILGORE (*Bul. North Carolina State Bd. Agr.*, 23 (1902), No. 3, pp. 34-37).—In connection with a brief discussion of the subject, 5 different fertilizer formulas suited for different localities are given.

Manufactures of tobacco, J. H. GARBER (*Twelfth Census United States, Census Bul.* 197, pp. 36).—This bulletin contains statistics on the production and manufacture of tobacco and on the imports and exports of the manufactured and unmanufactured article. Historical and descriptive notes on tobacco, its culture and manufacture, are also given.

Vicia angustifolia allioni, L. WITTMACK (*Mitt. Deut. Landw. Gesell.*, 17 (1902), Nos. 5, pp. 17-19; 6, pp. 25, 26).—This article treats mainly of the botanical characters of this vetch and the more commonly known species and varieties.

The assimilation of plant food by wheat, J. ADORJÁN (*Jour. Landw.*, 50 (1902), No. 3, pp. 193-230).—A review of the work on the assimilation of plant food in wheat is given, and the results obtained by the author in a study along the same line are reported in tables and discussed. Samples of the growing wheat plant taken at intervals of 10 and 5 days were air-dried and analyzed. Analyses are given for the entire plant and for its different parts. The results show that the assimilation of the plant food in wheat does not proceed in the same ratio as the formation of dry matter, but that generally the plant has a greater food requirement in the earlier stages of its growth than later on. During early growth, nitrogen is the principal requirement, and phosphoric acid is also taken up in large quantities. A heavy food requirement continues while the plant is heading. At this time phosphoric acid is needed in large quantities. At the blossom period this element is assimilated even faster than nitrogen and reaches the maximum. Under normal conditions no more phosphoric acid is taken up for the development of the plant after the maximum assimilation has been reached. After blossoming the assimilation of nitrogen is reduced to the needs of the plant for the formation of grain. Wheat takes up the greatest portion of its food in the early stages of growth, stores it up, and draws upon it later for the development of the grain.

Report of the wheat experimentalist, W. FARRER (*Agr. Gaz. New South Wales*, 13 (1902), No. 5, pp. 537-542).—This report describes in a general way the experimental work with wheat carried on at the different experimental farms of New South Wales.

HORTICULTURE.

Cantaloupe culture in Georgia, S. H. FULTON (*Georgia Sta. Bul.* 57, pp. 157-193, figs. 11).—This bulletin discusses Georgia methods of muskmelon culture and gives the results of some cooperative fertilizer experiments with muskmelons. The chief variety grown commercially is the Rockyford, and it is urged that the seed of this variety for planting be selected from the best Colorado-grown stock. Plant early—in South Georgia about the middle of March. Use 10 to 15 seeds per hill and thin to one plant. The following data were obtained in a thinning experiment:

Thinning muskmelon plants.

Plants per hill.	Marketable melons.	Average weight per melon.	Unmarketable melons.
		<i>Pounds.</i>	
One plant	90	1.09	19
Two plants	116	.98	30
Three plants	86	.99	27
Four plants	47	.79	57

While 2 plants per hill gave more marketable melons than 1 plant per hill, the melons were smaller and the percentage of unmarketable melons larger.

Tests of home-grown and Colorado-grown Rockyford seed have resulted in favor of the latter. In the cooperative fertilizer tests the best results were obtained from formulas analyzing 8 per cent phosphoric acid, 7 to 8 per cent potash, and 3 to 4 per cent nitrogen. A formula suggested for South Georgia consists of 1,000 lbs. acid phosphate (14 per cent), 250 lbs. muriate of potash, and 1,000 lbs. cotton-seed meal. From 600 to 800 lbs. of this mixture should be applied per acre 2 to 3 weeks previous to planting and thoroughly worked into the soil.

Detailed notes are given on harvesting, yield, grading, packing, and shipping muskmelons, and on the diseases and insects affecting them. For local market Augusta Market, Anne Arundel, New South, Delmonico, Chicago Market, and Long Island Beauty are considered desirable.

The effects of colored light, L. C. CORBETT (*Amer. Gard.*, 23 (1902), No. 403, p. 591).—The author notes the marked stimulating effect of red light on lettuce grown in the greenhouse. The light was used at night and was obtained from an arc light with a colored screen interposed. The use of green or blue lights did not have the same stimulating effect, but were not found harmful. In the experiment cited all the plants under observation received the ordinary daylight, the colored screens being used only at night. In the author's opinion artificial light has a decided forcing value, but hardly sufficient to warrant its use commercially.

A new edible tuber (Coleus coppini), E. HECKEL (*Agr. Gaz. New South Wales*, 13 (1902), No. 7, pp. 724, 725).—It is stated that this tuber is grown in many tropical French colonies as a substitute for potatoes, since in these situations potatoes run to vines. In a lot of these tubers raised in the Colonial Botanical Garden at Marseilles the tubers varied from $\frac{1}{2}$ to 1 $\frac{1}{2}$ in. long and from $\frac{1}{4}$ to $\frac{1}{2}$ in. in thickness. A number of analyses of the tubers showed the following average results: Starch, 14 per cent; fat, 2.5 per cent; glucose, 10.68 per cent; saccharine, 1.67 per cent; gum and pectic matter, 16.05 per cent; albuminous substances, 5.78 per cent; ash, 4.26 per cent; cellulose, ligneous matter, and loss, 40.71 per cent. Directions are given for cooking the tubers; in general this is like potatoes. The plant is believed to be worthy of trial in New South Wales.

Water cress in Erfurt, R. ENGELHARDT (*Möller's Deut. Gart. Ztg.*, 17 (1902), No. 22, pp. 250-263, figs. 5).—Cultural account of the water cress industry at Erfurt, Germany.

Experiments in mulching vegetables, R. A. EMERSON (*Twentieth Century Farmer*, 1902, No. 69, p. 1, fig. 1).—Experiments are reported on the use of straw or other similar material as a mulch for garden vegetables. Out of 40 growers that tried the mulch on beans, peas, cabbage, tomatoes, sweet corn, watermelons, muskmelons, cucumbers, and sweet potatoes, 22 report more favorable results than with cultivation; 15 favor cultivation; and with 3, results were about equally favorable to both methods. These results were obtained in Nebraska in an unfavorable year. It is believed that a better showing would have been made for the mulch had the growers practiced cultivation until the ground was thoroughly warm, and then applied the mulch. This practice is recommended.

The value of chemical manures, F. W. E. SHRIVELL (*Jour. Hort.*, 54 (1902), No. 2782, p. 80).—In seven years' experiments with garden crops it was shown that the commercial fertilizers could be substituted in part for barnyard manure with a saving in cost.

Report on experiments in fruit and vegetable drying at the experimental garden, Droitwich, 1901, J. UDALE (*Jour. Roy. Hort. Soc. [London]*, 26 (1902), No. 4, pp. 834-839).—The percentage product obtained in drying plums, apples, pears, cherries, potatoes, cauliflower, kidney beans, and a number of herbs, with the temperatures used in drying, are recorded. The amount of dried fruit obtained with plums varied from 19 to 33 per cent of the original product. The varieties most suitable for drying were Monarch, Czar, Prince Engelbert, White Perdrigon, and Victoria. The various varieties were dried from 12 to 18 hours. The product in some instances compared favorably with French and California goods. The experiments showed that all kinds of vegetables could be dried successfully, but it was not ascertained whether this could be done with commercial success or not.

The effect of hydrocyanic-acid gas on fresh fruit, H. SCHMIDT (*Arb. K. Gesundheitsamte*, 18 (1902), No. 3, pp. 490-517).—A record is given of some experiments undertaken to determine the effect of hydrocyanic-acid gas on fresh fruits for the purpose of preserving them. The work was undertaken as a result of the report of the German consul from Australia that apples were being preserved for shipment by subjection to the fumes of hydrocyanic-acid gas. The author's experiments showed that such fruits as peaches, plums, apples, pears, and lemons readily absorb this gas and that upon exposure of the fruit to the air part of the gas is given off. A part, however, remains in the fruit apparently in combination with sugar. When the gas was used in sufficient strength to prevent the growth of fungi the color and consistency of the fruit were so changed as to make it unsalable. In any case it appeared to have no preservative effect. When not used in sufficient quantity to destroy the fruit it did not prevent the development of rot. The results of the experiments as a whole go to show that hydrocyanic-acid gas will not prove of special value in the preservation of fresh fruits. The fact that the gas is retained in part in the fruit makes its use dangerous to health.

Fruit growing in New England and its development during the last fifty years, A. LOW (*Trans. Massachusetts Hort. Soc.* 1901, I, pp. 92-109).—This is a discussion of the development of the orchard, small fruit, and grape industries in New England during the last 50 years.

Experiments in orchard culture, C. G. MARSHALL (*Agriculture [Nebraska]*, 1 (1902), No. 8, pp. 18-20).—An account is given of experiments made by the horticultural division of the Nebraska Experiment Station to determine the most suitable manner of cultivating orchards in that State. The orchard was divided into 8 sections, one of which was cropped with vegetables, another with corn, and a third with oats. Other plats were cultivated the entire season, cultivated part of the season and

then planted to millet, cultivated part of the season and then cropped with oats, and cultivated part of the season and then allowed to run to weeds.

An examination of the moisture content of the soil of the different plats was made during the season and a table is given which shows the number of trees that failed to start into growth and the number of trees that died after starting. The amount of moisture in all the plats remained nearly uniform up to July 1, excepting in the case of the plat cropped with oats for the entire season. On this plat the moisture content was much lower than on any other. On August 15 the plat cultivated to corn contained less moisture than any of the other plats, while the plats cultivated part of the season and then sown to a cover crop contained slightly more moisture than those cultivated throughout the entire season or planted to vegetables. More than 50 per cent of the trees on the plat cropped with oats throughout the entire season failed to start or died after starting. The greatest loss on any other plat was about 20 per cent, and occurred on the plat given cultivation in the early part of the season and then allowed to grow up to weeds.

The results, on the whole, indicate that the sapping of the moisture from the soil in the latter part of the season, as was done by the corn and cover crops, did not have nearly as serious an effect on the trees as did the withdrawal of the moisture by the oat crop in the early part of the season. Another experiment in the cultivation of peach trees showed that cultivation throughout the entire season conduced to more dead trees than cultivation part of the season followed by a cover crop.

Orchard cover crops (*Amer. Agr. (mid. ed.)*, 69 (1902), No. 3, pp. 79, 100, fig. 1).—A discussion is given of the relative value of various leguminous cover crops for orchards and of some cooperative experiments carried out by the New York Cornell Station with orchardists in different parts of the State. Hairy vetch was one of the most useful plants employed. It is stated that this plant analyzed over 200 lbs. of nitrogen per acre for a growing period of 3½ months. This plant was not very vigorous in the early autumn where the shade was dense, but greatly improved later when the leaves began to fall. One difficulty in connection with the use of this plant is the scarcity of seed. It is stated, however, that if a small quantity is secured in the beginning, the orchardist can easily grow sufficient for his own use each year.

Stringfellow method of planting (*Rural New Yorker*, 61 (1902), No. 2745, p. 606).—A record is given of the growth of apples and grapes planted according to the Stringfellow method a year previous. Out of 132 apple trees planted on the land and given no attention other than a manure mulch, 37 have died. The others have made a ⅓ to ⅓ normal growth on the average. Check trees planted with whole roots show 75 per cent of normal growth. With the grapes, 64 out of 153 vines set have died. The others have made from 25 to 40 per cent of a normal growth. A peach orchard of 160 trees planted in the same way is reported as looking thin but most of the trees are still alive. The ground occupied is very poor and difficult to cultivate.

Locating orchards in Washington, S. W. FLETCHER (*Washington Sta. Bul.* 51, pp. 14, figs. 2).—A popular discussion of the fruit zones of Washington, with suggestions regarding the locating of orchards.

Planting orchards in Washington, S. W. FLETCHER (*Washington Sta. Bul.* 52, pp. 29, figs. 7).—The best methods for planting orchards in Washington are popularly discussed. In speaking of the Stringfellow system of planting, the author states that the results of the station work in that State indicate no advantage for this method.

Nursery stock for Washington orchards, S. W. FLETCHER (*Washington Sta. Bul.* 53, pp. 31).—Popular suggestions to farmers regarding the propagation and buying of nursery stock. A list is appended of the nurseries licensed to sell fruit trees in the State of Washington in 1902.

The commercial apple area, W. A. TAYLOR (*Amer. Gard.*, 23 (1902), No. 404, p. 610).—The author gives statistics from the Twelfth Census which indicate that more than three-fifths of the total number of apple trees grown in this country are found

in the North and South Central States. Missouri leads with 20,040,399 trees, followed by New York, Illinois, Ohio, Kansas, Pennsylvania, and Michigan in the order named, the number gradually decreasing from 15,054,832 trees in New York to 10,927,899 trees in Michigan. In the more Northern States the chief commercial varieties grown are Baldwin, Rhode Island Greening, Northern Spy, Tompkins King, Hubbardston, and Russets. Farther south Ben Davis, Winesap, York Imperial, Minkler, Grimes, and Willow Twig are the chief varieties.

Apple growing, pollination, and time of bloom, MASKREW (*California Cult.*, 19 (1902), No. 13, p. 193).—Some tabulated data are given showing the periods of first bloom, full bloom, and fall of bloom for 16 varieties of apples and 3 varieties of crab apples grown in Los Angeles County, Cal.

Comparing keeping qualities of apples, S. A. BEACH (*Amer. Agr. (ind. ed.)*, 70 (1902), No. 9, pp. 194, 196, 197).—The average life of 92 varieties of apples kept in a fruit storage house without refrigeration is tabulated. Some of the fruit has been regularly fertilized since 1892 with wood ashes, using 100 lbs. of wood ashes per tree. The data given do not show that the application of the ashes to these trees had any marked influence, one way or the other, on the keeping quality of the fruit. With the Northern Spy, the fruit from orchards in sod was more highly colored and kept better than that from cultivated orchards.

Apple and pear hybrid (*Garden*, 61 (1902), No. 1583, p. 199, fig. 1).—An illustration is given of the fruit of a supposed hybrid between the apple and pear. In general shape the fruit resembles the pear. In taste, however, it is said to resemble the apple.

Varieties of apples and peaches, J. T. STINSON (*Missouri Fruit Sta. Bul.* 3, pp. 21-54, pls. 3).—The author sent letters of inquiry to all the prominent fruit men of the State regarding the best varieties to grow in their respective localities. The replies from 30 of these growers have been tabulated with reference to peaches and apples, and 15 of the more promising varieties of apples are briefly described. The apple oftenest mentioned as most successful in Missouri and placed first as a commercial fruit is Ben Davis, with Gano second. Elberta is mentioned oftenest as the most desirable commercial peach.

The Peen-to peach group, H. H. HUMM (*Florida Sta. Bul.* 62, pp. 505-519, pls. 3).—The author states that this group of peaches is essentially adapted to sub-tropical conditions and particularly the State of Florida. It can also be successfully grown in Louisiana, Mississippi, Alabama, and the coast regions of Texas. It was first grown in Florida in 1869 by J. P. Berekinans from seed obtained from Australia. The trees are characterized as vigorous, upright in habit, prolific, and well covered with foliage. With age the heads become more open and spreading. The fruit is usually roundish in outline and occasionally blunt pointed. They are well colored and of good appearance and flavor. The stones may be either free or cling. The ripening period varies with the different varieties from April to the middle of July. Most varieties mature their fruit by July 1. Twenty-four varieties of these peaches are listed and described. A considerably less number are at present under cultivation. For the southern part of Florida the varieties Angel, Waldo, Bidwell Early, Bidwell Late, Dorothy N., Jewel, Maggie, and Peen-to are recommended; and for the northern part of the State, Angel, Bidwell Late, Jewel, and Waldo. Angel and Waldo are believed to be the most reliable. For the coast region of Texas, Angel, Jewel, and Waldo are recommended.

Orchard results from the sugar prune, C. W. REED (*Pacific Coast Fruit World*, 14 (1902), No. 4, p. 11, fig. 1).—This prune, originated by Luther Burbank, is now coming into bearing under orchard conditions. It ripens a month earlier than the ordinary French prune, and varies in weight from 6 to 10 per pound green and from 15 to 26 dry. The crop appears to get larger and heavier as the trees get older. Whole fresh fruit analyzed 23.92 per cent sugar. The sugar prune is

believed by the author to be superior to the French prune for all fancy and middle grade stocks. The tree has proved a splendid grower on either peach or almond stock.

Olives, G. E. COLBY and F. T. BIOLETTI (*California Sta. Buls.* 123 and 137, rev. ed., pp. 45, figs. 9).—These bulletins have been previously noted (E. S. R., 11, p. 46; 13, p. 747). Methods of olive cultivation, oil making, and pickling, as observed in California, are discussed, and the varieties most commonly grown described, together with the diseases which commonly affect them. A considerable number of analyses with regard to the percentage of oil in the different parts of the fruit, and data as to the number of olives per pound and the proportion of pit to flesh, have been added for a large number of different varieties of olives.

The olive; its culture, oil, and adulteration, L. CARRIÉ (*Der Olivenbaum, seine Kultur, sein Oel und dessen Fälschungen. Nice: Imprimerie des Alpes-Maritimes, 1901, pp. 38*).—This is a popular discussion of olive culture, including notes on its diseases and directions for the manufacturing and preserving of olive oil. Various chemical tests used to determine the purity of olive oil are also included in the work.

Cultivation, enemies, and commerce of citrus fruits, G. DEL VESCOIO (*Coltivazione malattie e commercio degli agrumi. Bari, Italy: Pasquale Losasso, 1900, pp. 176, figs. 36*).—Part 1 of this work includes, under the general heading of culture, notes on botany, propagation, nursery management, soils, climate, irrigation, yields and profits, chemical composition, fertilizing with commercial fertilizers and manures, etc. In part 2, under enemies, are considered the insects and diseases affecting citrus fruits, and climatic conditions. Part 3 is concerned with the production and commerce of citrus fruits.

Trees on sour and Citrus trifoliata stocks, G. L. TABER (*Florida Times-Union and Citizen, 1902, Aug. 8, p. 6*).—In 1899 the author planted an experimental plat of 100 orange and pomelo trees. There were 25 varieties and 4 trees of each variety. Half the trees were worked on sour stock and half on *Citrus trifoliata*. The trees on the sour and on the *C. trifoliata* stock were alternated in the orchard with each other and planted 30 ft. apart each way. At the time of writing (July 26, 1902) the average height of the trees on sour stock was 8 ft. 2 in. and the average breadth 9 ft. 2 in. The average height of the trees on *C. trifoliata* was 6 ft. 2 in. and the average breadth 7 ft. Adding together the fruit produced in 1901 and 1902 and averaging the amount, the trees on sour stock produced a total average of 69 oranges per tree for the 2 years. The trees on the *C. trifoliata* stock have averaged 93 oranges each for the 2 years, an increase of nearly $\frac{1}{3}$ over the trees on the sour stock. The fact that the trees on *C. trifoliata* could have been set $\frac{1}{3}$ to $\frac{1}{4}$ closer than the trees on the sour stock and that they might be frozen to the banking 1 year out of 3 and still produce a good crop of fruit 1 year out of 3 is taken as indicating the advantages of this stock for frosty sections. Not all varieties budded on *C. trifoliata* stock gave equally good results. Two varieties of orange, viz, Jaffa and King, and one variety of pomelo, Duncan, have made larger growth on *C. trifoliata* than the corresponding varieties on sour stock planted alongside of them. The following varieties on *C. trifoliata* also compare well as regards growth with those on sour stock: Du Roi, Early Oblong, Homosassa, Madam Vinous, Magnum Bonum, Nonpareil, Pineapple, and Tangerine. Another point brought out in this connection is that while *C. trifoliata* is naturally a much more dwarfed tree than most varieties budded on it, it will nevertheless invariably grow faster than the bud inserted on it. In other words, when the diameter of the bud just above the point of union is perhaps 3 in. the diameter of the *C. trifoliata* stock just below the union will be $3\frac{1}{2}$ in.

The trifoliata down South (*Florida Times-Union and Citizen, 1902, Aug. 22, pp. 5, 6*).—The value of *Citrus trifoliata* stock for adverse situations is discussed and some data given on the productiveness of buds on this stock. A bud 10 in. high of the Oblong Kumquat on this stock ripened 34 good-sized fruits. A bud of the same

variety 6 ft. high carried 2,500 fruits. A bud of the Royal Pomelo 5 ft. high matured 44 fruits. A Centennial bud 18 in. high ripened 3 good sized fruits. A number of Buttercourt buds 18 to 24 in. high ripened 9 to 13 fruits. In the opinion of the author, there is a great field for those who wish to grow trees close together, to restrict growth and produce a large amount of fruit on a small area.

Hybrid oranges in Texas, G. MARRI (*Florida Times-Union and Citizen*, 1902, Aug. 15, p. 6, from *Rural New Yorker*).—An account is given by the author of hybridizing *Citrus trifoliata* upon the Satsuma or Oonshiu orange, a hardy, dwarfish variety of the Mandarin kind, thornless, pretty near seedless, and of excellent quality. A number of other crosses were made, but this is the only one the author was able to raise of this parentage. The author states that "the resulting cross took almost every feature of the pollen parent, with its thorns, deciduous triple leaves, and hardy constitution. However, the fruit differs widely from both parents. It is perfectly round, being depressed neither in its blossom nor on its stem end; diameter both ways 2½ in. It has a roughish but even surface. The color is deep yellow or orange. The rind is extremely thin, merely a skin, but tough, adhering closely to the flesh, which is of a greenish-yellow color. It is very juicy and sweet, having just acid enough to make it sprightly and refreshing and of far better quality than the average California seedling orange. The fruit, however, ripens late—later than that of any of its parents." Considerable difference is noticed between the calyx of the hybrid and that of either parent. On the hybrid the calyx consists of 5 large, foliate, persistent sepals, which keep green and never drop, even when the fruit ripens. The author states that the original tree from which the hybrid fruit was obtained was lost by accident, but that he has 2 healthy grafts growing from it.

A number of other hybrids, mostly crosses of the dwarf type of Mandarin on *C. trifoliata*, have been made. These have bloomed, but all the flowers proved to be without pistils, and many of them proved to be as tender as the orange. A valuable characteristic of the Satsuma hybrid is that it has proved the latest of all to leaf out, even later than its parents. Its chief fault appears to be a lack of the orange aroma in the rind. Instead of this it has a rank odor which is stated to be a characteristic of the average California orange. In the opinion of the author, these experiments have proved that it will be impossible to ever obtain a hardy orange, but "that we can put a highly improved edible fruit on the hardy *C. trifoliata*."

Notes on lemon curing, D. JONES (*Queensland Agr. Jour.*, 10 (1902), No. 3, pp. 181-183).—The author states that a successful lemon grower in Victoria cures his lemons by gathering the fruit when it is just turning yellow. The fruit is cut off and a short piece of the stalk left on. It is packed in ordinary cases and stored in a well-ventilated cellar having a temperature of 53 to 57° F. It takes from 7 to 8 weeks to cure lemons, and sometimes longer. When cured, the short piece of stalk left on will drop off when touched. Lemons thus cured keep for 12 months. Oranges are cured in a similar manner, but they must be better colored before cutting than the lemons. They must be handled more carefully and on no account must they be too ripe.

The banana industry in Jamaica, W. FAWCETT (*West Indian Bul.*, 3 (1902), No. 2, pp. 153-171).—The author describes the banana plant, notes the varieties of bananas grown in Jamaica, and gives in considerable detail the cultural methods observed. The diseases of the banana are also noted and some data given on the cost of growing bananas in Jamaica and the returns obtained.

The cultivation of Japanese kaki (*Diospyros kaki*), figs (*Ficus carica*), *Punica granatum*, and almonds on the southern coast of the Crimea, V. AGGEENKO (*Selsk. Khoz. i Lyubov.*, 202 (1901), Sept., pp. 673-681).—The author describes the present state of cultivation of these plants in the Crimea and predicts success for their systematic culture.—P. FIREMAN.

Tea. C. A. GUIGON (*Le thé. Paris: Augustin Challamel, 1901, pp. 251, dym. 2*).—A treatise on the history, culture, and preparation of tea; countries producing it; statistics and commerce of tea; classification of teas; and tea mixtures.

Investigations on the quantity of caffen in several species of coffee trees, G. BERTRAND (*Agr. Prat. Pays Chauds, 2 (1902), No. 8, pp. 211-213*).—A table is given showing the place of origin and the water, ash, nitrogen, and caffen content of 12 samples of *Coffea arabica*; 3 of *C. liberica*; 2 of *C. stenophylla*; and one each of *C. canephora*, *C. laurina*, *C. congensis*, *C. mauritiana*, *C. humboldtiana*; and a variety called Cazengo.

Cacao, culture and preparation, P. PREUSS (*Le cacao, sa culture et sa préparation. Paris: Augustin Challamel, 1902, pp. 127, figs. 69*).—This book is the outcome of a journey in tropical and Central America, and deals particularly with the methods of cacao culture in Trinidad, Guatemala, Venezuela, and tropical and Central America. Buildings used for the drying of cacao are also described and analyses given of the seed of *Theobroma bicolor*.

Contributions to our knowledge of the composition of Norwegian small fruits, A. YSTGAARD (*Tidsskr. Norske Landbr., 9 (1902), No. 3, pp. 125-145*).—A discussion is given on the importance of the fruit industry in Norway, the chemical composition of fruits, and the variations to which the different components are subject, according to time of sampling, latitude of locality where the fruits were grown, etc.

The author does not consider the hypothesis of Schübeler correct, that fruits grown in northern latitudes contain a smaller percentage of sugar than the same kinds grown farther south, that "light produces aroma (flavor), and heat, sugar." So far as the analyses at hand furnish evidence on this point, the data for Norwegian wild or cultivated small fruits do not show a lower sugar content than for the same kinds of fruit grown in the Rhine Valley, for example. Neither does the acidity of fruits grown in the two countries vary regularly, Norway-grown fruits containing sometimes more, sometimes less, acid than those grown in Germany. Direct trials showed that the content of acid has a preponderating influence over that of sugar on the taste and flavor of fruits to such an extent that only 0.1 per cent of acid more than counterbalances 1 per cent of cane sugar.

The following compilation gives the average percentage composition of the different kinds of fruits analyzed by the author, with the range of variation. The acidity of the juice was determined both before and after decoloration with animal charcoal.

Analyses of Norwegian small fruits.

Kinds of fruit.	Number of samples.	Dry matter.	Cellulose.	Pentosans.	Total acidity.	Malic acid.	Citric acid.	Sugar.	Albuminoids.	Ash.

a Two samples. b One sample. c Four samples. d "Only a few hundredths of 1 per cent." e 0.02 per cent phosphoric acid. f Three samples. g In one sample, 1.04 per cent pentosans. h 0.04 per cent phosphoric acid.

A single sample of raspberries from Nordland contained 18.64 per cent dry matter, 4.09 per cent cellulose, 7.71 per cent pentosans, 5.02 per cent sugar, 1.47 per cent acid in original juice, and 1.52 per cent in decolorized juice, of which 1.40 per cent was citric acid, 0.14 per cent malic acid, and 0.04 per cent phosphoric acid with a trace of sulphuric acid.—R. W. WOLL.

New ideas in strawberry growing, R. M. KELLOGG (*Michigan Farmer; Canad. Hort.*, 25 (1902), No. 6, pp. 232-234).—Plants for propagation are grown in hills under the best natural conditions. They are set out in the spring and a scale card kept during the summer as to foliage, vigor, freedom from fungi, size of crown, disposition to throw out runners, and kinds of fruit buds developed. The following spring the plants scoring highest are allowed to fruit. As soon as blossom buds appear about one-half are removed, and when the fruit has set all the berries, except 2 or 3 on each stem, are removed, and the size, color, and firmness of the ripened fruit noted. Plants showing the highest scale are allowed to make runners for the following spring planting. This method of selection is kept up each year.

In the permanent bed, plants are set 30 in. apart in rows 30 to 36 in. apart. The runners are layered so that the plants stand about 10 in. in the row, after which all runners are cut off. It is claimed that berries thus grown are large, of an even size, bright in color, and rich in flavor. The yield is also larger than by any other method tried. Frequent tillage is practiced and irrigation in dry weather.

The sand cherry in cultivation, R. A. EMMERSON (*Agriculture [Nebraska]*, 1 (1902), No. 6, pp. 9-11).—The author notes the characteristics of the sand cherry and states that a number of hybrids between the sand cherry and various sorts of plums are being grown at the Nebraska Experiment Station. The hybrids have a larger fruit than the sand cherry but the fruit still retains much of the peculiar flavor of the sand cherry. It is hoped that later generations may give something of value. The sand cherry is a shrub growing a foot or two high in the sand hills and 5 to 6 ft. high on rich, moist soils. It is thought that it may be of considerable value in the drier and colder portions of the Northwest, and when further improved may be useful throughout the State.

Grafting green grapevines, J. ZAWODNY (*Gartenflora*, 51 (1902), No. 16, pp. 429, 430, figs. 6).—The grafting of green grapevines has been very successfully practiced by the author. The work is done in May, June, and the beginning of July when the stock is growing most luxuriantly. The graft is made obliquely through a node. The details of the method are clearly brought out in a series of drawings.

Hybridization at Beblenheim, C. OBERLIN (*Troisième Congrès International de Défense contre la Grêle et de l'Hybridation de la Vigne. Lyons: Soc. Rég. Vit., 1902, II, pp. 78-91*).—An account of the work, with a table showing the fertility, maturity, sugar content, and resistance to diseases of the hybrid direct producers grown.

Hybrid direct producers in calcareous soils, J. M. GUILLON (*Troisième Congrès International de Défense contre la Grêle et de l'Hybridation de la Vigne. Lyons: Soc. Rég. Vit., 1902, II, pp. 128-135*).—The general conclusions of the author are practically as follows: Direct producers are in general very resistant to chlorosis. A large number are not sufficiently resistant to phylloxera but may be practically so on deep fresh soils. The yields are generally lower than with grafted vines and the quality of the wine inferior. Nevertheless, several are satisfactory for consumption, for the production of alcohol, and for mixing. While the resistance of direct producers to fungus diseases is rarely complete, nevertheless it is nearly always sufficiently high so that the number of sprayings required by them is considerably less than with grafted vines. The culture of direct producers is recommended only in difficult situations and where it is wished to obtain wine without much expense or trouble. The results obtained up to the present time with direct producers are, on the whole, so promising that their further study should be actively encouraged.

Value of hybrids for wine, J. R. CHEVRIER (*Troisième Congrès International de Défense contre la Grêle et de l'Hybridation de la Vigne. Lyons: Soc. Rég. Vit., 1902, II, pp. 142-203*).—The value of a large number of hybrids for wine making is discussed and shown in tables of analyses.

The affinity of *Vitis vinifera* with *V. berlandieri*, T. V. MUNSON (*Troisième Congrès International de Défense contre la Grêle et de l'Hybridation de la Vigne. Lyons: Soc. Rég. Vit., 1902, II, pp. 139-142*).—*V. berlandieri*, in the author's experience, has proved one of the most satisfactory stocks for various varieties of *V. vinifera*. It is one of the most resistant species to fungus diseases and phylloxera. It is very resistant to drought.

The effect of phosphoric acid on the quality of wines and on the gray rot, E. MARRE (*Prog. Agr. et Vit. (Éd. L'Est), 23 (1902), No. 2, pp. 39, 40*).—In these experiments the vineyard was manured the first year with barnyard manure at the rate of 35,000 kg. per hectare; the second year with superphosphate, 500 kg. per hectare; the third year no manure was given. Since the employment of the superphosphate regularly the vines have been more vigorous and less subject to the "coulure," and there has been an increase in the production of about one-third. The maturity of the grapes on the plats manured with superphosphates has been hastened about 8 days, and the body of the wine increased from 1 to 1½ degrees. The leaves, shoots, and fruits seemed more resistant to fungus diseases. Thus in 1900-1901 it is estimated that 1/10 of the grapes was destroyed by the gray rot on the plats fertilized with barnyard manure, while on the superphosphated plats only about 1/200 was destroyed.

Contribution to the preparation of orchard fruit wines, E. HOTTER (*Separate from Ztschr. Landw. Versuchs. Oesterr., 5 (1902), pp. 68*).—This consists of a discussion of the cider and berry industries in the more important fruit-producing districts of Europe, the characteristics of certain varieties of fruits best suited for cider production, and the results of a number of experiments with different machines for pressing out cider. Both apples and pears are considered; and these are classified and their composition as regards sugar, acid, total extract, etc., is given in a series of tables. The analyses of the wines produced are also tabulated.

Pecans, F. H. BURNETTE, W. C. STUBBS, and H. A. MORGAN (*Louisiana Stat. Bul. 69, 2. ser., pp. 850-884, figs. 19*).—This is a popular discussion of pecan culture in Louisiana, giving methods of propagation, including budding and grafting, and the subsequent treatment to be observed in the nursery and orchard. A number of the better varieties are illustrated and briefly described. The States in which a number of the different varieties originated are also given. Seedling trees planted at the station in 1895 had reached a diameter of 11½ in. and a height of 34 ft. by 1902. The final chapter gives a brief discussion of pecan insects, with suggestions as to the best methods for their control.

The shrubs of Wyoming, E. E. NELSON (*Wyoming Sta. Bul. 54, pp. 47, pls. 5, figs. 16*).—This bulletin has been prepared as an aid in the identification of native shrubs, with the hope that it may be instrumental in interesting the people of the State in the more general planting of shrubs for home decoration. It is stated that most of the cultivated shrubs of the Eastern States will not thrive in Wyoming, especially in the higher altitudes. Brief popular descriptions are given of a large number of different shrubs belonging to 23 different families of plants. The bulletin is indexed with both the Latin and common names of the different shrubs described.

Bulb culture in North Carolina, W. F. MASSEY (*Amer. Florist, 19 (1902), No. 742, pp. 146-148*).—The author has been growing bulbs experimentally for a number of years in North Carolina, and here summarizes the results of his work. It has been definitely determined that sections about Raleigh, and all that portion of the State known as the lower Piedmont country, east of the Oconeechee, are unsuited

to the culture of bulbs except narcissi and the Italian hyacinth. These latter thrive in North Carolina to perfection. Roman hyacinths grow well in North Carolina in cold winters, but in mild winters it is hard to grow them well. Excellent results have regularly been obtained with gladiolus. Cannas have also been grown to a considerable extent. *Sternbergia lutea* does well when planted in August or early September. Guernsey lilies do satisfactorily when planted in August. The spotted-leaf calla is perfectly hardy and commonly planted in the fall. *Iris sanctum* is also perfectly hardy. Excellent results have been obtained in growing *Amaryllis johnsoni*. The author proposes transferring his experimental Bermuda bulbs to the coast plain of the State, where he believes that full success in their culture will be met with. In the author's experiments he has found that while the lily does not tolerate animal manures in contact with the bulbs, commercial fertilizers can be used as heavily as with onions, and the same is practically true of all other bulbs. Narcissi, however, do not object to well-rotted manure, and it is practically as good as commercial fertilizers for hyacinths.

Bulbs in Washington, L. C. CORBETT (*Amer. Gard.*, 33 (1902), No. 402, pp. 576, 577, figs. 2).—The author states that Mr. George Gibbs, of New Whatcom, Wash., is now successfully growing the following bulbs: Crocus, narcissus, tulip, hyacinth, and such lilies as *Lilium excelsum*, *L. album*, *L. auratum*, *L. candidum*, *L. columbianum*, *L. washingtonianum*, and *Longiflorum* from Japan and Bermuda. The increase with *L. longiflorum* has been especially satisfactory. One of the chief obstacles to the successful commercial development of the bulb industry on the Pacific Coast seems to be the cost of transportation to the East, freights being considerably greater by rail to the East than by water from the bulb-growing districts of Europe.

An experiment with hyacinths in water, E. E. BOGUE (*Amer. Florist*, 19 (1902), No. 749, p. 378).—The details of an experiment undertaken to determine whether the behavior of varieties was due to the variety itself or to the manner of culture. No difference in the growth of the hyacinths due to different cultural media could be detected, but there was a marked difference in the different varieties.

How to make money growing violets, G. SALTFOED (*New York: The Violet Culture Co.*, 1902, pp. 44, pls. 12).—This is a short, popular account of violet culture under cold frames and in the greenhouse.

Gilliflower and wallflower culture in Erfurt, R. ENGELHART (*Möller's Deut. Gart. Ztg.*, 17 (1902), No. 34, pp. 405-416, figs. 9).—A popular descriptive article discussing the methods of pot and field culture of these flowers and methods of commercially growing seed.

Hybridizing Gladiolus species, W. VAN FLEET (*Amer. Florist*, 19 (1902), No. 748, pp. 345-347).—A paper read before the International Plant Breeding Conference, held in New York, September 30 to October 2, 1902, in which the characteristics, markings, etc., of a number of different Gladiolus hybrids are given. The results obtained by the author in crossing many different species and varieties are also noted in the work. Out of 150,000 seedlings grown by the author during the past 16 years, only 2 have been thought worthy of naming and commercial introduction.

A classification of sweet peas, H. J. WRIGHT (*Jour. Hort.*, 54 (1902), No. 2815, pp. 250, 251).—This classification was made for the use of members of the National Sweet Pea Society of England. It is based on color.

Mendel's laws of alternative inheritance in peas, W. F. R. WELDON (*Biometrika*, 1 (1902), No. 2, pp. 228-254, pls. 2).—A discussion of Mendel's law and the data upon which it is based, with a summary of a considerable amount of other evidence concerning dominance in peas. The characteristics of a number of hybrid peas of the Telephone group are noted and their bearing on Mendel's law of segregation discussed. A bibliography of 32 papers bearing on the various phases of the subjects discussed by the author completes the article.

It appears from the evidence cited that a character which is sometimes dominant is not necessarily always so. "The degree to which a parental character affects off-

spring depends not only upon its development in the individual parent, but on its degree of development in the ancestors of that parent."

The history of the Telephone group of peas is shown to be clearly inconsistent with the universality of Mendel's law of dominance and segregation. These laws hold only for races of particular ancestry. Neglect to take this fact into account is, in the author's opinion, a fundamental mistake which will vitiate all work based upon Mendel's methods.

Mendel's law applied to orchid hybrids, C. C. HURST (*Jour. Roy. Hort. Soc. [London]*, 26 (1902), No. 4, pp. 688-695).—It has been shown that Mendel's formula is of value for the separation of characters in self-fertilized crosses. The author shows that the formula may be extended to the union of specific characters in intermediate primary hybrids. The advantages of orchid hybrids for observations in heredity are pointed out, and a table is given in which is shown the inheritance of pairs of specific characters in 113 distinct hybrids belonging to several genera. Out of 4,548 specific characters united by hybridization, 2,281 resembled either one of the parents, and 2,267 were intermediate between. Of the number resembling the parents, about half resembled one parent and half the other. If A be taken to represent one parent and a the other, and Aa characters intermediate between the two, the formula for the union of the characters becomes $A + 2Aa + a$, which is the same as Mendel's formula for the separation of characters with peas.

Culture of orchids in leaf mold, L. P. DE LANGHE-VERNAENE (*Gard. Chron.*, 3. ser., 31 (1902), No. 785, p. 26).—This method of growing orchids is said to have been originated 12 years ago by the concern of which the writer is a member. The basis of the compost used is oak and beech leaves, with other leaves mixed with them. Before using the compost all leaves not sufficiently composted are sifted out. If the mixture then seems too compact a little coarse sand is added to insure the passage of water. Pots of the usual form are used, the depth of which is about equal to the width near the top. The bottom of the pseudo-bulbs is put on a level with the upper edge of the pot, the soil made firm and covered with a light layer of sphagnum chopped into inch lengths. The amount of water given is regulated according to the genus of orchid. This feature must be learned.

A graft of hybrid *Crataegus-Mespilus*, J. JENSEN (*Amer. Gard.*, 23 (1902), No. 406, p. 638).—An unusual offspring obtained by grafting *Mespilus germanica* on *Crataegus oxyacantha*. The union developed 2 branches of entirely distinct character. One showed a distinct resemblance toward the *Crataegus*, while the other inherited more of the *Mespilus* character.

Fundamental principles of plant breeding, L. BURBANK (*Amer. Florist*, 19 (1902), No. 748, pp. 341-343; *Amer. Gard.*, 23 (1902), No. 406, pp. 639-642, fig. 1).—A paper read before the International Plant Breeding Conference, held in New York, September 30 to October 2, 1902, in which the author discusses some of the general principles of plant breeding and indicates the possibilities of this kind of work.

Pictorial greenhouse management, W. P. WRIGHT (*London and New York: Cassell & Co., Ltd.*, 1902, pp. 144, figs. 86).—This book gives brief cultural directions and shows pictorially how to pot, prune, and care for the more common flowers of the greenhouse during the different months of the year. An alphabetically arranged table is included, naming the best species or varieties, their color, height, season of blooming, temperature required, culture, etc.

A garden in the suburbs, MRS. LESLIE WILLIAMS (*London and New York: John Lane*, 1901, pp. 193, pls. 9).—This is a popular publication intended for the use of those having limited areas to devote to the growing of shrubs and flowers. Work for each month of the year is briefly noted and suggestions given regarding the buying of plants and similar problems.

European and Japanese gardens (*Philadelphia: Henry T. Coates & Co.*, 1902, pp. 162, figs. 148).—This is a collection of papers which were read before the American Institute of Architects at its thirty-fourth annual convention held in Washing-

ton, December 14, 1900. The papers discuss in a general way the principal features of gardening in the various countries of Europe and Japan, and are illustrated by many typical examples of gardening in these countries. The paper on Italian gardens was written by A. D. F. Hamlin, that on English gardens by R. C. Sturgis, French gardens by J. G. Howard, and Japanese gardens by K. Honda.

School gardens at School of Horticulture, Hartford, Conn., H. D. HEMENWAY (*Park and Cemetery*, 12 (1902), No. 7, pp. 362-364, figs. 2).—The author outlines the methods observed in the flower and vegetable gardens of the school with the different grades of pupils, and shows the success that is being attained in this work.

School gardens, their development and functions, D. J. CROSBY (*Outlook*, 71 (1902), No. 14, pp. 852-861, figs. 7).—An account of the present status and growth of the school garden movement in Europe and America, with statements as to the purposes of such gardens and their value from an educational standpoint. A bibliography of the literature of the subject is appended.

The preparation of essential oils in the West Indies, J. H. HART (*West Indian Bul.*, 3 (1902), No. 2, pp. 171-178).—This is a brief popular article calling attention to the possibilities of this industry in the West Indies.

Practical treatise on the culture of tropical plants, J. DYBOWSKI (*Traité pratique de cultures tropicales*. Paris: Augustin Challamel, 1900, vol. 1, pp. 589, figs. 87).—In the first chapters of this work the author discusses the general principles to be observed in the growing of tropical plants, considerable space being given to climate, management of soils, use of irrigation water and fertilizers, and the reproduction of plants by grafting, budding, etc. In the latter half of the work specific directions are given for the culture of a large number of tropical garden vegetables and fruits. The matter is treated in 2 chapters, the first dealing with vegetables and the second with fruits. The articles under each heading are arranged alphabetically. The preface to the work was written by E. Tisserand.

A quarter century's evolution in American horticulture, P. O'MARA (*Trans. Massachusetts Hort. Soc.* 1901, I, pp. 74-89).—The author reviews in a popular manner the progress of horticulture, more particularly the growing of plants under glass, during the past 25 years.

Gardencraft, old and new, J. D. SEDDING (*London and New York: John Lane*, 1902, pp. XXVIII + 215, pls. 9).—A discussion of the art in gardening, treating of principles rather than details. A memoir of the author by E. F. Russell is included.

FORESTRY.

Report on the forests and forest conditions of the Southern Appalachian mountain region, JAMES WILSON (*Washington: Government Printing Office*, 1902, pp. 210, pls. 78).—This report embodies the salient features of an investigation carried on during the past 2 years on the forests and forest conditions in the Southern Appalachian region. The investigation was undertaken in compliance with an act of Congress making appropriation for the investigation of the forest conditions of the region indicated, with a view to reporting upon the advisability of establishing a forest reserve in that part of the United States. Not only were the forests and general forest conditions examined into, but also the causes which have led up to the present condition, and the possibility of improving them either with or without Government ownership and supervision. The forests were carefully mapped as to their distribution, density, and relative proportion of forest covered and cleared lands, and studies were made on the general character and distribution of all the available species of trees and shrubs in the region, the stand of timber, the extent to which the timber has been cut or damaged by fire, the nature and value of the pres-

ent holdings, as well as the agricultural conditions of the region indicated. The investigation embraced the southern part of Virginia, southeastern West Virginia, western North Carolina, eastern Tennessee, northwestern South Carolina, and northern Georgia. As a result of the investigation it is recommended that a large forest reserve be established in this region under Federal supervision. As appendices, reports are given by different individuals on the forests and forest conditions in the Southern Appalachians; topography, geology, hydrography, and climate of the Southern Appalachians; and on the present status of the movement for the establishment of the proposed Appalachian forest reserve.

New forest reserves (*Forestry and Irrig.*, 8 (1902), No. 9, p. 351).—There have been recently established 7 new forest reserves, of which the Mount Graham, Santa Catalina, and Chiricahua occur in Arizona; the Madison and Little Belt Mountain Reserve in Montana; the Lincoln Forest Reserve in New Mexico; and the Alexandria Archipelago Reserve in southeastern Alaska. A number of changes have been made in other reserves, and at present the total area of National forest reserves is 58,850,925 acres, or about 2.5 per cent of the entire area of the United States.

The Michigan Forest Reserve, T. H. SHERRARD (*Forestry and Irrig.*, 8 (1902), No. 10, pp. 404-411, figs. 6).—The Michigan Forest Reserve includes about 60,000 acres of land about the headwaters of the Muskegon River. The geological formation is described and the different types of forest are enumerated. Of these, 44 per cent consist of oak forests, 39 of jack pine barrens, 11 of swamp lands, and 6 of hardwood lands. Based upon a survey of 100 acres, the average number of trees and the volume of timber is estimated. In the jack pine planes the pine predominates, and in the oak forests scarlet oak forms half of the growth on the flats, and the red oak and white oak about 60 per cent of the trees occurring on the ridges. The effect of forest fires on this region is shown, and the present value of the timber is estimated. For the protection of this reserve a form of organization is recommended, which includes a superintendent and such assistants as would be necessary to control the region. It is believed the whole annual cost would not exceed 5 cts. per acre.

The management of Michigan hard-wood forests, W. C. WINCHESTER (*Forestry and Irrig.*, 8 (1902), No. 10, pp. 411, 412).—An attempt is made to show why the hard woods of Michigan are not lumbered so as to make possible continuous crops of sawed timber. The principal reasons assigned are the immediate profits that can be realized in cutting the lands clean and the excessive taxation on timber lands, which at present makes it unprofitable to hold them for the second and subsequent crops.

The jack pine plains of Michigan, F. ROTH (*Forestry and Irrig.*, 8 (1902), No. 10, pp. 413-416, figs. 2).—A description is given of the jack pine barrens which are well represented in Michigan and regions adjacent to the Great Lakes. These lands are of poor quality and sparsely settled. The cultivated lands are small in extent and of low productive value. They are capable, however, of producing a good growth of jack pine timber, and with systematic treatment could possibly be reforested with still better species. It is believed that the abandoned farms and waste lands will be reforested with jack pine and other species so that the character of the land will be improved and a more certain crop secured.

The protection of the New Hampshire forests (*Forestry and Irrig.*, 8 (1902), No. 10, pp. 396-398).—A report is given of a meeting of the State Forest Association of New Hampshire at which steps were taken for the establishment of a forest reserve in the White Mountain region.

Forestry work on the South Mountain Reservation, G. H. WIRT (*Forest Leaves*, 8 (1902), No. 9, p. 135).—At its spring meeting the Forestry Reservation Commission of Pennsylvania decided to establish a forest nursery and white pine plantation on the South Mountain Reservation in Franklin County, Pa. In this region there are said to be many acres of abandoned farm land which are decreasing in value each year and are believed to afford a splendid opportunity for the beginning

of forestry work. To do this it was determined to grow the tree stock rather than buy seedlings from nurserymen. A half acre was prepared and sown in white pine seed, a production of from 200,000 to 250,000 seedlings being expected. Besides the seed sown there were planted in the nursery 10,000 1-year-old white pine seedlings and a start was made on a permanent plantation by the setting out of 5,000 white pine seedlings which were set 4 ft. apart each way. This planting is to be followed by improvement cuttings of the young growth occurring on the mountain sides.

Action of the [Pennsylvania] State Forestry Reservation Commission (*Forest Leaves*, 8 (1902), No. 9, p. 135).—At the spring meeting of the commission, purchase of land amounting to 80,500 acres were made. Preparations were begun for the establishment of a nursery for the growth of pine seedlings, and arrangements were made for the planting of 500,000 pine seedlings and 50,000 tulip trees. The nursery selected is considered ideal for the purpose, and water was piped so as to reach all points of the nursery when necessary. There is said to be a spontaneous growth of white pine on the tract which is about 20 years old, which will afford an opportunity for improvement cuttings.

Forestry on the Girard estate in 1901 (*Forest Leaves*, 8 (1902), No. 9, pp. 138, 139).—An account is given of the condition of the forest lands which are a part of the Girard estate and which are under the supervision of the Philadelphia Board of City Trusts. The reforestation of the mountain lands is said to be a serious question. The work of 25 years was almost entirely wiped out by forest fires which occurred in the spring of 1901. More than 4,250 acres of land which contained timber of from 1 to 12 years' growth were burned over, the estimated value of the timber destroyed being \$3,044.70.

Study of a chestnut wood lot, A. S. HAINES (*Forest Leaves*, 8 (1902), No. 10, pp. 150, 151).—A report is given of the study of a chestnut wood lot in Chester County, Pa., in which the current increment of trees was obtained by measurements made by the formula adopted by this Department. The trees were divided into 3 groups. The first, which averaged 80 years old, had attained a diameter of 24.5 in., with a current growth of 1.6 per cent. Because the rapid growth had ceased these trees had become very brittle, and the average value was estimated at \$2.60 each. The second class averaged 30 years and was 13.5 in. in diameter, with a current growth of 4.4 per cent. These were valued at \$1.50 each. The third class of trees, which averaged about 60 years, was 22.9 in. in diameter, with a current growth of 4 per cent, and was valued at \$4.10 each. At the present low value of land in the vicinity of this wood lot and with the proposed reduction in the taxes on wood lots, the author believes that areas planted to chestnut under these conditions would pay a larger interest on capital invested than that obtained from the staple agricultural crops.

Forestry in Ireland, W. DICK (*Farmers' Gaz.*, 61 (1902), Nos. 17, p. 317; 19, pp. 356, 357; 22, p. 403; 23, pp. 420, 421; 27, p. 485; 29, pp. 536, 537; 36, p. 670).—A series of articles in which the forest condition of Ireland is described and the urgent necessity for reforestation is shown. What are considered the best species for planting are enumerated and historical and other data given to show their relative growing rate, production, and value. The adaptability and importance in order of enumeration are Scotch pine, larch, and ash, followed by the sycamore-leaved maple, 2 kinds of poplar, and oaks.

The natural restoration of the forests of Switzerland, ENGLER (*Rev. Eaux et Forêts*, 41 (1902), No. 3, pp. 81-85).—The author shows the necessity for thinning, clearing cuttings, allowing seed trees to remain, and the proper production of shade for forest growth. For natural reseeding, the forest must never be wholly deprived of its cover. The best results usually attend the cultivation of mixed species, or at least groups of different species of trees. Natural reproduction is said to favor the production of trees of large size.

The reforestation of loose and worn soils, MATTHIES (*Rev. Eaux et Forêts*, 31 (1902), No. 6, pp. 161-177).—Suggestions are given for the reforestation of high mountains, loose sands, and worn limestone soils. The methods that have been successfully employed in different countries are described, particular attention being given to the forestation of sandy regions. The preliminary treatment for preventing the shifting of sands is described and the best species of forest trees for different soils and situations are enumerated. The rôle of the Government in such operations is discussed at some length.

Coppice in the Ardennes, C. DELVILLE (*Bul. Soc. Cent. Forest. Belg.*, 9 (1902), Nos. 4, pp. 197-206; 5, pp. 261-273).—A description is given of the present condition of the coppice woods of this region and the various means whereby the production and value of these forests have been decreased. Suggestions are also given of various methods for their restoration.

An excursion in the Campine region, E. NÉLIS (*Bul. Soc. Cent. Forest. Belg.*, 9 (1902), Nos. 4, pp. 207-213; 5, pp. 274-285; 6, pp. 348-353, pls. 2).—A description is given of the forests in the Campine region, which consists of an extensive area of sandy land extending through Belgium into Holland. This is partly covered by an artificial forest plantation, and the means adopted for the reforestation are described and results of a number of experiments with fertilizers on forest trees are shown.

On the preservation of the natural characters of forests and uncultivated regions, C. BOMMER (*Bul. Soc. Cent. Forest. Belg.*, 9 (1902), No. 6, pp. 338-348).—A report is given of a special commission appointed to consider the subject of forestry in Belgium and to suggest methods for its development and improvement.

The characteristics of various species of forest trees as nursery trees (*Bul. Soc. Cent. Forest. Belg.*, 9 (1902), Nos. 6, pp. 360-365; 7, pp. 439-445).—Compiled notes are given of the characteristics, value, and adaptability of a number of forest species which are proposed for cultivation and acclimation in Belgium. The species described in the present papers are all conifers.

Report of expert forester on the Hawaiian forests, E. M. GRIFFITH (*Honolulu*: 1902, folio).—A report is given on the present condition of the forests of the Hawaiian Islands, and suggestions made for their retention and improvement. With few exceptions the forests are said to be only valuable in conserving the water supply and increasing the rainfall. The only 2 species of trees which occur in sufficient quantity to be of any commercial importance are kao (*Acacia koa*) and algaroba (*Prosopis juliflora*). As the forests of the Hawaiian Islands contain a very limited amount of merchantable timber, the forestry problem is one of conserving the water supply, which depends upon the preservation of existing forests and restocking some of the denuded slopes, either by natural reproduction or by planting. The denudation of Hawaiian forests has been brought about to a large extent by the pasturing of stock in the forests. Wherever fences have been built the reclamation of forests is said to be as rapid as their destruction when stock are allowed to range freely. In order to place the work upon a thoroughly efficient basis, cooperation will be necessary between the government, planters, ranchers, and others owning or leasing land upon which water is the chief consideration.

The timber resources of the Australian Commonwealth, E. T. SCAMMELL (*Jour. Soc. Arts*, 50 (1902), No. 2580, pp. 533-546).—An address was given in which attention was called to the value of Australian timber, the object being to serve as far as possible the commercial interests of Australia by demonstrating the claims of Australian timber to the favorable consideration of engineers, architects, builders, etc. The forest area of Australia by divisions is given, in which it appears that about 9½ per cent of the total area is forested. The principal woods are briefly described, their uses indicated, and an appendix given in which the common names are alphabetically arranged. The value of a number of species for furnishing railroad ties is shown in tabular form.

The renewal of the forests in Cochin China, C. L. ROY (*Rev. Fleuve et Forêts*, 41 (1902), No. 1, pp. 17-19).—A brief account is given of the attempts being made to properly conserve and restore the valuable forests of Cochin China. Attempts have been made to introduce the cultivation of teak, and in 1898 and 1899 14 nurseries were established for the production of teak seedlings. Other nurseries have since been established and the planting of the young trees in permanent plantations was to be begun in August, 1902. Attention is called to some of the more valuable native timber trees, and their preservation and conservative exploitation encouraged.

Report of the forester, and the woods of Tonkin, BRENIER (*Bul. Écon., Dir. Agr. et Com. Indo-China*, n. ser., 5 (1902), No. 6, pp. 393-419).—A report of the forester is given in which are included the usual reports of the administration of the forests and the various decrees relative to the exploitation of forests and forest products. A list of the forest trees is appended, in which the species are arranged in 3 groups based upon their relative timber values. The arrangement is according to vernacular names, the scientific names being given wherever known, and the distribution and characteristics of the timber are briefly described.

Forest trees for calcareous soils, P. MOUILLEFERT (*Jour. Agr. Prat.*, n. ser., 3 (1902), No. 22, pp. 697, 698).—A description is given of the different kinds of trees adapted to growth in calcareous soils, and the author says that for dry calcareous soils containing a limited amount of clay, sand, iron, and humus, the best species for forest growth is the beech, with birch grown in short rotations. On richer soils which are exploited as coppice, beech, hornbeam, birch, pubescent oak, and species of alder, together with larch and fir in a 25-year rotation, are recommended. For high forests, ash, alder, black locust, spruce, and Scotch pine in 25 to 30 year rotations are recommended.

Profitable tree planting, J. G. KELLY (*Jour. Agr. and Ind., South Australia*, 5 (1902), No. 12, pp. 970-972).—An account is given of the income derived from planting a strip of poor sandy land with sugar gum (*Eucalyptus corymbosa*) and the broad-leaved wattle. These were planted in alternate rows 6 ft. apart, the land first plowed and harrowed as preliminary to the planting. At the end of the sixth year the wattles were peeled for their bark, but no accurate record was made of the quantity of bark taken off. In 1899 each alternate gum tree was removed, those cut making poles 18 to 20 ft. in length with a mean diameter of $4\frac{1}{2}$ in. The estimated cost of growing the trees and wattles from 1891 to 1902 was about \$80, while the bark and poles removed, together with the trees now standing, are estimated as worth \$140.

Trees for shelter (*Agr. Jour. and Min. Rev.*, 5 (1902), No. 14, pp. 458, 459).—The importance of shelter belts for protecting orchards, gardens, etc., against the cold winter and the hot drying winds of summer is pointed out, and the availability of a number of species of Australian and other trees for use as shelter belts in Australia and South Africa is described.

Street tree planting (*Forest Leaves*, 8 (1902), No. 9, pp. 140-142).—A report is given on trees for street planting and an account of the results of the street tree planting in Washington, D. C., between 1873 and 1887. During that time there were said to have been planted in Washington 78,000 trees, represented by 30 varieties, but seven-eighths of the number were embraced by 10 or 12 species. The characteristics of the different species for street planting are mentioned. The species best suited to the purpose, as shown by the results obtained, are the silver maple, Norway maple, American elm, sycamore, American linden, tulip tree, Carolina poplar, ash-leaved maple, gingko, and pin oak.

Shade trees, W. A. MURRILL (*New York Cornell Sta. Bul.* 205, pp. 24, pls. 3, figs. 10).—The object of this bulletin is to aid in increasing the growing interest in shade trees as material aids to the healthfulness and attractiveness of cities and towns, and to consider the principles underlying their selection and care. After a discussion of the value of shade trees, with some account of the various kinds found in different cities,

the merits of different trees in common use are considered and lists given of those which have been found by experience to be best fitted for street planting. Suggestions are also made on planting, pruning, protecting, and caring for wounds, and other operations connected with the general care of street trees. The author recommends for general street planting red, pin, scarlet, black, shingle, and willow oak; Oriental and American sycamore; Ailanthus, and Norway maple; and suggests that the gingko, American ash, hackberry, sweet gum, and Kentucky coffee tree merit further trial.

The alders, J. HOUBA (*Bul. Soc. Cent. Forest. Belg.*, 9 (1902), No. 6, pp. 353-359).—Descriptions are given of a number of species of alder, and their value in forest plantations, character of the timber produced, adaptability, etc., are discussed. The characteristics of the white alder are described at considerable length. The other species are said to be quite similar in their characteristics and uses.

The relationship of some American and Old World birches, M. L. FERNALD (*Amer. Jour. Sci.*, 4. ser., 14 (1902), No. 81, pp. 167-194, pls. 2).—Attention is called to the possible relationship of some of the species of birches found in the high latitudes of America and Asia.

The slippery elm, J. T. ROTHROCK (*Forest Leaves*, 8 (1902), No. 9, p. 136, pls. 2).—A description of the slippery or red elm (*Ulmus fulva*). Its characteristics, botanical characters, and physical properties.

Treatment of second-growth white pine, W. I. HUTCHINSON (*Forestry and Irrig.*, 8 (1902), No. 9, pp. 370-373, figs. 4).—Detailed directions are given for the management of second-growth white pine. It is said that the thinnings should be carried on sparingly until the end of the principal height-growing period, which occurs when the trees are about 40 years old. After this the thinnings should be increased, in order to remove the inferior and diseased specimens. If the wood lot does not consist of a pure stand of white pine the thinnings should be mostly of the hard woods. Where natural pruning is not sufficiently active it will be found advisable to assist in removing the lower and dead branches.

The Jersey scrub pine, J. T. ROTHROCK (*Forest Leaves*, 8 (1902), No. 10, p. 152, pls. 3).—The distribution, characteristics, and physical properties of the Jersey scrub pine (*Pinus inops*) are given.

Notes on the Noble fir (*Abies nobilis*), J. G. PETERS (*Forestry and Irrig.*, 8 (1902), No. 9, pp. 362-366, figs. 3).—Based upon investigations conducted during the summer of 1901, an account is given of the utility, distribution, growth, etc., of this fir, which is confined to the Northwestern portion of the United States, along the slopes of the Cascade Mountains. The rate of growth of seedlings during the first few years is slow, and a marked characteristic of this species is its intolerance of shade. Even the young seedlings require no shade when growing naturally, and are found only in clearings caused by fire or lumbering. The tree is subject to a number of diseases, the most severe of which are *Echinodontium tinctorium*, *Trametes pini*, and *Polyporus schweinitzii*.

The treatment of spruce in artificial plantations, C. BROILLIARD (*Rev. Eaux et Forêts*, 41 (1902), No. 1, pp. 1-9).—The adaptability of spruce to artificial plantations, the best distances of planting, methods of thinning, production, etc., as shown by numerous investigations, are discussed.

Note on the fuel value of cottonwood, C. E. BESSEY (*Abstr. in Science*, n. ser., 16 (1902), No. 395, p. 139).—There is said to be much prejudice against this tree having any value except for shade and wind-breaks, its fuel value being considered very low. Careful measurements and calculations, made by the writer, show that on account of its rapid growth the cottonwood (*Populus deltoides*) produces more heat-yielding fuel in a given time than any other commonly planted tree.

Some recent advances in the fireproofing treatment of wood, S. P. SADTLER (*Science*, n. ser., 16 (1902), No. 402, pp. 424-428).—A brief review is given of the

various efforts which have been made to render wood fireproof by chemical treatment, and a description is given of the Ferrell process of treating wood. This consists of impregnating the wood with a solution of sulphate of alumina under great pressure. It is said that if a piece of wood be saturated with a solution of sulphate of alumina to a depth of not more than three-eighths of an inch from the surface, and the point of the inner blue cone of a strong Bunsen flame be brought against it and kept in such a position, a boring effect takes place with an abundant separation of alumina. It required, on an average, over three hours for the flame to complete the boring of a piece of white pine 1 in. thick so treated.

Wastefulness in turpentine industry, C. HERRY (*Tradesman*, 48 (1902), No. 3, p. 76).—A brief account is given of an investigation conducted under the auspices of the Bureau of Forestry of this Department on turpentine production. According to the estimate of the author, there is a loss of 3 bbls. of turpentine for every 4 bbls. produced, on account of the wasteful methods pursued. The author is convinced that the present method of boxes cut in the pine tree is not only damaging to the tree, but does not secure the best results. Instead of cutting boxes in the tree, the author recommends a system of two flat faces cut on the tree, each containing a slanting incision about an inch deep, from which galvanized-iron gutters carry the turpentine. The importance of the improved method of handling the trees is shown and it is stated that had this method been employed the annual production of naval stores would have been increased nearly 100 per cent.

A first book of forestry, F. RORR (*Boston: Ginn & Co., 1902, pp. 291, figs. 98*).—The increasing interest in forestry in this country has shown the necessity for concise statements of the principles underlying forestry and forest management. In the book here noted the writer has prepared for use in high schools, normal schools, and other secondary schools, clear and concise statements describing the principles of forestry preservation and use, forest planting, reforestation, relation of forests to water supply, as well as giving specific directions for the management of the small woods lot. The various forest industries are described, and accounts given of the enemies of forests, such as fires, insects, diseases, etc., and methods are suggested of preventing injury from these sources. Keys are given by which the common species of trees can be readily distinguished and an alphabetical list of the more important woods and trees of the United States is appended. In this list the principal characteristics of the trees, their distribution and uses are shown. The illustrations are nearly all taken from American material, so that the problems of our own country are prominently presented. Although primarily designed for use in schools, this book is well adapted to the use of the individual reader seeking information along the lines treated.

DISEASES OF PLANTS.

Notes on some West American fungi, D. GRIFFITHS (*Bul. Torrey Bot. Club*, 29 (1902), No. 5, pp. 290-301, figs. 10).—Attention is called to more detailed descriptions of certain species of fungi which have been hitherto described, and the following new species are described: *Tilletia externa* on *Carex filifolia*, *T. carlei* on *Agropyron occidentale*, *Ustilago elegans* on *Chloris elegans*, *Sorosporium bigeloviae* on *Bigelovia* sp., *S. williamsii* on *Stipa richardsonii*, *Gymnoconia riddelliae* on *Riddellia cooperi*, *Puccinia bouvardiae* on *Bouvardia triphylla*, *P. burnettii* on *Stipa comata*, *P. micrantha* on *Oryzopsis micrantha*, *Aecidium grindeliae* on *Grindelia squarrosa*, *A. dakotensis* on *Aquilegia canadensis*, and *Claviceps caricoma* on *Carex nebraskensis*.

Concerning some fungi occurring on tropical economic plants, A. ZIMMERMANN (*Centbl. Bakt. u. Par., 2. Abt., 8* (1902), Nos. 5, pp. 148-152; 6, pp. 181-184; 7, pp. 216-221, figs. 8).—Economic and descriptive notes are given of a number of fungi

that have been observed in Java as affecting cultivated plants. Among those described are *Corticium javanicum* on twigs of cinnamon, cola, etc.; *Peronospora cubensis* atra n. var., on leaves of cucurbits; *Rhizophidium fungicolum* n. sp., on cacao fruits; *Antennaria setosa* n. sp. and *Capnodium javanicum* n. sp., on coffee leaves; *Physalospora fallaciosa* on banana leaves; *Nectria luteopilosa* n. sp. and *N. fruticosa* n. sp., on the fruit of the Liberian coffee; *Ophionectria jolicola* n. sp., *Placonectria coffeicola* n. sp., *Phyllachora macrospora* n. sp., *Myriangiella orbicularis* n. g. and sp., *Coniothyrium coffea* n. sp., upon the leaves of Liberian coffee; *Diplodia coffeicola* n. sp., on the fruit of Liberian coffee; *Glucosporium coffeanum* on the leaves of the same; *Cercospora coffeicola* on the leaves of Arabian coffee; *C. musæ* n. sp., on banana leaves; *Scolecotrichum musæ* on the same, and *Rhombostibella rosæ* n. g. and n. sp., on Liberian coffee leaves.

Cultures of Uredineæ in 1900 and 1901, J. C. ARTHUR (*Jour. Mycol.*, 8 (1902), No. 62, pp. 51-56).—During 1900 and 1901 the author demonstrated by means of cultures the life cycle of a number of rusts, as follows: *Uromyces euphorbia*, *Puccinia caricis*, *P. angustata*, *P. poculiformis*, *P. albiperidia*, *P. caricis-erigerontis*, *P. caricis-asteris*, and *P. holleyana*.

New species of Uredineæ, J. C. ARTHUR (*Bul. Torrey Bot. Club*, 29 (1902), No. 4, pp. 227-231).—The author describes a number of new species of Uredineæ, all but one of which are indigenous in the United States. The species described are *Uromyces rickermanii* on *Rumex geigeri*, *U. rotbælliae* on *Rotbællia speciosa*, *Puccinia tosta* on *Sporobolus cuspidatus*, *P. tosta lucurians* on *Sporobolus airoides*, *P. peru* on *Saxifraga mertensiana*, *P. turrita* on *Saxifraga bronchialis*, *P. adenostegiae* on *Adenostegia pilosa*, *Uredo panic* on *Panicum amarum*, and *U. cephalanthi* on *Cephalanthus occidentalis*.

A new species of Rhytisma, W. A. KELLERMAN (*Jour. Mycol.*, 8 (1902), No. 62, pp. 50, 51, pl. 1).—A description is given of *Rhytisma concavum* parasitic on the leaves of the *Ilex verticillata*.

New Alabama fungi, J. B. ELLIS and B. M. EVERHART (*Jour. Mycol.*, 8 (1902), No. 62, pp. 62-73).—Descriptions are given of about 60 species of fungi, some of which are parasitic on plants of economic importance.

Investigations on the experimental production of plant parasites among some common bacteria, L. LÉPOUTRE (*Compt. Rend. Acad. Sci. Paris*, 134 (1902), No. 16, pp. 927-929).—Experiments are reported with *Bacillus fluorescens liquefaciens*, *B. mycoides*, and *B. mesentericus vulgatus*, 3 very common bacteria in soils, air, and water, in which an attempt was made to produce infection upon potatoes, carrots, and parsnips. These roots were grown under conditions which were designed to diminish their resistant properties, after which they were inoculated with cultures of the bacteria. Characteristic rotting and destruction of the tissues took place showing the possibility of the infection of tissues weakened by various causes. The organic acids produced by the bacteria attacked and destroyed the sugar in the various tubers.

Pure cultures of Puccinia dispersa, H. M. WARD (*Proc. Roy. Soc. [London]*, 69 (1902), No. 458, pp. 451-466, figs. 2).—A description is given of a method by which the author has been able to obtain pure cultures of *Puccinia dispersa* grown upon species of Bromus. The method of conducting the experiments is described in detail and the effect of mineral supplies on the infection of the host plant is discussed. The results obtained seem to show that phosphoric acid resulted in the production of a long, limp growth of pale color, and the spots where the fungus was present showed corrosion and collapse of the tissue, instead of the normal appearance. A similar appearance was derived in the case of potash, except the plant was not so drawn or etiolated. When magnesium was added to the cultures the appearance of the plant and fungus spots were more nearly normal. The absence of lime from the cultures seemed to show little effect; but this is believed to have been partly due to the presence of a small quantity in the pots and soil. So far as the results obtained go they suggest that differences in the supply of minerals affect the development of mycelium

and of spores, owing to the effect on the host. In cultivating the host the parasite is also cultivated.

The parasitism of *Botrytis cinerea*, R. E. SMITH (*Bot. Gaz.*, 33 (1902), No. 6, pp. 421-436, figs. 2).—According to the author, too much importance has been hitherto ascribed to cellulose-dissolving enzymes upon the parasitism of *Botrytis* and similar fungi. Two stages in the process of attacking the host plant are clearly distinguished: First, a poisoning and killing of the cells; and second, their disintegration and utilization as food by the fungus. The first effect appears to be produced by a substance which the author believes to be oxalic acid formed by the fungus as a by-product of its metabolism. Following this, a number of different enzymes are secreted which digest the various constituents of the tissues. The identity of these enzymes probably varies in different cases and there are apparently several forms which affect different kinds of cellulose. The enzymes reported as causing the swelling of the cell walls in the lily disease studied by Ward, and the turnip disease reported by Potter, appear to be unlike that produced by *Botrytis cinerea*. The results obtained by the author's investigation are believed to have a suggestive bearing on the parasitism of many other fungi which bring about the rapid destruction of the tissues of the host plant.

"Take-all" in wheat, D. McALPINE (*Jour. Dept. Agr. Victoria*, 1 (1902), No. 1, pp. 74-80).—A disease of wheat locally known as "take-all" has existed in Australia for 40 years or more, and although investigated at various times the cause of the disease is still in dispute. Just before the stalks appear, the leaves of the wheat lose their color, the outer ones becoming yellow. When the stalk develops it is stunted and never matures. The entire plant soon dies and this may take place over a considerable area. The roots of the affected plants also have a very characteristic appearance. They are stunted and deformed at an early stage and may be thickened and knotted close to the stem. They are excessively covered with the root hairs and new roots are generally thrown out just above the old ones. The disease appears to occur in rather definite areas. It begins with small spots and gradually spreads, the plants dying off in larger or smaller patches according to the virulence of the attack.

Various causes have been assigned from time to time, among them several fungi, nematodes, faulty conditions of soil, drought, etc. The author's observations show that nematodes are a common accompaniment of the disease. Among fungi reported, *Ophiobolus herpotrichus* was found present in many instances, the basal portions of the stem being considerably blackened. A species of *Septoria* was found exceedingly common but no species of *Cladosporium* were observed, although this has been claimed to be one of the principal causes of the disease. A circular letter has been widely distributed in which the author seeks information regarding the disease which is still under investigation.

The presence of nematodes and stinking smut in wheat, R. MAIRE (*Bul. Soc. Mycol. France*, 18 (1902), p. 130; *abs. in Bot. Centbl.*, 89 (1902), No. 14, p. 396).—The author reports the coexistence of nematodes, *Tylenchus tritici*, and smut, *Tilletia tritici*, in the grain of wheat.

A new disease of winter barley, L. HECKE (*Ztschr. Landw. Versuchsw. Oesterr.*, 5 (1902), No. 5, pp. 746-748).—A brief description is given of a disease of winter barley which has been recently discovered in Austria. The leaves of the affected plants turn yellow and the plant finally dies. Upon diseased specimens, near the ground, between the stem and the leaf sheath, were found numerous round, yellowish-brown bodies which proved to be the sclerotia of an undetermined species of *Sclerotinia*. It is thought possible that the species may be the same as that described as producing the sclerotium disease of numerous species of grasses.

***Tilletia horrida* on rice in South Carolina, A. P. ANDERSON** (*Bul. Torrey Bot. Club*, 29 (1902), No. 1, pp. 35, 36).—The occurrence of smut of rice has been previously noted (*E. S. R.*, 11, p. 463), and was assigned by the author to the fungus *Tilletia corona*. Subsequent observations and comparisons with specimens from Japan have

proved the identity of the disease in the two countries, and the organism causing it is now said to be *T. horrida*. The appearance of the disease in South Carolina is traced to an importation of Japanese seed rice made in 1896.

Sclerospora macrospora, a parasite of maize, G. CUGINI and G. B. TRAVERSO (*Staz. Sper. Agr. Ital.*, 35 (1902), No. 1, pp. 46-49).—A preliminary note is given on the occurrence of *Sclerospora macrospora* upon maize. The fungus has been previously described as parasitic on plants of the genus *Alopecurus* in Australia.

Experiments in combating millet smut, L. HECKE (*Ztschr. Landw. Versuchsw. Oesterr.*, 5 (1902), No. 1, pp. 22-28).—The results of experiments, in which millet seed was given a preliminary treatment with solutions of copper sulphate, sulphuric acid, corrosive sublimate and formalin, are reported. A preliminary soaking of the seed for 5½ hours in a 0.5 per cent solution of formalin gave the best results, the plants produced being almost entirely without smut. The fungus in this case is *Ustilago crameri*.

Clover sickness, V. ANZIMIROV (*Selsk. Khoz. i Lysov.*, 204 (1902), Mar., pp. 523-542).—A report is given of experiments and observations of the author, and extensive quotations given from the investigations of Levitski, on the cause of clover sickness. The author quoted states that there is a continual struggle between the clover plant and the bacteria living in its roots. During the first period the bacteria live at the expense of the clover, receiving from it the carbohydrates necessary for their development. In the second stage the clover feeds upon the nitrogenous substances produced by the bacteria from the nitrogen of the air. Under ordinary conditions it is claimed that 2 distinct periods can be noticed in the development of the clover. While furnishing carbohydrates to the bacteria the growth is somewhat retarded, but when it begins drawing upon the nitrogenous substance in the tubercles the development proceeds rapidly. It is believed that too great a number of bacteria in the soil, many of which fail to be transformed into bacteroids, produces the so-called clover sickness. The author concludes that the application of artificial fertilizers and the reduction of the use of stable manure will, to an extent, prevent the occurrence of clover sickness.—P. FIREMAN.

A rust spotting of potatoes, F. BUBAK (*Ztschr. Landw. Versuchsw. Oesterr.*, 5 (1902), No. 3, pp. 396-398).—A description is given of a disease of potatoes in which the tubers presented spots of the color of iron rust. The tissues of the affected areas were brown and hard and had a decidedly bitter taste, while the sound tissue was of normal appearance. A microscopical examination showed marked differences in the tissues of the sound and diseased portions, and it is believed that the trouble was due to a fertilizer of turf acting upon the soil elements, resulting in an iron compound which had an injurious effect upon the development of the tubers.

Tomato blights, N. A. COBB (*Agr. Gaz. New South Wales*, 13 (1902), No. 4, pp. 410-414, figs. 2).—Descriptions are given of 2 blights of tomato, one of which is well known and the other of more recent discovery and less known. The first disease is the tomato leaf blight, due to *Septoria lycopersica*, which is described at some length, and the destruction of diseased material and the protection of vines with Bordeaux mixture are recommended. In addition, drainage of soil, trellising of the vines, and pruning are advised, together with the rotation of crops when convenient. The second disease of the tomato described is designated as rosette. This disease has made its appearance quite recently and seems to be of widespread occurrence. The losses due to it are usually confined to a few isolated plants, although mention is made of the destruction of a large number in one locality. The disease is characterized by the formation of rosettes of small leaves at the ends of the branches of the half-grown vine. Such vines seldom produce fruit of any considerable size, and when fruit is matured it is of a peculiar appearance and of questionable value. So far as the author's observations go, there is little evidence that the disease spreads from plant to plant, and in the present unsatisfactory state of knowledge of this

disease no method of cultivation or spraying can be recommended for its prevention. As the affected plants never produce satisfactory fruit, it is suggested they should be pulled up and destroyed as soon as recognized. The outward appearance of the tomato rosette strongly suggests the presence of nematodes or some insects, but so far no such cause has been observed. The fruit when ripened is abnormally colored and possesses an excess of core. The seed are somewhat peculiar in their position, and it is suggested that such seed should not be planted.

Bacteriosis of tomatoes, D. McALPINE (*Jour. Dept. Agr. Victoria*, 1 (1902), No. 3, p. 330).—The author reports having received from various parts of the country tomatoes which were affected by a disease which is believed to be of bacterial origin. The fruit arrives at complete maturity but the blossom end is flattened and discolored, ultimately becoming a pale olive tint. On cutting the tomato lengthwise the healthy part is found quite distinct from the diseased area, the latter being watery and of a dark olive-green color. Bacteria are universally present, and are believed to be the cause of the disease, which is to be investigated further.

The bacteriosis of kohl-rabi, L. HECKE (*Ztschr. Landw. Versuchsw. Oesterr.*, 5 (1902), No. 1, pp. 1-21, pl. 1).—A description is given of a bacterial disease of kohl-rabi which has been discovered by the author, and the results of his infection experiments are reported at considerable length. It is shown that this disease is of a truly bacterial nature, the bacteria occurring in the vascular bundles of the leaf, stem, and roots of the plant. It is believed to be due to the same cause as the black rot of cruciferous plants in this country. The bacteria (*Pseudomonas campestris*) gain access through wounds or the water pores of the plant, and in addition to kohl-rabi attack kale, cabbage, and other allied plants. The disease is said to be rather common and widely spread throughout Austria.

Diseases of plants and their remedies, D. McALPINE (*Jour. Dept. Agr. Victoria*, 1 (1902), No. 3, pp. 316-325, pls. 2).—Descriptive notes are given of the peach-leaf curl, shot-hole fungus, and scab. Suggestions are given for the prevention of these diseases by spraying, pruning, etc.

Canker and gummosis of fruit trees, F. T. BRZEZINSKI (*Compt. Rend. Acad. Sci. Paris*, 134 (1902), No. 20, pp. 1170-1173).—A summary is given of investigations begun in 1896 on the cause of the canker of apple and pear trees and of the gummosis of peach, apricot, plum, and cherry. The primary cause of these diseases, the author states, is bacteria. In all cases of the canker examined no instance was ever found in which bacteria were not present in the diseased tissue. In the case of the canker, inoculations were made in 1899 on branches of pear by piercing with a needle and introducing the organisms from pure cultures. After about 15 days the wounds became healed over, but the following year characteristic lesions of canker appeared at a distance of about 1 cm. from the healed wounds. A number of inoculations had progressed so well by the spring of 1902 that there was no doubt of the success of the inoculation. This seems to indicate that the canker is contagious and certain varieties of pear and apple seem predisposed to the disease. A brief description is given of the organism, and that occurring on the pear is said to be almost indistinguishable from that on the apple, although in artificial cultures some differences were noted. Their identity has not yet been proved by cross inoculation. The roots of both pear and apple never present cankerous wounds, but show certain excrescences, the cause of which is yet to be determined.

The gummosis of peach, apricot, plum, and cherry is analogous to that of the canker described above. Inoculations with bacteria in peach produced the characteristic gum flow of the disease, and the cause of gummosis in plums and apricots is believed to be the same as that which causes the disease in peaches. The bacteria causing the gummosis of cherries seems to be distinct from the others, its cultures being whiter and more opalescent.

Cure for canker on apple trees, G. D. HUET (*Agr. Gaz. New South Wales*, 13 (1902), No. 6, p. 683).—According to the author, the canker of apple trees may be cured by pruning and painting over the affected portions of the limbs with hydrochloric acid.

A new form of *Fusicladium dendriticum*, G. SCALIA (*Bol. Accad. Gioenia, Catania*, 70 (1901), pp. 1-5; *abs. in Bot. Centbl.*, 89 (1902), No. 14, p. 398).—A new form of *Fusicladium* on the Japanese loquat is described. It seems to have affinities with the well known *F. dendriticum*, and the recently described *F. eriobotryae*, and the name *F. dendriticum eriobotryae japonica*, is given it.

Black rot of oranges, N. B. PIERCE (*Bot. Gaz.*, 33 (1902), No. 3, pp. 234, 235).—A fungus disease of navel oranges has attracted attention in some of the orange-growing districts of California for the past 8 or 10 years. The losses occasioned by the disease frequently amount to as much as 3 to 10 per cent of the crop, and as the cultivation of the navel variety is extensive the total losses are proportionately heavy. The oranges are attacked through the navel, the fungus entering the cracks or imperfections of the peel in those parts. The cells of the pulp are destroyed and soon become black in color and bitter to the taste. The peel is left uninjured until the disease has made considerable progress within, but finally becomes thin and darkened in color over the affected parts. The fungus vegetates freely among the pulp sacks, which are wholly destroyed as far as the mycelium extends. The tissues involved rarely include more than one-fourth of the fruit, and the destruction is commonly confined to the tissues lying near and at one side of the navel. Infected fruit ripens prematurely, showing an exceptionally high color, and soon falls from the tree. The fungus producing this disease is a new species of *Alternaria* to which the name *A. citri* is given. A specific characterization of the fungus by Ellis and Pierce is given.

Disease of Maryborough oranges, H. TRYON (*Queensland Agr. Jour.*, 10 (1902), No. 6, pp. 481, 482).—A report is made on a shipment of oranges which was condemned in a market of New South Wales as being affected by disease. The fruit was found to exhibit various blemishes and injuries of the skin. The first noted was due to the action of hydrocyanic-acid gas, which had been used to fumigate the fruit. The second injury noted was attributed to an *Acarus*, the injury taking the form of linear markings, spots, blotches, and patches of irregular outline, which are well developed upon the surface of the fruit. These are usually of a dark or blackish-brown color and the coalescence of a number of spots make quite large infected areas, the surface of which is covered with an exudation that is something in the nature of resin. When a portion of this is removed it shows the presence of mycelial threads of fungi, although no particular species seems to be constantly present. The third disease described is one caused by the orange mite (*Phytopus oleivorus*). This disease is present only in a mild form and seldom causes more than a loss of luster to the fruit attacked.

On the development of the anthracnose of bananas, G. DELACROIX (*Agr. Prat. Pays Chauds*, 2 (1902), No. 7, pp. 89-91, fig. 1).—The fruit of the banana is said to be frequently attacked by the fungus *Glaosporium musarum*, which causes its ultimate destruction. The fungus is believed to occur as a wound parasite and infection is incurred through wounds occurring upon the green fruit.

A nematode disease of coffee, G. DELACROIX (*Agr. Prat. Pays Chauds*, 2 (1902), No. 7, pp. 80-88, figs. 2).—An examination of a number of specimens of Arabian and Liberian coffee from Martinique showed the presence of the nematode *Heterodera radiculicola* in great abundance, and it is thought probable that the same disease occurs in Guadeloupe. Accompanying the nematode was found the mycelium of a fungus which is believed to be a species of *Rosellinia*. Based upon experiments conducted elsewhere, it is thought that injecting carbon bisulphid about coffee trees would not only destroy the nematodes but would also kill the fungus.

Some nematode diseases of plants, G. DELACROIX (*Agr. Prat. Pays Chauds*, 1 (1902), No. 6, pp. 672-680).—Descriptions are given of a nematode disease occurring upon bananas in Egypt, previously reported (E. S. R., 14, p. 264), and a nematode disease of black pepper reported from Cochin China. The latter seems to be due to the common nematode *Heterodera radicicola*. This species of nematode has previously been reported in Java upon the betel pepper, a plant nearly related to the ordinary black pepper.

The epidemic occurrence of *Coronarium ribicola* in the Dahlen botanic gardens, P. HENNINGS (*Notizbl. Bot. Garten u. Mus., Berlin*, 3 (1902), No. 28, pp. 172-175).—During the summer and late fall of 1901 the different species of *Ribes* were severely attacked by the fungus *Coronarium ribicola*. It was first noticed upon a bush of *R. nigrum*, toward the end of June, and by the end of July and beginning of August nearly every species of the genus had been attacked, and by the end of August hardly a sound leaf was to be found. Of about 30 species and varieties examined *R. alpinum* was the only one free from the fungus.

Diseases of forced strawberry plants, J. CURÉ (*Rev. Hort. [Paris]*, 74 (1902), No. 12, pp. 286, 287).—The frequent occurrence of what the author terms mildew, or rust, is noted. It may be kept in check by spraying with Bordeaux mixture or by the use of 500 gm. potassium sulphid in a hectoliter of water. Healthy plants grown in rich soil and well watered do not seem to be as subject to injury as those grown under less favorable conditions.

Some diseases and parasites of vanilla, A. ZIMMERMANN (*Centbl. Bakt. u. Par., 2. Abt.*, 8 (1902), No. 15-16, pp. 469-481, pl. 1, figs. 11).—Notes are given of a number of fungus and insect parasites of the vanilla plant. Among the fungus diseases described are those due to *Nectria vanillæ* n. sp., *N. coffeicola*, *Physalospora vanillæ* n. sp., *Chaetotriplodia vanillæ* n. sp., *Colletotrichum macrosporum*, *C. incarnatum*, and *Fusicladium vanillæ* n. sp. In addition to the above, attacks of *Aspidiotus aurantii* and the larvae of an undetermined insect are described.

Two diseases of vanilla, G. DELACROIX (*Agr. Prat. Pays Chauds*, 1 (1902), No. 6, pp. 680-688).—Descriptions are given of *Calospora vanillæ*, the attack of which somewhat resembles an anthracnose, and the rust of vanilla (*Uromyces jogfrini* n. sp.).

Grape diseases and their treatment, F. GYOZDENOVIC (*Ztschr. Landw. Versuchs. Oesterr.*, 5 (1902), No. 3, pp. 497-500).—A brief account is given of the occurrence of *Peronospora*, anthracnose, and oidium of grapes. For the prevention of *Peronospora*, experiments were conducted with Bordeaux mixture of varying strengths, Bordeaux mixture to which potassium permanganate was added, a solution of nickel sulphate and lime, and zinc sulphate and soda. All of these proved beneficial in preventing attacks of the disease, the Bordeaux mixture and potassium permanganate probably giving the best results.

Suggestions for combating grape mildew, J. M. GUILLON (*Jour. Agr. Prat.*, n. ser., 4 (1902), No. 32, pp. 177, 178).—The author discusses the possibility of combating the downy mildew and powdery mildew of the grape by spraying with a single fungicide. For this purpose he suggests the addition of sulphur to any of the ordinary fungicides. The sulphur does not enter into chemical combination, but is held in suspension, and when sprayed upon plants influences but little the adhesive property of the fungicide and at the same time is efficient against the powdery mildew.

Brunissure and the California vine disease, E. H. TWIGHT (*Prog. Agr. et Vit. (Ed. L'Est)*, 23 (1902), No. 20, pp. 590-592).—The author calls attention to the claim of Viala and Sauvegeau that brunissure and the California disease of grapes were caused by species of *Plasmodiophora* (E. S. R., 4, p. 380; 5, p. 423). Recent investigations have thrown some doubt upon the existence of this parasite, and the author believes that the experience in California tends to discredit the theory of the parasitic nature of the disease, which continues locally in the vicinity of Anaheim. A

somewhat similar disease is reported as having occurred in Santa Clara County, but this disease was local and is believed to have been due largely to drought, accompanied by late frosts.

Court-noué of grapes in Yonne, G. CHAPPAZ (*Prog. Agr. et Vit. (Éd. L'Est)*, 23 (1902), No. 32, pp. 173-180, figs. 3).—This disease, which results in a peculiarly stunted growth of vines, was particularly troublesome in the vineyards of Yonne during 1902. No parasite has been identified with the disease, and it made its appearance immediately following a low temperature and hailstorms occurring early in May. Certain varieties seem to be more subject to injury than others, and the author believes that the injury is due to the hail and the low temperature. This disease, which has been previously described (E. S. R., 12, p. 260), is briefly characterized. During the period reported upon it has proved of very great importance, as most of the grapes which were not directly destroyed by the hail have since succumbed to the disease. No suggestions are given for its prevention.

An epidemic of brown rot in the vicinity of Paris, M. MOLLIARD (*Bul. Soc. Mycol. France*, 17 (1901), No. 4, pp. 280-282; *abs. in Bot. Centbl.*, 89 (1902), No. 11, p. 308).—A severe outbreak of brown rot, due to *Monilia fructigena*, upon apricots, peaches, quinces, and pears is reported, while plums and cherries did not seem to be attacked to any great degree. Inoculations made in April upon young twigs of apricot soon produced the characteristic appearance of the disease. The destruction of all mummy fruits and burning of dead branches are recommended as means for the prevention of the return of the disease.

Development of black rot, A. PRUNET (*Compt. Rend. Acad. Sci. Paris*, 134 (1902), No. 18, pp. 1072-1075).—This article is essentially the same as one noted from another journal (E. S. R., 14, p. 369).

Downy mildew of grapes, TRABUT (*Bul. Agr. Algérie et Tunisie*, 8 (1902), No. 10, pp. 238, 239).—The occurrence of the downy mildew on grapes in Algiers is reported and is said to have occasioned considerable loss. The ordinary characteristics of the disease as observed in other countries were not apparent, but microscopic examination showed the presence of the spores of *Peronospora*. The occurrence of the downy mildew coincided with an attack of brunissure, which led many to think the diseases were identical. Prompt action is recommended for the prevention of the spread of the disease.

The treatment of powdery mildew, J. DUFOUR (*Prog. Agr. et Vit. (Éd. L'Est)*, 23 (1902), No. 30, pp. 120, 121).—A spraying mixture composed of 100 liters of water, 500 gm. of black soap, and 500 gm. potassium sulphid is recommended for spraying upon grapevines for the prevention of the powdery mildew.

Rose rust, D. McALPINE (*Jour. Dept. Agr. Victoria*, 1 (1902), No. 1, pp. 81, 82).—A brief account is given of the rose rust caused by *Phragmidium subcorticium*, and suggestions given for its prevention. Collecting and burning of the fallen leaves and the use of the winter spray of a strong solution of copper sulphate, followed during the summer by sprayings of Bordeaux mixture, will protect the plants against injury.

Septoria disease of carnations, P. VOGLINO (*Staz. Sper. Agr. Ital.*, 35 (1902), No. 1, pp. 17-34, pl. 1).—A description is given of the attack of *Septoria dianthi* upon species of *Dianthus*. The life history of the fungus is briefly described and the effect upon the host is shown. The fungus is said to live saprophytically upon the dead leaves, and retains its vitality for at least 5 months. A temperature of 25 to 30° C., combined with excessive humidity, is very favorable for the rapid production of the conidia of the fungus, and for the rapid dissemination of the disease. It is recommended that the dried leaves and infected portions of the plant be collected and burned as a precaution against the spread of the disease.

Schizophyllum commune, a parasite of the horse chestnut, F. GUEGUEN (*Bul. Soc. Mycol. France*, 17 (1901), No. 4, pp. 283-298, figs. 5; *abs. in Bot. Centbl.*, 89 (1902), No. 11, pp. 307, 308).—The presence of this fungus in a number of park

trees is noted, and the appearance of the affected portion of the tree is described. Inoculation experiments upon sound horse chestnut trees gave negative results. The fungus is believed to be a wound parasite and is capable of serious injury to the trees. A weakened condition of the trees is favorable to the rapid development of the disease and thorough drainage of the soil is said to reduce the liability of attack.

Some new parasitic fungi of oaks, E. HENRY (*Bul. Soc. Bot. France*, 48 (1901), No. 5-6, pp. 151-155).—Descriptions are given of species of fungi which have been recently described as occurring parasitically upon oaks. Among those described are *Pseudorubra longipes*, *Aglaospora taleola*, and *Pezicula cinnamomea*.

Canker of *Abies balsamea* in Minnesota, A. P. ANDERSON (*Bul. Torrey Bot. Club*, 29 (1902), No. 1, pp. 23-34, pls. 2).—While engaged in botanical investigations in northern Minnesota in 1896, the author noticed the balsam firs were affected to a great extent with numerous canker-like growths and swellings. Not infrequently the cankers extended around the tree trunk or branch, causing its destruction. The rough bark of the canker was found to bear numerous ascomata which resembled those of *Dasycephala calycina* of Europe which produces canker upon the larch. Subsequent studies showed the fungus was probably identical with *D. resinaria*. A description is given of the organism, and although no European specimens have been at hand to compare, the author believes there is no doubt of the identity of the species. The characteristic smooth bark of the fir becomes rough at the canker spot by the formation of ridges and bark projections soon after the infection takes place. The outer bark is broken through and scales off on account of the rapid increased growth of the inner layers of the bark. The effect of the canker on the cortex and wood is described, and although no opportunity has been at hand to perform inoculation experiments, the conclusion is reached that the disease is caused by the fungus mentioned above. The fungus is always found on the bark of the canker spots and nowhere else on the tree. So far as possible to make out, the fruiting occurs on the dead stems and continues only for one season after the stems have been killed by the parasite. The absence of insects and the presence of the mycelium in the bark, as well as in the cambium, and the absence of ascomata from the normal bark of the living tree and its presence on the dead stems, is considered sufficient evidence for establishing the parasitism of the fungus.

The preparation of fungicides, L. DEGRULLY (*Prog. Agr. et Vit. (Éd. l'Est)*, 23 (1902), No. 19, pp. 548-553, figs. 2).—Formulas and directions for preparation are given for a number of forms of Bordeaux mixture, Burgundy mixture, a copper sulphate and soap mixture, verdigris, and potassium permanganate.

Purity and control of copper sulphate, E. CHUARD (*Chron. Agr. Canton Vaud*, 15 (1902), No. 15, pp. 462-465).—The varying purity of copper sulphate is commented upon, and attention is called to the Federal regulations concerning the analysis and certification of copper sulphate, sulphur, and similar chemicals.

ENTOMOLOGY.

Notes on economic entomology, F. V. THEOBALD (*Jour. Southeast. Agr. Col.*, Wye, 1902, No. 2, pp. 20-54, pl. 1, figs. 4).—*Current scale insects and their treatment* (pp. 20-27).—The author gives biological, economic, and descriptive notes on *Pulvinaria ribesiae*, *Lecanium coryli*, *Mytilaspis pomorum*, and *Aspidiotus ostreeformis*. Of the many remedies which have been recommended in the destruction of these insects the author has found only 3 to be of any real service in killing the scales. Caustic alcohol wash, if applied in the winter, removes scale insects and also lichens and moss. Resin wash also proved successful when applied in the following proportion: Resin, 24 lbs.; caustic soda, 3 lbs.; soft soap, $4\frac{1}{2}$ lbs.; water, 100 gal. Fumigation with hydrocyanic-acid gas is successful if properly applied. Brief notes are also

given on the natural enemies of scale insects, including parasitic and predaceous insects and birds.

Social pear sawfly (*Pamphilus flaviventris*) (pp. 27-31).—This insect caused considerable damage in 1889 and again in 1900. It occasionally strips large pear trees of their foliage. The adult appears in May and June. The eggs are laid during bright sunshine, in groups of from 30 to 60 and on the underside of the leaves, usually in rows. The young larvæ form webs, in which 30 or more may be found when half grown. If the larvæ are allowed to develop, the ground beneath infested trees should be treated with gas lime during the winter.

Buff-tip moth (*Pygæra bucephala*) (pp. 31-34).—The caterpillars of this species frequently defoliate elm, beach, birch, oak, and fruit trees. The moth appears in June; the larvæ are gregarious and feed upon the upper surface of the leaf. Where it is impossible to apply arsenical poisons the larvæ may be jarred from the trees and destroyed.

Some notes on ribes-feeding sawflies of Europe and America, and sawfly remedies (pp. 34-45).—Notes are given on the habits, life history, natural enemies, and means of combating *Nematus ribesii*, *N. consobrinus*, *N. appendiculatus*, *N. grossulariæ*, and *N. rufipes*. The number of broods of *N. ribesii* is nearly always more than 2, and according to the author's observations, frequently 4. If the larvæ are allowed to escape to the ground, their numbers may be reduced to some extent by treatment of the soil under infested bushes. This may be done by removal of the soil, or by applying some caustic substance around the bushes. Plowing the soil is usually not effective, since the cocoons must be buried deeply in order to prevent the insects emerging. Quicklime applied to the soil about the bushes has generally given satisfactory results.

Bee moth (*Galleria cereana*) (pp. 45-48).—The insect is described in its different stages and notes are given on its life history. This insect was previously a more serious pest than at present. The cocoons may be detected in the bottom of infested hives, and search should at once be made for any of the pests in the hives. The insect seldom gains a footing in strong, healthy colonies.

Introduction of foreign ladybirds (pp. 48-50).—A number of species of ladybirds have been imported into England from Tasmania. The species which were first sent were *Leis conformis*, *Orcus australasiae*, and *O. bilunutus*. The first-named species appears to be very hardy and attacks plant lice with far greater voracity than that which is manifested by native species of ladybirds.

General report on insect and other pests in 1901 (pp. 50-54).—In this section the author gives brief notes on a large number of injurious insects to which his attention was called. These species include brown-tail moth, pear midge, codling moth, cut-worms, Colorado potato beetle, flea-beetle, etc. Brief notes are also given on worms and insects infesting domesticated animals.

Seventeenth report of the State entomologist on injurious and other insects of the State of New York, E. P. FELT (*Bul. New York State Mus.*, 10 (1901), No. 53, pp. 699-925, pls. 6, figs. 29).—As usual in the annual reports of the State entomologist of New York, a brief general account is given of the work of the office, while the main bulk of the bulletin is occupied with a discussion of the insects which were most injurious during the season, shorter notes on less important species, reports of the voluntary observers throughout the State, a bibliography of the publications of the entomologist, and a list of the additions to the insect collection during the year 1901. In the appendix to the bulletin an account is given of the entomological exhibit of the State entomologist at the Pan-American Exposition, together with a catalogue of the insects exhibited.

The Hessian fly caused extensive damages during the season of 1901; detailed notes are given on the amount of injury in different localities and on the time of appearance of the insect. The species is described and notes are given on its habits,

life history, parasites, and means of combating it. It was found by comparing weather records with the time of appearance of the Hessian fly that there is some apparent connection between these two phenomena. An extensive bibliography of the literature on the Hessian fly is added to the article on this insect. During the season of 1901 a large number of other species of insects were more or less injurious, and notes are given on several of these species, among which the following may be mentioned: Fruit-tree bark-beetle, grapevine fidia, *Colaspis brunnea*, round-headed apple-tree borer, forest tent caterpillar, grapevine leaf-hopper, *Cenopsis diluvicostana*, elm-leaf beetle, *Rhabdophaga salicis*, carpenter moth, leopard moth, birch-leaf bucculatrix, blister beetles, flea-beetles, squash bug, rabbit botfly, garden flea, European praying mantis, croton bug, and orange dog.

Insecticide experiments were carried out by the author in developing effective remedies for controlling the San José scale. The apparatus used was a hand kero-water spraying machine, and the insecticides with which the experiments were made included mechanical emulsion of kerosene oil, crude petroleum, a mixture of whale-oil soap and crude petroleum, and whale-oil soap in water. As the result of these experiments it was found that a 20 per cent or 25 per cent mechanical emulsion of crude petroleum was most effective. The combination of crude petroleum and whale-oil soap gave good results but were not as effective as the mechanical mixtures of crude petroleum. None of these preparations caused any injury to the trees. The experiments with whale-oil soap indicate that this insecticide is valuable for checking the injuries of the San José scale but can not be relied upon to do as thorough work as crude petroleum. A few tests with undiluted crude petroleum confirm the author's previous experience that it is an unsafe insecticide.

Report of the government entomologist for the year 1901, C. P. LOUNSBURY (Cape of Good Hope Dept. Agr., Rpt. Gort. Ent. 1901, pp. 103, pls. 6).—The chief lines of work undertaken by the entomologist during the year 1901 were investigations of the heart-water disease of goats and sheep, malignant jaundice of dogs, fumigation of buildings with hydrocyanic-acid gas, and experiments with insecticides. The experiments previously reported by the author on the subject of malignant jaundice in dogs indicated that this disease was transmitted by the tick known as *Hemaphysalis leachi*. Further experiments along this line served to confirm the results already obtained. They show also, as previously suspected, that the tick is innocuous in its larval and nymphal stages and pathogenic only in the adult condition.

Many experiments have been tried in importing various natural enemies of injurious insects. *Cryptolomus montrouzieri* was introduced from Australia and California, for the purpose of holding mealy bugs in check. The beetles were distributed in several places, but apparently did not survive. Similar experiments in introducing beneficial insects were made with *Chilocorus bivulnerus*, *Hippodamia convergens*, *Megilla maculata*, and *Erochomus pilatei*, as well as with fungus diseases. Some of these experiments were unsuccessful, the insects failing to survive, while in other cases good results appear to have been obtained.

An extensive series of experiments was made to determine the relationship of the bont tick (*Amblyomma hebraeum*) to heart-water disease of sheep and goats. The account of the author's experiments in cooperation with the veterinary service of Cape Colony is preceded by a general description of the disease and discussion of its symptoms, etiology, and distribution. Special devices were adopted for preventing ticks with which experiments were being made from leaving the experimental goats and sheep upon which they were placed. The numerous experiments which are reported in this paper indicate uniformly that *A. hebraeum* is alone concerned in the transmission of this disease, while *Rhipicephalus evertsi*, *R. decoloratus*, and *Onithodoros savignyi* are not concerned in the transmission of heart water. It was shown during the experiments that one single specimen of bont tick was capable of producing fatal infection in a healthy susceptible animal. Adult ticks fed as nymphs on sick animals

are capable of transmitting infection, and the same was found to be true of adult ticks which had fed as nymphs on cows, but as larvae on diseased animals. It appears, therefore, that cattle may serve to carry the disease, while not being infected. The disease was experimentally transmitted by adult ticks which had fed in a nymphal stage on long recovered goats, but on sick animals in the larval stage. Experiments indicated that animals which have recovered from heart water are still subject to infection, but that their power of resistance increases after they have been kept exposed to reinfection for some time. It was shown experimentally by the author that the bont tick is normally innocuous so far as heart water is concerned, and that the progeny of pathogenic bont ticks is noninfectious. Each tick, in order to become dangerous, must at some stage of its existence suck the blood of diseased animals. It was found also during these experiments that bont ticks dropped during the period of incubation were harmless. As the result of the author's experiments it is recommended that diseased animals be promptly isolated, and that careful attention should be given to the behavior of the flock in order to attack the first case of heart water which may appear. It is believed that this infection can be eliminated from any given area by excluding all susceptible animals for a period of greater or less length.

The authors' experiments in the fumigation of buildings with hydrocyanic-acid gas indicate that flies are more susceptible to the gas than fleas and bedbugs, while *Argas persicus* is quite unaffected by it. The eggs of the bedbug, flea, and small cockroaches are destroyed by the gas. The remedy, however, was found not to be effective in destroying weevils and other insects which are deeply embedded in masses of food stuff or other material.

Experiments with insecticides were conducted by C. W. Mally in the treatment of *Diaspis pentagona*, *Aspidiotus aurantii*, and woolly aphis. The conclusions reached from these experiments are that lime, sulphur, and salt wash is the best remedy for white peach scale; that resin wash of standard strength is a cheap and effective remedy for woolly aphis (above the surface of the ground); that several applications of this insecticide will hold the red scale in check, while on the other hand the remedy is useless for white peach scale. Soap washes proved unsatisfactory for use against the white scale, and mechanical mixtures of kerosene with water seemed to be of little value.

Second report of the government entomologist, 1901, C. FULLER (*Natal Dept. Agr., Rpt. Gort. Ent. 1901, pp. 72, pls. 3, figs. 23*).—The greater portion of the report is occupied with biological and economic notes on the large variety of insects and fungus diseases which caused losses to crops during the season 1901. The species of insects thus discussed include *Sesamia fusca* injurious to young corn; a species of *Animula* which attacks aecia; a number of species of fruit-piercing moths injurious to guavas and peaches; *Heteronychia arator* which attacks corn under ground and causes considerable damage; *Ceratitis corysa* injurious to grapes and other fruits; *Hippobosca struthionis* parasitic on ostriches, pigeons, and other birds; sheep tick; *Acridium pupuriferum*; black peach aphis; and clover mite. The treatment for *Heteronychia arator* recommended by the author includes the use of lantern traps for attacking the beetle, hand picking, and applications of salt. In combating the plague locust the use of arsenic baits is recommended, as well as spraying with soap solution and other well-known remedies. A general discussion is presented on the efficacy of the South African locust fungus. The author believes that attention was first called to this parasite by J. M. Wood in 1895. In the experience of the author the fungus is of some value, but is not sufficiently effective to justify its use except where other remedies have proved useless or inapplicable. Notes are also given on a sugarcane disease supposed to be due to *Strumella sacchari*, peach-leaf curl, dodder on alfalfa, varieties of oats which are resistant to rust, and *Phytophthora infestans*.

Descriptive notes are given in an appendix on a spraying machine devised by

A. M. Pearson for spraying a number of rows of vines or hops simultaneously. The sprayer is arranged to be propelled by horse power.

The results of some experiments with insecticides on some garden and greenhouse pests. R. NEWSTEAD (*Jour. Roy. Hort. Soc. [London], 26 (1902), No. 4, pp. 745-754, figs. 5*).—Experiments with kerosene emulsion in treating *Lecanium persicae* have been continued with the result that this insecticide is highly recommended for killing the scale. It is urged, however, that care must be used in its preparation in order to make it most effective.

Special studies were made of 2 species of subterranean mealy bugs, *Ripersia terrestris* and *Dactylopius radicum*. *R. terrestris* was found infesting the roots of Stephanotis, and later was found on the roots of palms and maidenhair fern. *D. radicum* was found to be injurious to strawberries, but its natural food plants appear to be grasses and *Ameria maritima*. In treating infested plants or greenhouses for these pests it is recommended that infested plants should not be turned out of the pots while in the conservatory; they should be removed and all soil shaken from the roots, after which the roots should be washed clean. The exposed roots and soil may then be sprayed with carbon bisulphid. The pots are to be scalded and plants may be replaced immediately after spraying.

It is reported that *Selandria atra* was especially injurious during 1899 to wall-trained pears and cherries. Notes are given on the habits and life history of this species. It is recommended that the soil be removed from around the base of the tree to the depth of 4 in. and that this soil be deeply buried or subjected to a high degree of heat. Boiling water, according to the author, is not sufficient to kill the pupae. It is recommended that trees be sprayed with Paris green at the rate of 1 oz. to 20 gal. of water. The first application should be made when the leaves are very small, and the second about the middle of July, at which time the percentage of Paris green may be doubled. Experiments with lime dressings, hot water, and kerosene emulsion gave negative results. Notes are also given on fruit-tree tortrix (*Penthina variegana*). The habits and life history of the species are described. In combating this insect it is recommended that an application of Paris green be made when the buds are opening, at the rate of 3 oz. to 20 gal. of water, and a second application after the larvæ have spun the leaves together, at the rate of 2 oz. to 20 gal. of water.

Insect enemies of the pear, plum, peach, and cherry. C. P. GILLETTE (*Colorado State Bd. Hort. Rpt. 1901, pp. 55-77, figs. 21*).—Notes are given on the habits, life history, and means of combating the more important insect pests of these fruits. Among the insect enemies of the pear the following are discussed: Flat-headed apple-tree borer, apple-tree slug, Putnam's scale, apple aphid, woolly aphid, and pear-leaf blister mite. Notes are given on the following insect enemies of the peach: Peach aphid, peach-tree borer, peach-twig borer, and peach lecanium. Among the enemies of plums the following are discussed: Fruit-tree bark-beetle, plum gopher, and plant lice.

Remedies for insect and fungoid pests of the orchard and farm. A. M. LEA (*Pub. Dept. Agr. Tasmania, 1902, pp. 38*).—The codling moth is considered the most serious insect pest of Tasmania. Where the orchard is small and isolated it is suggested that perhaps the best way of combating the insect is to destroy the entire fruit crop for one season. In Tasmania this insect is single brooded. The author's experience indicates that 3 sprayings with arsenites, once before the lobes have closed, furnish quite effective means for combating this insect. It is considered necessary, however, to pick off the infested apples and bandage the trees. The Tasmanian custom of placing a bundle of sacking in the fork of the tree is considered less effective than the band.

Descriptive and economic notes are also given on potato moth, cabbage worm, cherry slug, scale insects, woolly aphid and other plant lice, a number of plant bugs, grasshoppers, earwigs, red spiders, pear-leaf blister mite, clover mite, and black spot

and bitter rot of apples as well as peach-leaf curl, fire blight, and potato scab. Formulas are given and also directions for preparing Paris green, arsenic and soda, hellebore, lime-sulphur-and-salt wash, whale-oil soap, kerosene emulsion, resin wash, Bordeaux mixture, ammoniacal copper carbonate, and other insecticides and fungicides. The 2 beetles which are most injurious to strawberries are considered *Otiorhynchus sulcatus*, *Rhinaria perdis*. The only boring insect especially injurious to fruit trees in Tasmania is said to be *Maroga gigantella*.

Injurious and useful insects, L. C. MIALL (London: George Bell & Sons, 1902, pp. VIII + 256, figs. 103).—As stated by the author, this volume is intended to help beginners in identifying the common species of injurious insects and to stimulate interest in the relation of insects to economic agriculture, horticulture, and forestry. The general anatomy of insects is described in considerable detail, and special chapters are devoted to the common injurious species of beetles, moths, butterflies, Hymenoptera, Diptera, plant lice, scale insects, and other miscellaneous injurious insects. Notes are given by way of description and identification of common species in the various orders. In part 4 of the volume the author discusses methods of preventing or checking the injury caused by insects.

The enemies of agriculture, A. L. HERRERA (*Las plagas de la agricultura. Mexico: Ministerio de Fomento, 1902, pp. 178, pls. 2*).—This is a general treatise on the subject of injurious insects and methods of combating them. It includes the classification of insects, the preparation and use of fungicides and insecticides, and special notes on different methods of treatment, including mechanical methods and the use of natural enemies of insects. In addition to detailed formulas and directions for the preparation of insecticides and fungicides, notes are given on combinations of fungicides and insecticides and on methods to be adopted in combating the attacks of the more important injurious insects. The various agricultural and horticultural crops are arranged in alphabetical order and mention is made under each plant of the more important insect enemies which attack it.

Caterpillars and their moths, IDA M. ELIOT and CAROLINE G. SOULE (New York: The Century Co., 1902, pp. 302, pls. 80, figs. 2).—In this volume the authors have discussed the developmental stages and life history of a considerable variety of moths selected on account of their suitability for class work and beginners in entomology. The subjects discussed in the volume include the arrangement of an insectary, a description of the various stages and general habits of insects, methods of rearing insects, methods of collecting insects in various stages, parasitic insects, and special descriptive notes on the appearance, habits, and life history of representative species of a number of families of moths.

Enemies of wheat, G. F. DE CHAMPVILLE (*Les ennemis de blé. Paris: F. de Launay, 1902, 3. ed., pp. 152, figs. 6*).—In this pamphlet the author attempts to present a practical treatise on entomology, taking as his illustrative examples the insects which are injurious to wheat. The species which are considered by the author include the Angoumois grain moth, *Calandra granaria*, *Bruchus granarius*, *Tinea granella*, *Tenebrio mauritanicus*, larvae of cock chafers, *Cephus pygmaeus*, Hessian fly, *Chlorops lineata*, *Zabrus gibbus*, *Agrotis segetum*, *Ochsenheimeria taurella*, *Agriotes lineatus*, grain aphid, and locusts. In addition to a discussion of insects injurious to wheat the author presents a brief account of other enemies, including *Tylenchus tritici* and rust. Attention is also called to the desirability of protecting bats, toads, and insectivorous birds, on account of their beneficial action in destroying injurious insects.

The diamond-back moth, G. H. CARPENTER (Jour. Dept. Agr. and Tech. Instr. Ireland, 2 (1901), No. 2, pp. 275-279, figs. 7).—This insect is reported as having caused unusual damage to cultivated cruciferous plants during the season of 1901. Notes are given on the habits and life history of the species. A number of birds have been found to feed upon the insect, and it may also be destroyed, under favorable circumstances, by spraying with kerosene emulsion. At times it is difficult to control

their ravages, but when they are especially numerous it is suggested that some help may be derived by frequent shaking and brushing of the plants accompanied with thorough cultivation between the rows.

Report on codling moth investigations in the Northwest during 1901, C. B. SIMPSON (*U. S. Dept. Agr., Division of Entomology Bul. 35, n. ser., pp. 29, pls. 5, fig. 1*).—During the season of 1901 there was an unusually small crop of apples in Idaho and the injuries from the codling moth were excessively great. The remains of as many as 23 eggs were found on a single apple. Pears were only slightly infested and no cases were found where the codling moth had attacked quinces, rose hips, peaches, prunes, or plums. Of the different varieties of apples Pewaukee was always badly infested and Winesap was least infested. The greatest amount of infestation was observed in the Upper Sonoran life zone. On an average about 83 per cent of the first generation of larvæ entered the apple at the calyx end. The majority of the larvæ of the second generation entered at some other point than the calyx. The average length of time for the larvæ to become full grown was about 22 days, and the time required for spinning the cocoon, 5 days. In the summer about 21 days elapsed between the spinning of the cocoon and the emergence of the moth. A greater number of female moths were observed than males. Nearly all of the eggs of the first generation were laid upon the fruit, while those of a later generation were deposited upon the fruit and leaves.

Special attention was given to the question of the number of generations. From extensive records kept of the number of larvæ under hands it is concluded that there are only 2 generations, or that if there is a third it is of little or no importance. In the Northwestern States comparatively few eggs hatched. The causes of this appear to be infertility, dryness, and the effect of the sun's rays. Experiments thus far conducted indicate that it is impracticable to combat this insect in the egg stage. The 3 remedies most enthusiastically recommended are spraying, banding the trees, and picking and destroying wormy fruit. It is recommended that trees be sprayed immediately after the blossoms fall, and that a second spraying be given about a week or 10 days later. The writer believes that the first spraying is the most important of all and is perfectly effective if thoroughly done. Late sprayings are not recommended. As material for spray Paris green in the proportion of 1 lb. to 160 gal. of water, with 2 lbs. of lime is recommended. Arsenate of lead is equally effective. The use of trap lanterns and baits for the moths are considered ineffective.

The codling moth, J. H. CROWLEY (*Colorado State Bd. Hort. Rpt. 1901, pp. 30-39, figs. 2*).—In this article the author relates his experience in combating the codling moth. Notes are given on the life history of the insect in Colorado. The author recommends that trees be sprayed as soon as the flowers have been pollenized by bees and that the application of Paris green be repeated at intervals according to the season. The author also used bands and examined them at intervals of 8 days until September 1.

Successful treatment for codling moth, W. S. COBURN (*Colorado State Bd. Hort. Rpt. 1901, pp. 78-82*).—The trunks and larger branches of the trees were carefully scraped and the soil underneath the trees was thoroughly cultivated in order to destroy the pupæ which might be concealed near the surface. After the petals fell the insecticide treatment applied consisted in the use of the following formula: $\frac{1}{2}$ lb. white arsenic, 4 lbs. sal soda dissolved in hot water and boiled for 15 minutes; this was diluted so as to make 40 gal., and 4 lbs. of lime was slaked and added to the mixture. It was found that best results were obtained when several applications were made so as to destroy part of the second brood of the codling moth. Infested apples were hooked off the tree as soon as detected and eaten by hogs and sheep which were allowed to run in the orchard.

The California peach-tree borer, C. W. WOODWORTH (*California Sta. Bul. 143, pp. 15, figs. 7*).—This insect is said to be the most injurious insect in the Santa Clara

Valley and is abundant on peach and apricot trees and on prune trees which are grown on peach and plum roots. The insect does not appear to be injurious in any other part of California. The moth has been collected, however, in nearly all parts of the State. Brief notes are given on the members of the family Sesiidae in California, including the species discussed in the bulletin of which the proper name is *Saminioides opalescens*. The life history of this species is not well known. The insect is active throughout the winter season and pupation does not occur until late spring. The most obvious sign of the presence of the larvæ in a tree is the exudation of gum. This, however, is not a certain evidence of the presence of the larvæ, since gum may appear on trees which do not contain the peach-tree borer, and may be absent in trees which are infested with this insect. The burrow of the larvæ is usually in a vertical direction. The moth lays a large number of eggs upon the trunks of the trees. During the summer moths are produced continually and eggs and larvæ of various sizes may always be found. It appears, however, that there is only 1 brood of the insect per year.

The remedies which have been applied in Eastern States to the eastern peach-tree borer have not proved economic or effective in California. By far the best results in fighting the peach-tree borer were obtained from the use of carbon bisulphid. It appears that this is the cheapest remedy, and when properly handled there is little or no danger to trees. It is stated that some growers pour the liquid directly on the bark of the trees without bad effects. The character of the soil is the most important factor in determining whether or not the trees suffer injury from the insecticide. If the soil is loose and reasonably dry the fluid volatilizes rapidly and does not injure the tree. It is recommended that the carbon bisulphid be poured on the ground near the trunk of the tree and that the earth be thrown up around the trunk in the form of a mound. As a rule about 1 oz. is sufficient for each tree. In common practice, however, the amount is made dependent upon the size of the tree. A small can has been devised in which the proper amount may be readily measured and poured upon the ground around the tree. Treatment with bisulphid of carbon has been confined almost wholly to the winter season; since much injury is done by the borers during the summer it appears advisable to make 1 or more applications during the summer. If but 1 application is to be made it is recommended that this be done early in the winter.

Two peach scales, H. A. GOSSARD (*Florida Sta. Bul. 61, pp. 469-498, pls. 4*).—An application of undiluted crude petroleum was given to pear, plum, and peach trees on January 25. Two of the pear trees died later of blight, but the scales were apparently killed by the crude oil. A number of plum trees of 8 different varieties which were treated with the undiluted crude petroleum died, and the number of trees which died during the year following the spraying was larger than that of check rows. The same application was made to 9 bearing peach trees of the Florida Gem variety. Of this number only 2 or 3 ever showed any signs of life during the succeeding season, and all died. Several young plum and peach trees of different varieties were sprayed with from 15 to 30 per cent mechanical mixture of petroleum and water in February without suffering any injury. Applications of kerosene in mechanical mixture of water at the same time gave less satisfactory results than the crude oil. No injury was done to the trees by these diluted applications.

The parasitic fungus *Spharostilbe coccophila* is said to have developed so vigorously in some localities as to render insecticide operations against the San José scale unnecessary. Notes are given from correspondence with practical orchardists who report good results from the distribution of this fungus. One orchardist states that after 2 years' experience with crude oil he considers the San José scale as a very easy pest to control. This orchardist used 25 per cent mechanical mixture of crude petroleum. When the proper winter treatment has been given, summer treatment is seldom required. Crude petroleum, however, can not be used in summer nor upon evergreen

plants. A 10 to 15 per cent mixture of kerosene and water may be applied on sunny days, or whale-oil soap at the rate of 1 lb. to 4 gal. water. An examination of a 40-acre peach orchard about 12 years of age indicated that although San José scale had been present for 6 or 7 years, *Sphaerosilbe coccophila* had held the scale in check without the assistance of any insecticide treatment. It is believed that at least during the warm rainy weather the fungus is capable of controlling the scale. Spraying with kerosene, crude oil, whale-oil soap, or resin wash destroys the fungus, while fumigation with hydrocyanic-acid gas does not affect it.

White peach scale (*Diaspis pantagona*) was first observed in Florida in 1889. The infestation appears to have come from California. A list of the food plants of this species is given, together with notes on its appearance and life history. This scale may be controlled by the winter treatment recommended for San José scale or by fumigation under tents. The chief natural enemies are *Chilocorus bitorulatus*, and the parasitic fungus mentioned as an enemy to San José scale.

Treatment for San José scale in orchards. II, Spraying with kerosene and crude petroleum. F. A. SIRRINE (*New York State Sta. Bul.* 213, pp. 25-51, pls. 4).—The experiments in controlling the San José scale reported in this bulletin were made on Long Island and in Westchester County, N. Y. The applications of oil were made by means of pumps for producing a mechanical mixture with water. It was found that the mixture produced by such pumps always varied to the extent of 5 per cent on either side of the percentage which was desired. During the experiments in the use of kerosene it was found to be unsafe to use low-grade kerosene in a 15 per cent mixture in water on peach trees in a dormant condition. The same mixture appeared to injure apple trees, even in a dormant condition. It is believed, therefore, that low-grade kerosenes are unsafe at all seasons of the year and for all kinds of trees. Moreover, it proved to be unsafe to use 150° flash-test kerosene in a 15 per cent mixture of water on dormant peach, or to spray apple trees with pure kerosene or a 50 per cent mixture as late as March 13. It was found during these experiments that mechanical mixtures of kerosene varying from 15 to 25 per cent may be used on apple and pear while the trees are in full leaf, but that similar mixtures varying from 10 to 15 per cent are liable to cause damage to stone fruits in the same condition. In the author's experiments it was found safe to apply a good grade of kerosene to pear and apple trees in a dormant condition, but that these trees were injured if sprayed after the beginning of growth in the spring. With stone fruits the reverse condition held true. The use of dilute mechanical mixtures of kerosene on dormant peach invariably killed the tree, while pure kerosene was applied when the buds were swelling with but little injury. The tests with crude petroleum were made on plum, peach, pear, and apple. It was found that pure crude petroleum, or even a 50 per cent mechanical mixture, could not be safely used on apple, peach, or pear. Crude petroleum of a specific gravity of 0.795 in a mechanical mixture of 15 per cent injured pear buds to some extent, while a mixture of 50 to 60 per cent killed all the buds. The trees apparently recovered from the treatment, however, and put forth other buds from which a good crop of fruit was developed. A 15 per cent mechanical mixture of crude petroleum killed all the fruit buds on peaches and a 25 per cent mixture killed the trees outright. A 15 to 25 per cent mechanical mixture of crude petroleum had no bad effect on peaches and plums when applied after the buds had begun to swell. During these experiments it was shown that 1 application of a 15 per cent mechanical mixture of crude petroleum did not kill all the scales, but that 2 applications of this strength, or 1 of 25 per cent mixture, killed all the scales which were touched with the spray. The cost of spraying pear trees 12 ft. in height with crude petroleum was 12 cts. per tree, while the cost of spraying standard apple trees with crude petroleum was 40 cts. per tree. While spraying under favorable conditions costs only about one-third as much as fumigation, it is urged that spraying is a disagreeable method of controlling San José scale, and that the narrow margin

between the quantity of oil required to kill the scale and the amount which will injure the tree renders the result uncertain.

Treating San José scale in Southeastern New York, F. H. HALL and F. A. SIRRINE (*New York State Sta. Buls.* 209 and 213, popular ed., pp. 8, figs. 2).—A popular summary of Bulletins 209 (E. S. R., 13, p. 1064) and 213 (noted above) of this station.

Experiments for the destruction of San José scale, W. J. ALLEN (*Agr. Gaz. New South Wales*, 13 (1902), No. 6, pp. 644-646).—The results of a number of experiments by the author and various fruit men in the destruction of the San José scale are reported. Good results were obtained from the use of lime, salt, and sulphur spray containing 30 lbs. of lime, 20 lbs. of sulphur, 15 lbs. of salt, and 60 gal. of water. The use of kerosene also gave excellent results and the scales in most instances seemed to be entirely exterminated. Some injury to the trees, however, is reported from the use of pure kerosene.

A new method of destroying Tortrix pilleriana and other injurious insects, P. VERMOREL and GASTINE (*Jour. Agr. Prat.*, n. ser., 4 (1902), No. 30, pp. 106-108).—Experiments were carried on for a number of years in the destruction of *Tortrix pilleriana* and *T. ambiguella* by the use of ordinary insecticides in a fluid and gaseous form. None of the numerous insecticides used in either of these forms proved effective in the destruction of these insects. Resort was finally had to the use of heat. It was found that most insects, including the 2 species mentioned, were destroyed by exposure to a temperature of 48 to 50° C. for a period of 3 or 4 minutes. They were also destroyed by exposure to a temperature of 45° C. for 10 minutes. This temperature was found to be without injurious effect upon grapes. The apparatus used in these experiments consisted of a bell-shaped metallic vessel which was supported over the plant and the necessary degree of heat was obtained from hot water maintained in a vessel under the bell-shaped apparatus. As soon as a temperature of 40 to 45° C. was reached in the bell-shaped device the insects began to come out from their hiding places and fall into the water, where they were immediately destroyed. It is believed that this method is worthy of further trial and promises good results in destroying the species mentioned as well as other insects.

An account of the black currant bud gall mite, E. J. LEWIS (*Jour. Southeast. Agr. Col.*, Wye, 1902, No. 2, pp. 55-80, pl. 1, figs. 2).—A general account is given of the habits of the family of mites to which this species belongs. The author discusses the spread of the disease and describes the mite in the various stages, and the symptoms by which infestation by the mite may be recognized. Notes are given on the life history of the mite and its possible enemies. The variety of currant which has been chiefly attacked had until lately been the Baldwin. Lately several others have been almost equally infested. A brief account is given of the means of distribution of this mite, and of the remedies which have been recommended for combating it. These remedies have almost without exception proved useless. The author undertook extended experiments for the purpose of determining the possible value of fumigation with hydrocyanic-acid gas in combating this mite. In none of the author's experiments was the disease entirely checked. Even where the best results were obtained there were still a few infested buds to be found on inspection after fumigation. In many cases a large percentage of the mites remained unaffected by treatment with the gas. The gas apparently had no effect upon the eggs. It is suggested that 2 or 3 fumigations at intervals of not too great length might be more effective than a single application of gas.

Grasshoppers in California, C. W. WOODWORTH (*California Sta. Bul.* 142, pp. 36, figs. 17).—Grasshopper outbreaks of more than usual severity occurred in Roseville, Fair Oaks, and Orangevale. When an attempt was made to induce the local authorities to adopt the proper methods for destroying the grasshoppers upon their breeding grounds it was found that such measures could not be safely adopted on account of the possibility of local authorities becoming responsible for damages.

Notes are given on the habits and life history of grasshoppers and brief descriptions are presented of the various species which occur in California. The author presents a list of the more important outbreaks of locusts which have occurred in California up to the present time. It is stated that danger from locusts in California arises chiefly from a comparative narrow strip of rolling land used for pasture. This land lies on the east of the Sacramento and San Joaquin valleys. Notes are given on the conditions which determine migration of locusts.

For controlling flying swarms of locusts the author recommends driving away by means of smudges, by armies of men, and poisoning by means of baits. For controlling drifting swarms, barriers, smudges, plowing under, poisoning by baits, and the use of a hopperdozer are recommended. Practical tests of the method of sacking trees to prevent injury from locusts indicate that this method is dangerous. Most of the trees are injured and lose their lives or show an unthrifty condition. For controlling locusts in their breeding grounds it is recommended that the ground be plowed in the fall, or that the area be burned over before the locusts are able to fly. Hopperdozers may be used quite effectively upon the breeding grounds. In order to prevent the depredations of locusts upon fruit trees it is considered necessary to make a careful survey to determine the breeding grounds of the locusts, especially such areas as are contiguous to large fruit-raising districts, and to secure legislation which will empower the local authorities to carry out the necessary measures for destroying the locusts.

Departmental notes on insects that affect forestry, No. 1, E. P. STEBBING (*Calcutta: Supt. Govt. Printing, India, 1902, pp. IV+149, pls. 5*).—In this report the author presents notes on a considerable variety of insects injurious to forest trees in India. An alphabetical list of the chief forest trees is given, with mention of the more important injurious insects under each species. Detailed notes are given on the habits and life history of a large number of insects, among which the following may be mentioned: *Trypoxalis nasuta*, *Oxya velox*, *Sinoxylon crassum*, *S. anale*, *Apriona germari*, species of *Scolytus*, *Trabala vishnu*, *Lymantria amplata*, *L. obsoleta*, *L. todara*, *L. mathura*, *L. birittata*, *L. grandis*, *Agrotis ypsilon*, *Boarmia selenaria*, *Monophlebus stebbingii*, *M. dalbergiae*, and *M. tectonae*. Brief notes are also given on the use of Paris green in spraying trees for the destruction of caterpillars.

Insect enemies of shade trees, E. P. FELT (*Colorado State Bd. Hort. Rpt. 1901, pp. 164-170*).—Economic and biological notes are given on imported elm-leaf beetle, forest tent caterpillar, imported elm bark-louse, gypsy moth, leopard moth, white-marked tussock moth, Antiope butterfly, cottony maple scale, cottonwood-leaf beetle, and *Saperda calceolata*.

Galls and insects producing them, I, II, M. T. COOK (*Ohio State Univ. Bul., 6, ser., No. 15; reprinted from Ohio Nat., 2 (1902), pp. 263-278, pls. 4*).—The author describes the anatomy of plant galls caused by a number of groups of insects, including plant lice, Phytoptus, Cecidomyia, and Cynipide. In this paper galls are classified in two groups, those produced by biting and those produced by oviposition. The anatomical structure of the gall was found to depend upon the genus of the insect which produced it rather than upon the species of plant upon which it was produced.

The chemical composition of insecticides and fungicides, with an account of the methods of analysis employed, J. K. HAYWOOD (*U. S. Dept. Agr., Bureau of Chemistry Bul. 68, pp. 62, fig. 1*).—In cooperation with the Division of Entomology the Bureau of Chemistry collected about 300 samples of insecticides and fungicides, including all the more important ones which are on the market, and of this number 156 were selected for analysis, mainly insecticides. The author describes the methods employed in different classes of these materials, and discusses the results at some length. Except in the cases of Paris green, London purple, whale-oil soap, hellebore, pyrethrum, and tobacco extracts, only single analyses are reported.

In 45 samples of Paris green, "neither the amount of moisture nor sand is in any case sufficient to be objectionable. As to sodium sulphate, which is always present in samples of Paris green on account of the method of manufacture, there is no reason why a sample which had been at all well washed should have more than 1 per cent present. The table shows that 16 of the samples of Paris green have between 1 and 2 per cent, 2 have between 2 and 3 per cent, and one has between 3 and 4 per cent, making a total of 19, or 43 per cent, which have more sodium sulphate than should be allowable. . . .

"The figures for total arsenious oxid show that no green contains less than 56.20 per cent. There are 7 greens containing between 56 and 57 per cent, 24 containing between 57 and 58 per cent, 11 containing between 58 and 59 per cent, and the remaining 3 containing between 59 and 62 per cent. These figures would seem to indicate that there is no reason for a sample of Paris green containing less than 56 per cent of total arsenious oxid, and that the States having laws regarding this subject should change them so as to require the presence of 56 instead of 50 per cent of arsenious oxid.

"The figures for copper oxid vary from a minimum of 27.58 to a maximum of 31.16 per cent. More than half of the samples contain between 30 and 31 per cent.

"If the Eastern and California standard of 4 per cent be adopted for free arsenious oxid, and the 10-day water extraction method be used, there are only 13 samples, or 29 per cent, of the above Paris greens that would pass; but if the 6 per cent limit, which we consider the better, be used, 38 samples, or 84 per cent, of the greens would be accepted. . . .

"The figures representing the soluble arsenious oxid by the sodium-acetate-extraction method seem to show that most supplies of Paris green really contain very little arsenious oxid as such. . . .

"It appears from the work that has been done on the subject that the sodium-acetate method gives more closely the true percentage of free arsenious oxid in the sample of Paris green, while the water-extraction method gives the percentage of free arsenious oxid in the green plus some arsenious oxid obtained by the decomposing action of the water on the Paris green. In some very coarse samples of Paris green, which are supposed not to be made as well as the finer samples, the author found recently that the sodium-acetate-extraction method gave very low figures for free arsenious oxid (showing that only a small amount of free arsenious oxid as such was present), while the water-extraction method gave very high figures (seeming to show that although only a small amount of arsenious oxid was present in the free state, there was present a certain portion of the green, which was in a very loose combination, and consequently was easily broken up). That portion of the green which was in such a loose combination would, in all likelihood, when applied to the plant soon break up and scorch the foliage. It therefore appears that while the sodium-acetate-extraction method, as before mentioned, gives more closely the actual percentage of free arsenious oxid present in the green, the water-extraction method gives some idea of its stability, and consequently will express more closely the value of the compound in actual orchard practice."

It is suggested that in adding lime to Paris green to prevent the scorching of the foliage, it would be better, from a theoretical standpoint, "to mix the green, in suspension in water, with the lime about 10 days before use and stir the mixture occasionally, since the free arsenious oxid does not go into solution in much less time than this, and consequently is not acted upon as well by the lime to form the less harmful compound calcium arsenite."

In 11 samples of London purple, the water varied from 1.87 to 4.9 per cent, and the sand from 1.36 to 9.74 per cent, although the latter was rarely over 3.5 per cent. It was found that the arsenic was not present exclusively as calcium arsenite, but "both as calcium arsenite and calcium arsenate. The amount of these two sub-

stances varies very much, but where both the arsenious and arsenic oxids are calculated to arsenic it is found that the percentage of this constituent is fairly constant in different samples." This fact affects the interpretation of the analysis as to the harmfulness of the sample.

"Wherever a sample contains only a small quantity of soluble arsenious oxid it contains a very large quantity of soluble arsenic oxid, so that the total amount of arsenic that is dissolved from any sample of London purple is very great. This perhaps explains the unaccountable manner in which London purple often scorches the foliage when an analysis has shown that only a small quantity of arsenious oxid is present. . . . Where a large part of the soluble arsenic is present as the calcium salts of arsenious and arsenic acid, as shown by the fact that large amounts of lime also go into solution, it appears that plants can endure much more of these salts than they can of the free acids. Work along this line is much needed."

Remedies and formulas adopted by the State board of horticulture for the extermination of pests injurious to tree and plant life (*Colorado State Bd. Hort. Rpt. 1901, pp. 273-292*).—Notes are given on the formulas and methods of preparing the common insecticides, such as Paris green, London purple, white arsenic, arsenic bran mash, white hellebore, Bordeaux mixture, kerosene emulsion, resin wash, lime-salt-and-sulphur wash, and whale-oil soap. A brief description, together with remedies, is given for the chief insect enemies of apple, pear, plum, peach, small fruits, shade trees, roses, and other farm and garden crops.

An index to Bulletins Nos. 1-30 (new series) (1896-1901) of the Division of Entomology, N. BANKS (*U. S. Dept. Agr., Division of Entomology Bul. 36, n. ser., pp. 64*).—In this bulletin the author has compiled an index of authors, illustrations, species of insects, and subjects which are included in Division of Entomology Bulletins 1-30, new series.

Report of the twenty-second annual convention of the Colorado State Beekeepers' Association (*Colorado State Bd. Hort. Rpt. 1901, pp. 309-420, pt. 1*).—The twenty-second session of this association was held at the State capitol building, Denver, Colo., November 18 to 20, 1901. A number of brief papers were read on various subjects, including methods of killing ants, grading honey, breeding bees, growing basswood for bee food, the construction of a honey house, honey pasturage, abnormal swarming, spring management, the extraction of honey, and long-tongued bees.

Studies on the silkworm during the pupal condition, R. DUBOIS and E. COUVREUR (*Ann. Soc. Lim. Lyon, n. ser., 48 (1901), pp. 157-163*).—The investigations reported in this paper were chiefly concerned with the elimination of carbonic acid and water from the pupæ, the influence of the presence or absence of the cocoon on the rapidity of the metamorphosis of the pupæ, and the influence of carbonic acid on the spinning powers of the larvæ. It was found that during the 3 days in which the larva spins the cocoon a large quantity of carbonic acid and water vapor was excreted, while after this period the carbonic acid accumulated to a considerable extent in the tissues.

FOODS—NUTRITION.

Dietary studies in New York City in 1896 and 1897, W. O. ATWATER and A. P. BRYANT (*U. S. Dept. Agr., Office of Experiment Stations Bul. 116, pp. 83*).—The results of 36 dietary studies carried on in the thickly congested districts of New York City are reported. In some cases the families had a fairly large income, but most of them were of the sort receiving frequent assistance from charitable organizations. For convenience in discussing the results the families were divided into 6 groups, viz, those in which the cost of the daily diet per man (1) was less than 13 cts., (2)

ranged from 13 to 16 cts., (3) from 17 to 20 cts., (4) from 21 to 23 cts., (5) from 25 to 28 cts., and (6) over 28 cts. The average results obtained follow:

Average results of dietary studies made in New York City.

[Amounts per man per day.]

	Number of fam- ilies.	Cost.	Protein.	Fat.	Carbohy- drates.	Fuel value.
		<i>Cents.</i>	<i>Grams.</i>	<i>Grams.</i>	<i>Grams.</i>	<i>Calories.</i>
Group 1	10	11	75	79	271	2,151
Group 2	19	15	94	102	352	2,779
Group 3	8	18	103	120	312	2,944
Group 4	9	22	125	138	420	3,514
Group 5	7	26	138	154	456	3,864
Group 6	6	38	178	222	643	5,432

According to the authors, in some instances the income was so limited that it was too small for the purchase of a sufficient amount of nutritious food. Although some of the families made good use of their resources, in a majority of cases it is believed that they would have been benefited by instruction regarding the purchase, selection, and preparation of food.

"Certain it is that improvements in the selection of food so as to secure more and better nutriment at less cost, in the cooking so as to make palatable dishes from inexpensive materials, and in the setting of the table so as to make it an attractive feature of home life, will be important means for the material and moral uplift of families like those whose dietary practice is described in this and the previous report." (E. S. R., 9, p. 1074.)

Practical dietetics, W. G. THOMPSON (*New York: D. Appleton & Co., 1902, 2. ed., pp. XXIV + 828, pls. 9, fig. 1*).—The author states that this volume has been revised throughout and in part rewritten, and that considerable new matter has been added. As a whole the book treats of the nutritive value of different foods and food preparations, stimulants, beverages, and condiments; cooking food; digestion; diet in relation to different diseases; diet for prisons, asylums, etc.; and related topics.

The complete Indian housekeeper and cook, FLORA ANNIE STEEL and GRACE GARDINER (*London: W. Heinemann, 1902, 3. ed., pp. XIV + 373*).—This volume is designed as a guide for English housekeepers in India. Such subjects are treated of as horse and stable management, cows and dairy, poultry, and gardening, though the bulk of the volume is devoted to food and its preparation, household management and hygiene, and related topics. The authors state that this edition has been revised and corrected.

Origin and preparation of the most important food materials and condiments, F. SEEL (*Gewinnung und Darstellung der wichtigsten Nahrungs- und Genussmittel. Stuttgart: F. Enke, 1902, pp. VII + 478*).—It has been the author's purpose to discuss the origin, method of manufacture, preservation, uses, regulations regarding the sale, etc., of the more important animal and vegetable foods and beverages. The volume is designed as a text-book and work of reference for chemists, pharmacists, physicians, and those interested in legal chemistry.

Comparative studies of the composition of beef from different regions of France and the colonies, BUSSON (*Monit. Sci., 4. ser., 15 (1901), pp. 597-609; abs. in Ztschr. Untersuch. Nahr. u. Genussmittel, 5 (1902), No. 20, pp. 980-982*).—Analyses are reported of a large number of different cuts of beef, from France and the French colonies, the study being undertaken with special reference to canning meat for the French army. The author also reports figures showing the amount of cooked meat obtained with the different sorts of beef studied.

Tenderness of meat and its relation to the thickness of the muscle fibers, L. ISAAK (*Inaug. Diss., Würzburg, 1901, pp. 13; abs. in Ztschr. Fleisch u. Milchhyg., 12 (1901-02), pp. 175-177*).—The author examined the flesh of 3 steers and 2 calves with a view to learning the connection between muscle fibers and tenderness. His principal conclusions follow:

The muscle fibers of a full grown steer are 2 to 2.5 times thicker than those of the calf. The thickness of the fibers does not exert any direct effect upon the tenderness of the flesh. The thickness of the fillet and flank was not proportional to the tenderness of the flesh. The author believes that possibly the connective tissue determines the tenderness though this is not proven. He suggests further that differences in the structure of the muscle fibers, in the thickness of the sarcolemma, or in the chemical composition of the sarcoplasm have an effect upon the tenderness of meat.

Study of a new proteid preparation "Proton," E. O. HULTGREN (*Skand. Arch. Physiol., 13 (1902), No. 1-2, pp. 144-169*).—Analyses of Proton (a food prepared from milk casein) and Proton bread, as well as the results of digestion and metabolism experiments undertaken to determine the nutritive value of Proton, are reported. A bibliography of the literature of artificial proteid foods is included.

Studies with the Egyptian fermented milk called leben, E. RIST and J. KHOURY (*Ann. Inst. Pasteur, 16 (1902), pp. 65-84; abs. in Ztschr. Untersuch. Nahr. u. Genussmit., 5 (1902), No. 18, p. 872*).—The micro-organisms causing the peculiar fermentation of leben, a fermented beverage made from milk, were studied.

Buttermilk as an infant food, A. BAGINSKY (*British Med. Jour., 1902, No. 2175, pp. 692-694*).—The successful use of buttermilk in the feeding of infants is discussed on the basis of the author's hospital experience. The buttermilk is prepared as follows: "To 1 liter 15 to 25 gm. of wheat flour and 35 to 50 gm. of cane sugar are added. With constant stirring it is allowed to boil for at least 2 minutes (as a rule we allow the mixture to boil up 3 or 4 times). The milk is then poured into bottles which have been previously sterilized, stoppered by means of cotton, and kept in the ice box until used."

Manufacture of semolina and macaroni, R. P. SKINNER (*U. S. Dept. Agr., Bureau of Plant Industry Bul. 20, pp. 31, pls. 5, figs. 6*).—The possibility of the profitable production of true Durum wheats in America suitable for making semolina and Italian pastes is discussed, and the manufacture of such goods described.

Concerning the water content of bread, WALTER (*Schweiz. Wehnschr. Chem. u. Pharm., 40 (1902), p. 75; abs. in Ztschr. Untersuch. Nahr. u. Genussmit., 5 (1902), No. 14, p. 667*).—The author's analyses confirmed the estimate of 40 per cent as the maximum water content of Swiss bread.

Concerning a new bread rich in cellulose, R. BARANY (*Wiener Med. Wehnschr., 52 (1902), p. 411; abs. in Ztschr. Untersuch. Nahr. u. Genussmit., 5 (1902), No. 14, p. 668*).—Experiments are reported on the use of bread rich in cellulose as a remedial agent in constipation, corpulence, and diarrhea.

Chemical and sanitary studies of bread sold in Jurjew, J. F. MASING (*Inaug. Diss., Jurjew, 1901; abs. in Ztschr. Untersuch. Nahr. u. Genussmit., 5 (1902), No. 14, pp. 667, 668*).—Analytical data are reported.

Sandy bread, H. KREIS (*Ber. Kanton. Lab. Basel-Stadt, 1901, p. 8; abs. in Ztschr. Untersuch. Nahr. u. Genussmit., 5 (1902), No. 14, p. 667*).—The amount of sand in a sample of bread was estimated.

Hygienic studies of flour and bread. X, New studies on the acidity of bread, its cause, and methods of estimating it, K. B. LEHMANN (*Arch. Hyg., 44 (1902), No. 3, pp. 214-237*).—According to the author, that portion of the acid material of bread which is insoluble in ether is largely soluble in water. The water-soluble portion contains much phosphoric acid, probably potassium monophosphate.

The slight acidity of the bread, after extraction with ether and water, according to the author, may be referred to proteids present. Provided bread was cooled and covered, the acidity did not increase on standing. Methods of estimating the acidity of bread are discussed.

Concerning the differences in composition of low and high milling products, L. LINDET (*Jour. Pharm. et Chim.*, 6. ser., 14 (1901), pp. 433-437; *abs. in Ztschr. Untersuch. Nahr. u. Genussmtl.*, 5 (1902), No. 14, pp. 665, 666).—On the basis of the data reported, high milling is, according to the author, preferable to low milling.

Some methods of estimating the value of flour, P. G. IVANOV (*Inaug. Diss.*, St. Petersburg, 1901; *abs. in Ztschr. Untersuch. Nahr. u. Genussmtl.*, 5 (1902), No. 14, p. 666).—The comparative value of different methods of examining milling products was studied.

Banana flour (*Nouveaux Remèdes*, 17 (1901), p. 121; *Chem. Ztg.*, 25 (1901), *Repert.*, p. 116; *abs. in Ztschr. Untersuch. Nahr. u. Genussmtl.*, 5 (1902), No. 14, p. 667).—An analysis of flour made from Jamaica bananas is quoted.

Yams (*Ipomoea batatas*), L. BONNIN (*Bul. Assoc. Chim. Sucri. et Distill.*, 18 (1900), pp. 1028, 1029; *abs. in Ztschr. Untersuch. Nahr. u. Genussmtl.*, 5 (1902), No. 8, p. 368).—The chemical composition of yam flour, the vines, and residue from the manufacture of yam starch is reported. The vines are used as a feeding stuff for milch cows.

The legal regulations governing the sale of edible fungi in the Munich markets, K. GIESENHAGEN (*Ztschr. Untersuch. Nahr. u. Genussmtl.*, 5 (1902), No. 14, pp. 593-603).—Regulations governing the sale of edible fungi are discussed.

Estimating the value of fig coffee, O. VON CZADEK (*Ztschr. Landw. Versuchs. Oesterr.*, 5 (1902), No. 5, pp. 761-763).—Analytical data are reported and discussed.

Do the volatile bodies of tea and coffee affect the respiration of man? K. B. LEHMANN and G. ROHRER (*Arch. Hyg.*, 44 (1902), No. 3, pp. 203-213).—So far as could be observed in experiments which are reported in full, neither tea nor coffee distillate had any noticeable or lasting effect upon the rate of respiration.

Experiments on the effect of muscular work upon the digestibility of food and the metabolism of nitrogen, C. E. WAIT (*U. S. Dept. Agr., Office of Experiment Stations Bul.* 117, pp. 43).—Continuing earlier work (*E. S. R.*, 13, p. 72), a number of experiments on the effect of muscular work on the digestibility of a mixed ration and the metabolism of nitrogen are reported. Under the experimental conditions neither factor was influenced by the muscular work performed. The author also studied the possibility of determining the composition of a simple mixed diet from the analysis of composite samples of it, the results obtained being favorable to this method.

The physiological effects of route marching, N. ZUNTZ and SCHUMBURG (*Physiologie des Marsches*. Berlin: August Hirschwald, 1901, pp. XVI+VIII+361, pt. 1, figs. 46).—To study the physiological effects of marching, a large number of experiments were carried on with 5 military students over a course of 24.75 kilometers, the maximum load which they carried being 31 kg.

The effect of muscular exertion (motion of forward progression and in addition carrying a load) upon the action of the heart, upon the liver, the condition of the blood, the vital capacity of the lungs, the elimination of nitrogen by the skin and kidneys, and the metabolism of nitrogen was studied, as well as the respiratory quotient. It was found that the elimination of nitrogen by the skin and kidneys was not markedly increased by the marching. When an increase did occur it was most noticeable on the day following that in which the muscular work was performed. The average amount of nitrogen eliminated in the perspiration was found to be 0.284 gm. per liter, the amount of nitrogen diminishing as the amount of perspiration increased. Marching had little effect upon the composition of the feces and the digestibility of the food, which consisted of a simple mixed ration. In the tests in

which the respiratory changes were studied, 2 of the subjects marched on a sort of treadmill, which inclined upward slightly.

From a study of the results obtained the authors calculate that for motion of forward progression one of the subjects required 509.3 calories per kg. of body weight per 1,000 meters of the distance covered, and 7.5535 calories per kilogram-meter for the work of lifting the body. Similar values for the second subject were 527.14 calories and 7.487 calories. The conclusion was drawn that, generally speaking, the energy expended in walking is very nearly proportional to the mass moved forward; but under favorable circumstances, of which perhaps the most important is that the load carried be properly distributed, the body plus the load is moved with a smaller proportional expenditure of energy than the body without the load.

During marching the authors calculate that the energy expended would produce an amount of heat sufficient to raise the body temperature 1° in 8.7 minutes. Nevertheless, the temperature was raised only 1 to 1.5° C. after the heaviest marching, the extra heat being carried off largely by the increased elimination of water through the skin.

The authors believe that the observed changes in the respiratory quotient show that the carbohydrates in the body are quickly used up, leaving the fats as the energy-yielding material. Other observations are discussed at length in relation to the clothing and diet of soldiers and their physical health, etc. The book also contains a historical and critical review of earlier experiments on the general subject of marching considered as a form of muscular work.

The digestibility of foods in the stomach with special reference to hygiene, C. FERMI (*Arch. Anat. u. Physiol., Physiol. Abt., 1901, Sup., pp. 1-83; abs. in Ztschr. Untersuch. Nahr. u. Genussmittel, 5 (1902), No. 20, pp. 975, 976*).—The greater number of the author's experiments with foods were made with dogs and pigs, and a small number with man. Many deductions are drawn regarding the comparative digestibility of foods and related topics.

Heat of combustion and physiological nutritive value of foods. II, The nutritive value of meat extract, J. PRENTZEL and N. TORIYAMA (*Arch. Anat. u. Physiol., Physiol. Abt., 1901, pp. 499-512; abs. in Ztschr. Untersuch. Nahr. u. Genussmittel, 5 (1902), No. 20, p. 983*).—According to these authors, some two-thirds of the energy of albumin-free meat extract is available for the body.

Concerning the effect of sunlight upon the gaseous exchange in man, H. WOLPERT (*Arch. Hyg., 44 (1902), No. 4, pp. 322-338*).—A number of experiments are reported and discussed.

The harmfulness of boric acid as a food preservative, J. KISTER (*Ztschr. Hyg. u. Infektionskrank., 37 (1901), p. 225; abs. in Hyg. Rundschau, 12 (1902), No. 9, pp. 463, 464*).—Experiments with animals led to the conclusion that boric acid was harmful.

Review of the literature of foods for the year 1900, A. J. J. VANDEVELDE (*Repert. Geschr. Voedingsmiddel., 1900, pp. 140*).—A large number of titles of publications on the general subject of foods and food products are included in this volume, bibliographical data being accompanied in most cases by notes regarding the ground covered by the publications cited.

Review of articles on foods published during the year 1901, A. J. J. VANDEVELDE (*Repert. Geschr. Voedingsmiddel., 1901, pp. 165*).—This is the second annual volume reporting titles of articles on analytical methods, water, milk and cream, bread and flour, sugar, and related topics. In most cases the bibliographical data are accompanied by brief notes regarding the scope of the articles cited.

ANIMAL PRODUCTION.

Feeding value of different forage plants, R. DUMONT (*Prog. Agr. et Vit. (Éd. L'Est)*, 23 (1902), Nos. 19, pp. 553-557; 21, pp. 610-612; 22, pp. 637-642).—The comparative feeding value of natural meadows, annual leguminous plants, grasses, and less common forage plants and mixtures is discussed.

Feeding animals; brewers' grains and malt, F. WEBER (*Jour. Agric. [Paris]*, 13 (1902), No. 149, pp. 143-148).—The nutritive value of these feeding stuffs is discussed.

The utilization of the by-products of malting and brewing, A. VAN ROOST (*Rev. Gén. Agron. [Louvain]*, 11 (1902), Nos. 4, pp. 220-224; 5, pp. 249-253).—The utilization of by-products of malting and brewing as feeding stuffs and fertilizers is described.

Cakes from oil-bearing seeds, L. BUSSARD and G. FRON (*Ann. Sci. Agron.*, 1901, II, No. 1, pp. 117-160).—The authors describe the principal sorts of cakes from oil-bearing seeds, and methods of studying their value with the aid of the microscope, etc.

Sugar and muscular energy, L. GRANDEAU (*Jour. Agr. Prat.*, n. ser., 4 (1902), No. 32, pp. 174-176).—The value of sugar as a source of energy for muscular work is discussed, a number of experiments, especially those of Steinitzer, which were favorable to this use of sugar, being quoted.

Molasses in mixed feeds, H. VAN DE VENNE (*L'Ing. Agr. Gemblour*, 12 (1902), No. 9, pp. 437-448).—The composition of a number of molasses feeds is quoted, and their nutritive value discussed.

The feeding value of beet pulp, B. C. BUFFUM and C. J. GRIFFITH (*Colorado Sta. Bul.* 73, pp. 3-10).—On the basis of data recorded in station bulletins and Department of Agriculture publications, the authors discuss the feeding value of beet pulp with special reference to local conditions. The results obtained by some practical feeders are briefly noted.

The feeding of farm animals, H. J. PATTERSON (*Maryland Sta. Bul.* 84, pp. 155-193).—The principles of animal nutrition are discussed and tables are given which show the composition of digestibility of some common feeding stuffs. The author also discusses rations for different animals, the methods of computing rations, and related topics.

Animal breeding, T. SHAW (*New York and Chicago: Orange Judd Co.*, 1902, pp. XII + 406, pt. 1, figs. 7).—The author discusses the principles of animal breeding and related topics, the information being arranged so that the volume may be used as a text-book.

Session of Improved Live Stock Breeders' Association (*Missouri State Bd. Agr. Rpt.* 1902, pp. 339-372).—Papers presented at this association's meeting are included in this report.

The rearing of calves on milk substitutes, H. HAYWARD (*Pennsylvania Sta. Bul.* 60, pp. 12, pls. 2).—The results of feeding milk substitutes to 13 calves are reported. A number of other calves which were included in the test died, either before a successful substitute for milk had been found or from some cause not attributable to the experiment.

Various combinations of flour, flaxseed meal, linseed meal, sugar, glucose, coconut meal, dried blood, fenugreek, and fennel seed were tested in a preliminary way. According to the author, "all of the kinds of sugar tried seemed to have a bad effect upon the bowels, so much so that the attempt to use sugar in the ration was soon abandoned. Fenugreek and fennel seed did not seem to produce an effect that would warrant their use as part of the meal. Flaxseed meal, on account of its laxative properties, was not employed in the first successful combination adopted, but a small proportion of it was added in the second meal, used in the later part of the trials."

Two substitutes for milk were finally determined upon. The first was made up of 3 parts of wheat flour, 2.5 of cocoanut meal, 2 of Nutrium, 1 of linseed meal, and 0.2 of dried blood. One pound of this mixed meal was added to 6 lbs. of hot water, and after stirring a little was allowed to cool to 100° F., when it was fed from a pail or calf feeder, the latter method being regarded as preferable. The second mixture, which was regarded as somewhat inferior to the first, was made of 1.03 parts of corn meal, 2 of Nutrium, 0.15 of flaxseed, 0.2 of dried blood, 3 of flour, 0.6 of cocoanut meal, and 0.6 of sifted oat chop. For purposes of comparison 2 calves were fed in the usual way on skim milk. The length of the feeding period varied with the different calves. The gains made by each calf are reported.

The author states that the calves were fed on an average 7.6 lbs. of meal for 7.7 days. For 5 days they consumed on an average 5.4 lbs. of milk and 0.77 lb. of meal. For 83.4 days on an average they were fed meal mixture only, consuming on an average 2.17 lbs. each. In several cases a little milk was fed after the calves had been accustomed to the mixed-meal ration. According to the author—

"The calf meal is not as satisfactory a food as whole milk for very young calves, and it is quite likely that for the first few weeks upon this ration the calf does not have the vigor or power of resistance that it would have if fed upon its natural food. As a consequence, calves that are to be raised upon a milk substitute should have provided for them warm and dry quarters that will keep the animal comfortable at all times. This feature of raising calves can not be too strongly emphasized.

"From the results of these trials the following conclusions seem warranted: There is little difficulty in raising prime dairy calves without milk after they are 2 weeks old. The cost of raising calves on a milk substitute up to the time they can be put on a hay and grain ration, or when they are between 3 and 4 months of age, need not exceed \$10, exclusive of care. Calves from high-class, well-bred dairy stock when raised in this way are worth much more than they cost, and afford the only means by which a milk dairyman can raise his herd to a high standard of excellence."

In connection with the above experiments the composition of Nutrium was determined.

Baby beef, H. M. COTTRELL (*Kansas Sta. Bul. 113, pp. 39-49*).—The comparative value of alfalfa hay, prairie hay, corn, Kafir corn, and soy beans for the production of baby beef—that is, well-fattened young cattle—was tested. For this purpose 130 calves, which had just been weaned, were divided into 6 lots and fed for a period covering 7 months. The following table shows the results obtained:

Average results of feeding tests with young cattle.

Rations fed.	Average gain per animal in 7 months.	Grain eaten per pound of gain.	Hay eaten per pound of gain.
	<i>Pounds.</i>	<i>Pounds.</i>	<i>Pounds.</i>
Alfalfa hay and corn	407	4.70	5.44
Alfalfa hay and Kafir corn	379	5.24	6.26
Prairie hay with corn and soy beans, 2:1	378	5.20	4.86
Prairie hay with Kafir corn and soy beans, 2:1	342	5.94	5.39
Alfalfa hay and corn following skim milk	440	4.39	4.36
Alfalfa hay and corn following whole milk	404	4.70	4.20

Thirty-two of the animals were steers. These averaged 838 lbs. in weight at the conclusion of the trial, and sold for \$5.40 per hundred. Of the heifers, 74 averaged 758 lbs. in weight, and sold for \$5.35 per hundred, and 18 averaged 741 lbs. in weight, and sold for \$5.15 per hundred. The author notes that the amount of food required per pound of gain in fattening young animals is comparatively small; furthermore, that the heifer calves made practically as high returns as the steers.

"The calves used in this experiment were 'common bred' ones, and they made good gains. The farmer whose business was producing baby beef would use the best type of bull that he could secure—short-legged, thick-meated, blocky, and quick-maturing." He would select well-bred cows of strongly pronounced beef type that were good milkers. "With good breeding and good feeding an average weight of 1,000 lbs. may be secured at 12 to 14 months of age."

Results of a cattle-feeding test, W. J. KENNEDY and F. R. MARSHALL (*Iowa Sta. Bul. 66, pp. 223-255, figs. 10*).—This was a cooperative experiment conducted at the Brookmount Farms. Using 11 lots of 20 steers each, averaging 1,043 lbs. in weight, the authors studied the value of condimental stock feeds, corn by-products, cotton-seed meal, linseed meal, and dried blood when fed in addition to corn, and also the advisability of changing cattle on a full grain ration from dry food to pasture.

At the beginning of the test, which covered 92 days, all the lots were fed 15 lbs. per head daily of snapped corn (on the ear), with wheat straw in addition. As the test progressed shelled corn, corn-and-cob meal, and finally corn meal were substituted for the snapped corn. During the test, considered as a whole, snapped corn, shelled corn, corn-and-cob meal, corn meal, and wheat straw were fed to all the lots in about the proportion of 2:1:5:10:10. Lot 1 was fed the basal ration only. In addition to the basal ration, lots 2 to 6 were fed at the beginning of the trial 2 oz. per head daily of oil meal, cotton-seed meal, gluten meal, Buffalo gluten feed, and germ-oil meal, respectively; lot 7 was fed 0.1 lb. of dried blood; lots 8 to 10 were fed respectively 0.4 oz. of Iowa Stock Food, International Stock Food, and Standard Stock Food. Lot 11 was not fed any concentrated feed in addition to the basal ration, but after 6 weeks was allowed the run of a 21-acre timothy pasture. All the amounts fed were increased as the test progressed until the cattle were on full feed, which required about 5 weeks. After 42 days feeding the steers fed cotton-seed meal (lot 3) became suddenly sick. Three of the animals died and the rest becoming blind and refusing to eat were marketed and the test with this lot discontinued. A post-mortem examination of the steers which had died showed that the stomachs "were very much inflamed, being red and blue in color."

The test progressed regularly with the other lots, except that on account of accidents 1 steer was removed from lots 1, 4, and 5. The steers were sold in Chicago, the price received ranging from \$7 in the case of lot 10 (Standard Stock Food) to \$7.65 per 100 lbs. in the case of lot 4 (gluten meal). The following table summarizes the principal results obtained including those of the slaughter test:

Results of a steer-feeding test.

Rations fed.	Average daily gain per steer.	Cost of feed per pound of gain.	Average net profit per steer.	Shrinkage in shipping.	Proportion of dressed to live weight.	Shrinkage in cooling carcass.	Loose fat.	Weight of hide.	Value returned per bushel of corn.
	Lbs.	Cts.	\$	Lbs.	Per ct.	Per ct.	Per ct.	Lbs.	
Lot 1, corn (basal ration)	2.39	10.71	\$14.49	55	58.8	2.1	4.8	77.1	\$0.98
Lot 2, corn and oil meal	2.51	11.02	14.85	54	60.6	1.8	6.1	76.2	.95
Lot 4, corn and gluten meal	2.92	9.34	17.99	62	59.6	1.4	5.2	81.7	1.04
Lot 5, corn and Buffalo gluten feed	2.88	9.65	17.60	51	60.6	1.8	5.8	79.0	1.03
Lot 6, corn and germ oil meal	2.32	11.64	12.16	65	60.3	1.9	5.4	75.1	.885
Lot 7, corn and dried blood	2.42	11.08	15.36	68	59.5	1.9	6.1	77.1	.96
Lot 8, corn and Iowa Stock Food	2.30	10.51	13.09	60	59.6	1.8	5.6	74.9	.925
Lot 9, corn and International Stock Food	1.97	13.41	6.33	71	59.6	1.9	5.8	73.5	.72
Lot 10, corn and Standard Stock Food	2.17	11.95	5.52	68	58.7	1.9	5.0	74.7	.705
Lot 11, corn and pasturage	2.49	10.20	14.97	90	59.8	1.6	5.1	74.7	.705

At the beginning of the trial 20 pigs, averaging 142 lbs. each in weight, followed each lot of steers, receiving no feed in addition to what they could gather. The gains made were small and at the end of 8 weeks the number in each case was diminished to 10. The pigs were not in good condition for market at the close of the test and were marketed later. Omitting data for the cotton-seed meal lot (No. 3) the total amount gained by the 10 lots of pigs was 506, 465, 362, 427, 435, 540, 435, 525, 397, and 707 lbs., respectively. The small gain made by lot 3 is explained by the fact that the cotton-seed-meal steers, which they followed, were fed only a part of the test.

Analyses are reported of the feeding stuffs used in the tests. Definite conclusions are not drawn from this trial, as according to the authors further experiments are needed. It is purposed to continue this line of investigation.

Quality in beef, H. M. COTTRELL and V. M. SHOESMITH (*Kansas Sta. Bul. 111, pp. 24, pls. 15, fig. 1*).—Six steers were fed and slaughtered for the purpose of demonstrating to a class of students the effects of breeding, form, etc., on the quality of beef produced. Two of the steers were of the beef breeds, 2 dairy breeds, and 2 scrubs. During the whole test, which covered 205 days, the steers were fed corn, corn chop, and alfalfa hay. The Shorthorn and the 2 scrubs weighed about 1,050 lbs. each at the beginning of the test and the other steers on an average about 875 lbs. The average results of the test follow:

Average results of feeding steers of different types.

Type of steer.	Total gain.	Corn eaten per lb. of gain.	Alfalfa hay eaten per lb. of gain.	Per-centage of dressed beef.	Per-centage of tallow.	Per-centage of hide.	Cost of feed per lb. of gain.	Value of dressed carcass per lb.
	<i>Pounds.</i>	<i>Pounds.</i>	<i>Pounds.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Cents.</i>	<i>Cents.</i>
Shorthorn	395	9.78	5.46	63.5	5.0	6.0	3.75	8.50
Angus	288	11.38	5.04	62.6	4.2	6.9	3.75	7.50
Jersey	348	9.36	5.98	59.5	7.6	7.0	2.85	8.00
Holstein	411	8.16	5.08	59.6	4.5	6.7	3.25	7.75
Scrub, red	435	7.70	4.91	59.8	4.0	6.4	3.25	7.50
Scrub, spotted	306	10.43	6.92	59.7	5.2	6.1	3.25	7.00

The beef was cut up by the Kansas City method. The authors state that the beef-grade steers (the Shorthorn and Angus) furnished 27.8 per cent of the high-priced cuts, viz., loin and rib, the dairy grades (Jersey and Holstein) 27.5 per cent, and the scrubs 26.7 per cent. There was a loss to the slaughterers in every case unless the value of the offal was taken into account. In the opinion of those making the test the beef from all the steers was of good flavor, ranking in this respect about in the order of the prices at which the dressed carcasses were valued.

"This trial shows what every careful test has shown, that steers of the dairy breeds, properly fed, will make good beef—beef better than that usually found on the market but not of as high quality as that secured from well-bred special beef animals."

Fattening steers without hogs to follow, H. M. COTTRELL and J. G. HANEY (*Kansas Sta. Bul. 112, pp. 25-36, pls. 2*).—According to the authors pigs can not profitably be employed, owing to losses from hog cholera, to follow cattle and utilize the waste which attends the ordinary methods of feeding. A test covering 116 days was, therefore, undertaken to learn whether the steers would not utilize ground grain and cut hay more economically than ordinary feeding stuffs, 4 lots of 20 steers each, averaging 1,036 lbs. in weight, being used. Lots 1 and 2 were fed shelled corn and lots 3 and 4 corn meal, lots 1 and 3 receiving whole alfalfa hay and lots 2 and 4 alfalfa hay cut into inch lengths. The alfalfa hay was gradually substituted for prairie hay. After 11 weeks soy-bean meal was fed to all the steers for 26 days, as much as 4 lbs. per head daily being given during a part of the time. This feed caused excessive

scouring and was dropped. The average daily gains with steers was: Lot 1, 2.26 lbs.; lot 2, 2.21; lot 3, 2.35, and lot 4, 2.52 lbs. The grain eaten per lb. of gain was 7.89, 7.71, 7.56, and 6.8 lbs. respectively, and the hay, 4.09, 3.87, 4.01, and 3.45 lbs. respectively. During the period in which soy beans were fed the steers made an average daily gain of 1.16 lbs., 30.79 lbs. of grain and 0.87 lbs. of hay being required per pound of gain. The steers were sold and slaughtered, the dressed weight being on an average 59.3 per cent of the live weight. The yield of fat was 6.7 per cent. "The steers having corn meal made 8.8 per cent more gains and ate 7.95 per cent less grain and 6.28 per cent less hay than those fed whole corn." The calculated saving in grinding would range, according to the authors, from 1.59 cts. per bushel when corn is worth 20 cts. to 4.77 cts. when it is worth 60 cts. a bushel.

"The steers fed cut hay made 2.6 per cent more gains and ate 6.08 per cent less grain and 9.63 per cent less hay for each 100 lbs. of gain than those fed whole hay. This indicates that if the feeder has the machinery it will pay to cut the hay, but for a small lot of steers it will not pay to buy cutting machinery to be used only for cutting hay for the steers."

The authors believe that grinding grain and mixing it with cut hay is of benefit since the animals spend more time in chewing the feed, and that owing to this and its mechanical condition it is in a more favorable form for digestion. Scouring was not observed with this method of feeding.

"One of the writers of this bulletin has just inspected 270 head of year-old calves that were being forced for baby beef. These calves were eating 3 lbs. of cotton-seed meal each per day, in addition to a heavy ration of corn meal. The grain was thoroughly mixed with cut alfalfa hay when put in the feed boxes. Not a single calf was found that showed any signs of looseness, and the droppings were of the most desirable character. An inspection of 1,800 head of fattening steers that were being rapidly forced for 100 days' feeding showed the same condition of bowels—no scouring, and normal condition of the droppings. . . .

"Feeders on this high-priced land will have to do what manufacturers have already done—more thoroughly utilize the materials which they handle. With the old methods, a large portion of the corn was not digested by the steer, and this kept him in an unhealthful condition. The old methods gave 4.5 to 5.5 lbs. of gain from a bushel of corn. The best method used in this experiment gave more than 8 lbs. of gain per bushel of corn."

In discussing the substitution of alfalfa hay for other hay the authors have found that "when stock has not been accustomed to eating alfalfa hay, full feeding of it induces scours. We usually take 30 days to get either horses, steers, or dairy cows on full feed of alfalfa hay, and when this is done there is no trouble in feeding it. While getting stock on full feed of alfalfa, either prairie or timothy hay or straw may be fed."

Beef cattle, W. L. HUTCHINSON and E. R. LLOYD (*Mississippi Sta. Bul. 76, pp. 24, figs. 19*).—Data are given regarding the station herd, the cost of feed for cows and calves, the value of the calves fed, characteristics of the breeds of cattle kept, the value of the manure with especial reference to the cotton-seed products eaten, and related topics. The station herd has been kept on a pasture some 7 months of the year and fed during the winter, from 135 to 150 days principally on cotton-seed meal and hulls. The calves have been allowed to run with their dams and to have all the milk as soon as they could drink it. Provided the pasture is good "it is an easy matter to have the calves weigh over 500 lbs. when they are 12 months old." The average weight of 5 steer calves 1 year old was 589 lbs. and of 5 heifer calves 525 lbs.

To compare the influence of breeding upon profitable feeding 2 grade Angus calves and 2 native calves were given the same treatment until 2 years old. During the summers they were pastured, running with their dams the first year. They were finished on a mixture of cotton-seed meal and corn chop, supplemented by cotton-

seed hulls, no other coarse fodder being fed. They were sold for slaughtering at 4.75 cents per pound live weight. The average weight of the grade steers was 970 lbs. and of the native steers which were a little older 1,067 lbs. The percentage of the different cuts in both lots of steers is recorded. "The native steers dressed 60 per cent.; the grades, 60.4 per cent. The natives made as good gains as the grades and gave as large amounts of the choice cuts."

In a brief account of a test of the desirability of giving additional feed to calves running with their dams, the authors emphasize the fact that small animals require less feed for maintenance than large ones, and that young animals may be more profitably fed than those which are older and heavier. Four calves 7.5 to about 9 months old, weighing on an average 419 lbs., were fed during the winter. The feed consumed by the calves cost \$20.07, and that eaten by their dams \$36. The average daily gain of the calves was 1.73 lbs. Three calves with their dams, but given no feed in addition, made a daily gain of 1.54 lbs.

In discussing feeding under local conditions the authors state that the determinations of the relative value of feeds at the station "show that a ton of cottonseed will produce about one-sixth more beef than a ton of corn, and a ton of cotton-seed meal will produce twice as much. Cowpea hay and Johnson-grass hay are about equal in value. One and a half pounds of corn stover are about equal in value to 1 pound of cowpea hay. The cotton-seed hulls that we have been using this season are nearly equal in value to good Johnson-grass hay—12 lbs. of the hulls giving as good results as 10 lbs. of hay."

Regarding pasturage, oats sown in the early fall on cotton land where there was more or less Johnson grass furnished excellent pasturage the following summer for a limited number of cattle. Bermuda and white clover hay in the valley land and lespedeza on the upland have furnished the principal grazing. "Other grasses that have furnished some grazing are reedtop, orchard grass, large water grass, turf oats, and hairy vetch. . . ."

"Some of our young animals have gained as much as 400 lbs. during the grazing period, others have gained from 200 to 300 lbs. Our conditions have not been such as to enable us to determine the average gains that should be gotten during a pasture period, but it should not be less than 200 lbs. for each animal."

Fattening steers with different quantities of grain. R. S. SHAW (*Montana Sta. Bul. 35, pp. 15-19*).—To study the relative merits of light, medium, and heavy grain rations, supplemented by leguminous hay, 3 lots of steers were fed for 85 days, the experimental period being preceded by a preliminary period of 24 days and followed by a supplemental period of 14 days. During the latter period the object was simply to maintain the steers in weight until a favorable opportunity occurred for marketing. The preliminary period was necessary in order to get the steers on full feed after dehorning them. Lots 1 and 2 contained 7 animals each, and lot 3 contained 8. All the steers were fed clover hay and barley meal, consuming respectively 19.3, 19.4, and 19.8 lbs. per head daily of the former, and 5.0, 6.73, and 8.9 lbs. of the latter. At the beginning of the experiment proper the average weight of the steers in the 3 lots was 6,850, 7,240, and 9,080 lbs. The average daily gain per head was 2.33, 2.26, and 2.23 lbs., respectively, the feed eaten per pound of gain being 10.4, 11.5, and 12.9 lbs., and the cost of a pound of gain 4, 4.81, and 5.80 cts. The steers were sold at a net profit of \$7.66 per head. According to the authors this sum does not represent the total profit, as the value of the feed was estimated at local market prices which were much above its actual cost. The conclusions drawn follow:

"Because of the quality of Montana-grown food products and the favorable climatic conditions during the winter feeding period, maximum returns can be secured from a minimum amount of food. In fattening steers, when alfalfa and clover are used, not more than $\frac{1}{2}$ lb. of grain to the hundredweight of live weight is necessary to produce the most satisfactory results. Contrary to local impressions, some grain must be used throughout a period not less than 120 days in order to get a good finish."

Bullock feeding experiment (*Midland Agr. and Dairy Inst. [Kingston] Rpt. 1901, pp. 71-76*).—A test was made with 3 lots of 2 steers each of the relative merits of undecorticated cotton-seed cake and linseed cake, 1:1; ground decorticated cotton-seed cake and maize meal, 1:1:2, and undecorticated cotton-seed cake, in every case supplementing a ration of Swedish turnips, chaffed barley straw, and hay. For 15 days before the test proper began the grain ration of all the steers consisted of undecorticated cotton-seed cake. The test as a whole covered 124 days. The average gain per head in the 3 lots was 2.18, 2.1, and 1.73 lbs., respectively. Taking into account both the gains made and the profits per lot, the conclusion is reached that there is very little profit in feeding the steers and that the differences in gains made are not marked enough to warrant any deductions.

Cattle raising, H. WERNER (*Die Rinderzucht. Berlin: Paul Parey, 1902, 2. ed.; rev. in Jour. Landw., 50 (1902), No. 2, pp. 176, 177*).—It is stated that this well-known work has been thoroughly revised.

Polled cattle (*Kansas State Bd. Agr. Quart. Rpt. 1902, Sept. 30, pp. 189, figs. 37*).—This bulletin contains a number of statistical and descriptive articles by different authors on Aberdeen-Angus, Galloway, Red Polled, and Polled Durham cattle.

Study of the races, varieties, and crosses of French cattle, DE LAPPARENT (*Bul. Min. Agr. [France], 21 (1902), Nos. 1, pp. 177-243; 2, pp. 322-394*).—A descriptive and statistical article.

Comparative results from feeding lambs, 1-year wethers, 2-year wethers, and aged ewes, R. S. SHAW (*Montana Sta. Bul. 35, pp. 1-14, figs. 2*).—The relative profits obtained in feeding sheep of different ages under local conditions was tested with 4 lots, comprising, respectively, 55 lambs, 51 year-old wethers, 53 2-year-old wethers, and 53 old ewes. All the lots were fed 0.68 lb. unground barley per head daily in addition to clover hay, the amount eaten in the different lots being 2.05, 3.77, 4.05, and 2.33 lbs., respectively. The average weight of the animals in the 4 lots at the beginning of the test was 62.9, 94.9, 115.7, and 91.6 lbs., respectively. In the 88 days covered by the test the average gains per head were: Lambs, 23.7; yearling wethers, 23.5; 2-year-olds, 24.3, and old ewes, 15.6 lbs. The dry matter eaten per pound of gain was 10.16, 16.6, 17.1, and 17.5 lbs., and the average cost of a pound of gain in the 4 lots was 4.18, 5.83, 5.90, and 6.78 cts., respectively. All the lots were sold in Chicago, the lambs yielding a profit of \$1.73, the yearlings \$1.40, the 2-year-olds \$1.57, and the old ewes 1.8 cts. per head. During transportation the shrinkage in weight in the case of the ewes was 11.3 per cent and in the case of the other lots it was very nearly equal, averaging 8.6 per cent. According to the author—

“The feeding of lambs for market is more profitable than wethers or ewes, providing the ration is so adjusted as to give their rapid increase a finish. Owing to the growthy tendency of the lamb, its ration must possess more fat-producing material than the mature sheep. Where grain is not available, the mature wether, though making a smaller proportionate increase, will fatten more readily than the lamb on clover or alfalfa alone. The use of from $\frac{1}{2}$ to $\frac{3}{4}$ lb. of grain, along with clover or alfalfa, throughout a period of from 70 to 90 days, is necessary to produce a proper finish for shipping. . . .

“The suggestion, resulting from personal experience, is offered . . . that sheep will withstand shipping better if kept on a limited allowance during transit rather than on full feed; but that feed and rest are essential toward the close of trip. The total net profit from the car of sheep was \$251.29. Even though the cost of marketing is a large item, still this is offset by cheap feeders and an abundance of cheap food of good quality, which renders the feeding business a profitable industry.”

The results of a swine feeding experiment, W. J. KENNEDY and F. R. MARSHALL (*Iowa Sta. Bul. 65, pp. 209-222, figs. 5*).—This test was undertaken to learn the value of beef meal, tankage, and Standard Stock Food when fed to pigs in addition to corn meal. These animal feeding stuffs, which are slaughterhouse by-products, have been recommended on account of their high protein and ash content. The

authors report analyses of the feeding stuffs used, and discuss briefly the method of manufacturing tankage and beef meal. Briefly stated these products consist of meat scraps, fat trimmings, and scrap bones cooked by steam under pressure. After the fat is removed the resulting product is dried, pressed, and ground.

Five lots of 6 cross-bred pigs each were used in the test. Lot 1 was fed corn meal only, consuming when on full feed 10 lbs. per head daily. Lots 2, 3, and 4 were fed, respectively, Darling's Beef Meal, Swift's Digester Tankage, and Armour's Tankage in addition to corn meal, consuming when on full feed 1.67 lbs. of the special feed and 8.67 lbs. of corn meal per head daily. Lot 5 was fed Standard Stock Food in addition to corn meal, consuming when on full feed 0.333 lb. of the former and 10 lbs. of the latter per head daily. At the close of the test the pigs were sold in Chicago for \$7.55 per 100 lbs. The following table shows the principal results obtained:

Average results of feeding various animal feeds to pigs in addition to corn.

Feeding stuffs.	Average weight at the beginning.	Average daily gain per pig.	Cost of feed per pound of gain.	Shrinkage in shipping.	Net profit per pig.	Returns for 1 bu. of corn.
	<i>Pounds.</i>	<i>Pounds.</i>	<i>Cents.</i>	<i>Pounds.</i>		<i>Cents.</i>
Lot 1, corn	197	2.08	5.1	10.67	\$2.39	83.0
Lot 2, corn and Darling's Beef Meal	197	2.40	4.8	13.33	2.93	93.0
Lot 3, corn and Swift's Digester Tankage	202	2.57	4.5	13.83	3.22	97.5
Lot 4, corn and Armour's Tankage	198	2.27	4.9	13.67	2.57	88.0
Lot 5, corn and Standard Stock Food	197	2.23	5.0	10.50	2.61	84.0

According to the authors, in the fattening of young pigs, a ration containing more protein and ash than a corn ration gave better results than a ration of corn only. Attention is called to the fact that this conclusion is based upon but one test and may be modified by future experiments.

Pork production experiments and hog ranching, R. L. BENNETT (*Arkansas Sta. Bul.* 73, pp. 45-57).—A reprint from publications previously noted (*E. S. R.*, 8, p. 816; 10, p. 1085).

Experiments with sugar as a feeding stuff, ALEKAN (*Ann. Sci. Agron.*, 1901, II, No. 1, pp. 38-48).—In a paper presented at the International Congress of Agricultural Experiment Stations, June, 1900, the author briefly reports the results of experiments in which sugar formed part of the ration of horses. Rations containing sugar were regarded as especially satisfactory.

The history of horseshoeing, E. AUREGGIO (*Ann. Soc. Agr. Sci. et Ind. Lyon*, 7. ser., 8 (1900), pp. 65-87, figs. 34).—A discussion based on the exhibit at the Paris Exposition in 1900.

Cooperative experiments on the cost of egg production, H. H. WING (*New York Cornell Sta. Bul.* 204, pp. 23-67).—The station cooperated with a number of practical poultry feeders to secure information regarding the winter production of eggs and the number of eggs produced per fowl under different systems of feeding, care, and management. The flocks included ranged from 25 to 600 fowls, exclusive of males. A summary of the tests follows:

In the 17 weeks from December 1 to March 29 in 12 flocks, representing 8 owners and 2,100 fowls, the average daily production of eggs was 23.2 per 100 fowls. During the same time the average food cost of 1 doz. eggs was 16.3 cts. The flocks that laid most eggs during December and January laid most eggs also in March.

The egg production of pullets (hatched in 1901) was notably in excess of that of hens, particularly in the earlier periods, when the price of eggs was highest. The average cost of feeding 100 hens for the 17 weeks was \$32.43. The average excess of production over cost of food for 17 weeks was \$23.93 per 100 fowls.

Two hundred eggs a year per hen; how to get them, E. L. WARREN (*Wolfeboro, N. H.; Author, 1902, pp. 80, figs. 7*).—A general discussion of egg production and poultry raising for profit.

The iron content of hens' eggs, C. HARTUNG (*Ztschr. Biol., 43 (1902), No. 2, pp. 195-212*).—Feeding experiments reported in detail led to the conclusion that it was not possible to materially increase the iron content of eggs by supplying a diet rich in iron.

The production of oxygen in hens' eggs, K. A. HASSELBALCH (*Skand. Arch. Physiol., 13 (1902), No. 1-2, pp. 170-192*).—Respiration experiments with fertile and infertile eggs are reported.

DAIRY FARMING—DAIRYING.

Some feeding experiments with cows, H. J. PATTERSON (*Maryland Sta. Bul. 84, pp. 121-154*).—Four series of experiments conducted at the station from 1896 to 1901 are reported in detail, and a paper upon the production of protein feeds upon the farm, including a number of rations for dairy cows, is appended.

Comparison of an exclusive corn meal ration with a balanced ration of mixed grains (pp. 121-126).—Corn meal and a mixture of corn meal, wheat bran, and gluten meal (5:3:2) fed in equal quantities were compared with 6 cows. For the most part the rations were fed alternately by lactation periods. The results in all cases were considered in favor of the mixed grain ration, not only as regards production and profit, but in some instances as regards the health of the cow.

Mixed grain rations of different degrees of richness in protein (pp. 126-135).—Fourteen cows which had received uniform treatment for some time were divided into 2 equal lots and fed experimentally for about one year, during which time the nutritive ratio for one lot was gradually increased to 1:7.9 and that for the other lot was decreased to 1:5.2. The results, which are given in full in tabular form, seem to indicate that under Maryland conditions a ration having a nutritive ratio between 1:6.9 and 1:7.9 is the most economical for milk production. The subject is to be investigated further in connection with the study of the different sources of protein.

The new corn product as roughage for cows (pp. 136-142).—Six cows were fed soiling corn for 2 weeks and the new corn product for the 2 weeks following. During the second period the total yield of milk was increased 28 lbs. and the yield of butter 17.2 lbs., the amount of grain consumed, however, being 29 lbs. greater. The new corn product was also compared with mixed hay and shredded corn fodder in an experiment lasting 4 months in which 6 cows remained for the whole period. The new corn product was fed during the first and third months of the experiment, hay during the second month, and corn fodder during the fourth month, the results showing a maximum yield of butter with a minimum consumption of grain feed when the new corn product was used. The yield of milk, however, was not so large as on mixed hay.

Test of sugar feed ration (pp. 142-146).—A test was made of a proprietary feeding stuff reported as made up of ground fodder, grain, and beet molasses, and showing the following composition: Water 11.80, protein 16.97, fat 1.87, nitrogen-free extract 51.25, crude fiber 12.34, and ash 5.77 per cent. Seven cows were used in the test, 4 being fed exclusively on the sugar feed for 16 days, and 3 on a grain and grass ration. The rations were then reversed and the feeding continued for a second period. The sugar feed was not eaten very readily by some of the cows. Those that did, however, showed an increase in the yield of milk in changing to this ration and a decrease when it was discontinued, indicating, according to the author, that this feed has considerable value as a food for cows and is capable of serving as a complete ration.

Experiments on the feeding of dairy cows, L. GRANDEAU (*Jour. Agr. Prat., n.*

ser., 4 (1902), No. 45, pp. 632-635).—Experiments conducted by L. Nicolas are reported and discussed. Two rations were compared with 2 lots of 10 cows each, the experiment lasting 2 months. Ration 1 was composed of beets, oil cakes, bran, hay, and oat straw; contained 1.030 kg. of protein, 6.222 of carbohydrates, and 0.361 of fat; and had a nutritive ratio of 1:8.57. Ration 2 was composed of molasses, bran and middlings, beets, chaff, and oat straw; contained 0.592 kg. of protein, 5.139 of carbohydrates, and 0.158 of fat; and had a nutritive ratio of 1:11.89. A record was kept of the live weight of the cows, the yield of milk, and the fat content of the milk during every tenth day of the experiment. The results showed a diminution in live weight and in milk production on the molasses ration as compared with the ordinary ration. The author, however, attributes the results not to the molasses, but to its substitution in too small quantities for concentrated feeds.

Feeding beet pulp and sugar beets to cows, B. C. BUFFUM and C. J. GRIFFITH (*Colorado Sta. Bul.* 73, pp. 11-24).—A ration containing 24 lbs. of beet pulp was compared with one containing 12 lbs. of sugar beets. The rations in other respects were alike and had the same nutritive ratio. The experiment included 4 cows for 11 weeks, 1 cow for 4 weeks, and 5 cows for 3 weeks. Detailed data are presented in tables, and notes are given on the different cows. The results for the 5 cows longest in the experiment showed an average weekly gain in live weight of 6.2 lbs. and an average weekly yield of 131.1 lbs. of milk and 6.76 lbs. of butter when fed pulp, and an average weekly gain in live weight of 0.2 lb. and an average weekly yield of 127.4 lbs. of milk and 6.90 lbs. of butter when fed beets. The profit from feeding pulp at \$1 per ton was over 3 times as much as the profit from feeding beets at \$4 per ton. With butter at 20 cts. per pound the feeding value of pulp is estimated at \$2.61 per ton and that of beets at \$5.06 per ton.

Demonstration experiments on the feeding of dairy cows conducted at the expense and under the supervision of the government during the winter of 1901-2 (*Bul. Agr. [Brussels]*, 18 (1902), No 6, pp. 880-972).—Detailed data are given for a large number of feeding experiments carried out in the different provinces of Belgium, with a view to improving the rations in ordinary use. In each instance the ordinary and modified rations and the yield of milk and butter and other data are given, together with comments and conclusions.

Influence of kola feeding stuff upon milch cows, O. HAGEMANN, J. HUTH, and E. H. STEIN (*Landw. Jahrb.*, 31 (1902), No. 4, pp. 519-527).—The influence of this feeding stuff upon milk secretion was tested with one cow during 2 periods of 1 month each and the digestibility of the material was determined. A slightly favorable action upon milk secretion was considered as shown by the results.

Milking sheds, R. CROWE (*Jour. Dept. Agr. Victoria*, 1 (1902), No. 6, pp. 574, 575, pls. 5).—An illustrated description of the type of milking sheds extensively used in Victoria.

Investigations on the micro-organisms in the air of stables, in freshly drawn milk, and in the mammary gland, C. BARTHEL (*Rev. Gén. Lait*, 1 (1902), Nos. 22, pp. 505-516; 23, pp. 529-542).—The investigations here reported were made at different times from 1899 to 1902, and included determinations of the number of micro-organisms and studies of the different kinds. Cultures made from the udders of 14 cows showed the presence of micro-organisms in every instance. As, however, control cultures from other tissues gave similar results and as the experiments were not carried on under entirely favorable aseptic conditions, the author was unable to decide whether or not micro-organisms are normally present in the healthy udder. The work was directed mainly toward determining the species present. The general conclusion is drawn that the micro-organisms found in the air of stables, in freshly drawn milk, and in the udder of the cow are only the species commonly found in the air and have in general no action on milk, and that they are therefore very probably without practical interest in dairying.

A new micrococcus isolated from straw, causing ropy milk, J. HOHL (*Rev. Gén. Lait*, 1 (1902), No. 22, pp. 516-522).—The author reports a study of the biology of a micrococcus to which the name *Karphococcus pituitoparus* is given. The organism was isolated from the interior of a bale of straw from France, and was capable of causing ropiness in both sterilized and unsterilized milk.

Creaming of milk during its sale, W. FREAR and M. H. PINGREE (*Jour. Amer. Chem. Soc.*, 24 (1902), No. 11, pp. 1136-1138).—A deep can containing 2 gal. of milk was set in cold water and pint samples of milk were taken by means of a dipper at irregular intervals during a period of about 8 hours and examined for fat content and specific gravity. Seven samples were thus examined. "The results show very clearly that customers buying the second to sixth portions of milk, inclusive, would receive much more than their share of the fat, and the last comers a greatly impoverished milk, when the conditions of sale resemble those of this experiment."

The ripening of cream, M. HENSEVAL (*Rev. Gén. Lait*, 2 (1902), No. 1, pp. 1-8).—Methods are described, practical suggestions are given, and the advantages of pasteurizing cream and ripening with pure cultures are pointed out.

Chemical analyses and physical constants of milk, M. G. QUESNEVILLE (*Abs. in Rev. Gén. Lait*, 2 (1902), No. 2, pp. 34-37).

The specific gravity and water content of milk serum, J. NISIUS (*Milch Ztg.*, 31 (1902), No. 27, pp. 417-419).—Formulas are given for these calculations.

Action of lactic acid solutions upon copper, with especial reference to the manufacture of sour-milk cheese, M. SIEGFELD (*Milch Ztg.*, 31 (1902), No. 26, pp. 401-403).—Determinations were made of the copper and tin dissolved by a 1 per cent solution of lactic acid and by whey having practically the same acidity. In 24 hours the whey, at 35 to 40° C., dissolved 2.7 mg. from a copper plate having a surface of about 100 square centimeters. The author discusses the poisonous properties of copper, and concludes from the results of his experiments that there need be no fear of poisoning from the use of copper kettles in the manufacture of sour-milk cheese.

Concerning the heating of milk with special reference to dairies, A. TJADEN, F. KOSKE, and M. HERTEL (*Arb. K. Gesundheitsamte*, 18 (1901), No. 2, pp. 219-254, pls. 3, figs. 19).—Extended laboratory experiments are here reported, and a bibliography is appended. It was found that the momentary heating of milk to 98° C. was not always sufficient to kill the tubercle bacillus. The quality of the milk, however, was considered as having considerable influence in the experiments. With the new forms of apparatus for heating milk, and under dairy conditions, it is considered that continuous heating to 90° is sufficient to render disease-producing germs harmless, and that with a rapid heating of the milk to that temperature under thorough agitation, followed by prompt cooling to a low temperature, the chemical and physical properties of the milk undergo practically no change.

Bitter milk and cheese, F. C. HARRISON (*Rev. Gén. Lait*, 1 (1902), Nos. 20, pp. 457-469; 21, pp. 485-499).—During the latter part of 1901 the author investigated the cause of a bitter flavor in milk and cheese, the trouble being met with in cheese factories in Ontario. A yeast was isolated from samples of bitter curd which was capable of producing a bitter flavor when added to sterile milk. From milk inoculated with this yeast bitter cheese was made in a number of experiments. The yeast, to which the name *Torula amara* is given, was found in the milk from nearly every farm supplying one of the cheese factories. A study of the biology of the yeast is reported in detail, and the literature relating to the subject is reviewed, a bibliography being appended. The yeast was not found in milk drawn into sterile dishes nor in the air of the stables but was found regularly in mixed milk, cheese, whey, and can washings. It was also found on the leaves of certain species of maple. The yeast was not destroyed in cans by washing with water at about 200°F., according to the usual

farm practice. It grew well in whey in the presence of 1 per cent of acid, and acted energetically on lactose. Butter made from cream which had been sterilized or pasteurized and inoculated with the yeast was very inferior in quality, having, in the case of pasteurized cream, a pronounced bitter, disagreeable taste. The results of a bacteriological examination of the air of the stables, the first milk, the mixed milk, and the washings of milk cans at 96 dairies are presented in tabular form.

Curing of Cheddar cheese with especial reference to cold curing, S. M. BABCOCK and H. L. RUSSELL (*Wisconsin Sta. Bul. 94, pp. 44, figs. 10*).—Changes occurring in cheese during ripening and theories regarding the cause of these changes are briefly stated; various methods of curing which have been employed in this country are described, special attention being given to methods involving the control of temperature, such as the use of subearth ducts; 5 series of experiments in curing cheese at low temperatures are reported; and the advisability of cooperative curing rooms is discussed.

An account of the greater part of the experimental work reported in this bulletin was given in the last report of the station (E. S. R., 13, p. 988). Additional data, however, are given on series 3 and 4 of the experiments not previously completed, and a fifth series, in which cheeses were made with 6 and 9 oz. of rennet per 1,000 lbs. of milk and cured at temperatures of 33, 40, and 60° F., is reported. The results of the experiments are discussed at greater length than in the previous article, the advantages and disadvantages of cold curing being considered from a commercial standpoint.

The authors consider that the cheese cured at temperatures of from 33 to 50° was superior in flavor, commercial value, keeping qualities, and in other respects, to the cheese cured at 60°, and that the losses due to mold and shrinkage were much less.

"While the cold-cured cheese is exceptionally mild in flavor, even when a year or more old, it is possible to subsequently develop almost any degree of flavor desired by exposing the cheese to higher temperatures (60° F.) for varying periods of time after they have been thoroughly broken down under cold curing conditions. The danger of developing abnormal or undesirable flavors is much less in this subsequent treatment than it is where the green cheese is held for a period at high temperatures.

"In cold-cured cheese it is permissible to use much larger amounts of rennet than can be safely used in cheese cured at 60° F. or above. This increase in rennet hastens the course of the ripening and has a tendency to make the cheese more open in body, but even with two or three times the normal amount of rennet the flavor of cold-cured cheese is still clean and mild and the texture smooth and silky. . . .

"[Cold curing of cheese] can not well be applied to the handling of the product of a single factory as it entails the use of refrigeration (natural or mechanical) to secure the desired temperatures. If, however, cooperative effort is secured between a number of contiguous factories, or a system of factories under syndicate control, the cost of constructing a properly insulated and equipped cold-curing station will be no more than must be expended in building proper curing rooms in a dozen to twenty factories. Where a consolidated curing station is erected, the making factories may be of simplest construction and do not need any provision for curing the cheese, as the product should be shipped every few days to the central curing station. There are numerous other evident advantages that will accrue from this method of handling cheese, all of which will tend to lower the cost of the product, such as the lessened expenses of buying, of transportation, etc., while at the same time the product is of better quality, more uniform, and of much better keeping quality."

VETERINARY SCIENCE AND PRACTICE.

The practice of veterinary surgery. I, Operative technique, J. A. W. DOLLAR (*New York: Wm. R. Jenkins, 1902, pp. 269, figs. 272*).—The present volume is the first of a series of 3. intended to cover the whole field of veterinary surgery. The subjects treated in this volume are those which relate to operative technique, and special mention may be made of the following: General discussion of operations; means of throwing and securing animals for operations; anaesthesia; antiseptics; division of tissues; the use of setons; cauterization; methods of uniting wounds; scarification; transfusion; methods of preventing hemorrhage; injection of medicine into the blood, subcutaneous tissue, trachea, œsophagus, larynx, and parenchyma of organs; bandaging and dressing; massage and castration. The volume is based on the author's personal experience and on modern operative technique, especially as developed by the leading German and Italian veterinarians.

Operative veterinary surgery, G. FLEMING (*New York: Wm. R. Jenkins, 1902, Vol. II, pp. XXVII + 431, figs. 345*).—In this part of the author's work on operative veterinary surgery especial attention is given to a discussion of methods of securing animals for operation; the employment of anaesthetics, elementary operative veterinary surgery, general operations, operations on the digestive apparatus, abdominal, respiratory apparatus, thoracic cavity, larynx, trachea, urinary apparatus, generative apparatus, eye, ear, and foot.

Animal castration, A. LIAUTARD (*New York: Wm. R. Jenkins, 1902, 9. ed., pp. 165, figs. 45*).—In this edition of the author's handbook on castration of domesticated animals the results of recent veterinary practice and experimentation along these lines has been thoroughly incorporated. The volume, as before, contains a detailed discussion of the castration of Cryptochids by the various methods which have been devised, methods of castrating the various species of domesticated mammals and birds of both sexes, and the complications which may follow upon these operations.

American horse, cattle, and sheep doctor, R. McCURE (*Chicago and New York: The Henneberry Co., 1901, pp. 413, figs. 43*).—This volume contains a brief discussion of the diseases of horses, cattle, and sheep. The diseases are arranged alphabetically under the head of these different animals. The various medicines which are in use in veterinary practice are also arranged in an alphabetical manner, and brief notes are given on the properties and use of these methods. A number of formulas are given for preparing remedies for specific purposes, and a brief statement is presented of the comparative doses of medicine for different animals.

The veterinary compendium, W. E. VAN AME (*Ft. Wayne, Ind.: The Live Stock Proprietary Remedy Co., 1902, pp. 160*).—Brief popular descriptions of the common diseases of the various domesticated animals.

A manual of bacteriology, clinical and applied, R. T. HEWLETT (*Philadelphia: P. Blackiston's Son & Co., 1902, 2. ed., pp. 523, pls. 20, figs. 64*).—In this new edition of the office work on bacteriology, several sections have been rewritten and an attempt has been made to bring the whole subject matter up to date as nearly as possible. Special attention is given to a discussion of those portions of bacteriology which are of particular interest in medicine and hygiene. As a rule, diseases which are strictly confined to the lower animals are not discussed. The following subjects may be mentioned among those which are treated in the volume: Nature, structure, and functions of bacteria; methods of cultivating bacteria; preparation of tissues; methods of studying bacterial diseases; antisera and antitoxins; anthrax; acid-fast bacteria, including the organisms of tuberculosis, glanders, etc.; tetanus; malignant edema; blackleg; pathogenic protozoa; antiseptics and disinfectants; and various other diseases which are confined to man.

Cellular toxins or the chemical factors in the causation of disease. V. C. VAUGHAN and F. G. NOVY (*Philadelphia and New York: Lea Brothers & Co., 1902, 4. ed., pp. 495, pl. 1, figs. 2*).—The present volume in its enlarged and revised form contains an elaborate review of the factors which are concerned in the production of diseases and a critical discussion of the experimental work which has led to the formulation of modern theories of disease. Special mention may be made of the following subjects which are treated in the volume: A general account of the etiology of bacterial diseases; the classification and definition of chemical products of bacteria, including ptomaines, bacterial proteids, bacterial cellular proteids, and toxins; a historical sketch of bacterial poisons; detailed discussions of the bacterial poisons of various infectious diseases, including anthrax, Asiatic cholera, tetanus, diphtheria, tuberculosis, hog cholera, rabbit septicemia, malignant edema, glanders, etc.; germicidal properties of blood serum, including alexins and nucleins, specific precipitins, lysins, and agglutinins; the theories of immunity; and the chemistry and physiological action of ptomaines and leucomaines.

Protargol in veterinary surgery. W. E. A. WYMAN (*Jour. Comp. Med. and Vet. Arch., 23 (1902), No. 5, pp. 269-273*).—This remedy has been extensively used by the author with good results in the treatment of a number of diseases, including glossitis, osteomyelitis, poll evil, fistula, mastitis, and wounds.

Lysol in agriculture (*El lisol en agricultura. Barcelona: Mora & Co. [1900], pp. 64, figs. 39*).—In this pamphlet a general account is given of the methods of applying lysol as an antiseptic remedy in the treatment of animal diseases, and in the treatment of various insect pests of field crops, fruits, and garden vegetables.

Intravenous injections of corrosive sublimate in the treatment of infectious diseases. A. DEGIVE (*Ann. Med. Vet., 51 (1902), No. 1, pp. 25-33, figs. 4*).—A brief review is given of the literature relating to experiments in making intravenous injections of corrosive sublimate in the treatment of foot-and-mouth disease, swine erysipelas, contagious coryza, glanders, septicemia, anthrax, erysipelas, and syphilis. The author believes that experiments thus far conducted with this substance indicate that it exercises an active therapeutic effect in infection by a number of contagious diseases.

The disinfection of stalls and railroad stock cars by means of glycoformal with Lingner's disinfection apparatus. RÜDER (*Berlin. Thierärztl. Wchnschr., 1901, Nos. 51, pp. 777-781; 52, pp. 789-794, figs. 3*).—A critical discussion of the literature on this subject is given in connection with a bibliography. Lingner's disinfection apparatus consists of a circular copper kettle containing $1\frac{1}{2}$ liters of hot water, the water being maintained at the boiling point by an alcohol flame underneath. In an iron receptacle, which is placed inside of the ring-shaped kettle containing the hot water, 2 kg. of glycoformal is poured. The fumes of this substance are driven off by means of heat. The author's experiments were made on the bacilli of anthrax and glanders and on the virus of the foot-and-mouth disease, as well as on fowl cholera. As a result of the author's extensive experiments it is concluded that disinfection of stalls and railroad cars by means of glycoformal with the use of Lingner's apparatus is exceedingly effective, easily practiced, safe, and not expensive. The stalls and cars need not be out of use more than 5 or 6 hours, since in this length of time the pathogenic organisms are certainly destroyed, and the stalls or cars may be readily prepared for receiving animals after being ventilated.

State and Territorial laws relating to contagious and infectious diseases of animals, 1901 (*U. S. Dept. Agr., Bureau of Animal Industry Bul. 43, p. 72*).—This bulletin contains copies of the various State and Territorial laws relating to infectious diseases of animals which were enacted during the year 1901. The various laws are arranged alphabetically under the names of the respective States and Territories.

Report on the veterinary service in the Kingdom of Saxony for the year 1901 (*Ber. Veterinärw. Königr. Sachsen, 46 (1901), p. 253*).—This annual report contains an account of the personnel of the veterinary commission of Saxony, together with short reports from a large number of district veterinarians, notes on inspection of animals before and after slaughter, and governmental insurance of food animals. A description is also given of the curriculum and work done at the Veterinary High School of Saxony. The reports of the various district veterinarians are summarized by Siedamgrotzky. Indemnities were paid for losses from glanders, anthrax, blackleg, foot-and-mouth disease, and cerebro-spinal meningitis. Special notes are given on the prevalence of anthrax, blackleg, rabies, glanders, foot-and-mouth disease, pneumonia, mange of horses, sheep scab, swine erysipelas, swine plague, fowl cholera, and tuberculosis. Many of the cases of these various diseases presented peculiar symptoms of post-mortem conditions, and these peculiarities are especially mentioned in the report. Notes are also given on the use of potassium iodid in treating milk fever, silver preparations in treating petechial fever of horses, and various other drugs in the treatment of different diseases.

Annual reports of proceedings under the diseases of animals acts, the markets and fairs (weighing of cattle) acts, etc., for the year 1901, A. C. COPE and J. T. TENNANT (*London: Bd. Agr., 1902, pp. 82, pls. 4*).—An extensive outbreak of hog cholera occurred in different parts of England during the year 1901. The number of cases definitely identified by the Board of Agriculture was 3,140. Many theories were held by different stock owners as to the etiology of this outbreak. It was suspected that foreign feeding stuffs or the swill from hotels had produced the disease in certain instances. These hypotheses, however, were shown to be unfounded. The hog cholera was thought by some to be the same as typhoid fever in man, but inoculation experiments showed definitely that such was not the case. An extensive outbreak of foot-and-mouth disease occurred in 1900, but was finally eradicated in April, 1901. The most stringent measures were taken, including the slaughter and destruction of all affected animals and strict isolation of animals which had been exposed. It is believed, therefore, that this disease can be controlled by vigorous sanitary measures.

It is stated that the general condition of horses imported from the United States and elsewhere during the year was very good. Cases of glanders and other dangerous infectious diseases among imported horses were exceedingly rare. Glanders is on the increase among horses in England. The number of infected stables is increasing with considerable rapidity and the authors believe that the law relating to glanders will require some alteration before it will be possible to check or eradicate this disease.

Rabies, although practically exterminated in England, is occasionally detected. Large numbers of supposed cases are reported to the Board of Agriculture, but nearly all of them prove to be cases of some other disease. One case of rabies was discovered in a cow, and it appears from this fact that rabies must exist in one or more dogs in the locality where the cow was found. Details are given on the treatment and sanitary measures adopted in outbreaks of foot-and-mouth disease, hog cholera, rabies, anthrax, and sheep scab. The prevalence of sheep scab is gradually becoming less and the area of distribution is being restricted.

Human and bovine tuberculosis, R. KOCH and J. W. SCHÜTZ (*Arch. Wiss. u. Prakt. Thierh., 28 (1902), No. 1-2, pp. 167-196*).—This article is a report made by the authors to the Minister for Agriculture, Public Domains, and Forests on July 1, 1901. A detailed account is given of numerous experiments conducted for the purpose of comparing the virulence of human and bovine tubercle bacilli for calves, sheep, and pigs. The introduction of the tubercle bacilli into the experimental animals was effected in 5 ways—by feeding, subcutaneous injection, intra-abdominal

injection, intravenous injection, and by inhalation. The results of the experiments on calves showed that cattle were not susceptible to the bacillus of human tuberculosis, while the bacillus of bovine tuberculosis possessed a very great virulence for these animals. It is recommended that for a quick determination of the origin of tubercle bacilli a hypodermic injection be made in calves. After such injection infection takes place rapidly if the tubercle bacilli are of bovine origin, while such infection does not occur if bacilli of human origin are used. The results obtained from experiments on sheep and hogs were similar. Experiments in feeding and subcutaneous, intraperitoneal, and intravenous injections of tubercle bacilli of human origin showed that the hog is not susceptible to these organisms, while the bacilli of bovine origin were exceedingly virulent for hogs. Similar results were obtained on sheep. The tubercle bacilli of human origin in many instances retained their virulence for a long time at the point of inoculation, but did not show a tendency to distribute themselves from this point and produce a general infection in the inoculated animal.

The comparative virulence for animals of tubercle bacilli of bovine and human origin. A. DE JONG (*Ann. Med. Vet.*, 51 (1902), Nos. 4, pp. 181-190; 5, pp. 251-259).—The experiments, the results of which are published in this paper, are said to have been made previous to Koch's address at the British Congress. In general the results obtained by the author are contradictory to those of Koch. In making inoculations with tubercle bacilli, the intravenous method was usually chosen, since that is considered the most rapid and certain method of producing an infection. The author's conclusions may be stated as follows: The tubercle bacilli of human origin are capable of producing tuberculosis in cattle and also in other domesticated animals, such as sheep, goats, dogs, etc. Tuberculous infection produced in animals by tubercle bacilli of human origin is usually less serious than that produced by bacilli of bovine origin. It is admitted, therefore, that the bacilli of bovine origin are more virulent than those of human origin. The author believes that man must be considered as a factor of as much importance in the tuberculous infection of cattle as are cattle in infection of man by tuberculosis. It is urged, therefore, that the tuberculosis of cattle deserves more attention from the standpoint of human sanitation than has previously been accorded it.

A discussion of the relation between human and bovine tuberculosis, with special reference to primary infection in children through the alimentary tract. A. D. BLACKADER (*Boston Med. and Surg. Jour.*, 145 (1901), pp. 665-671).—A review is given of the work on tuberculosis which laid the foundation for the general belief that the milk and meat of tuberculous animals are dangerous to man. The author presents evidence for the belief that a species of bacterial organism like the tubercle bacillus may gradually undergo changes in morphology and virulence by a continued sojourn in the body of a different species from that in which it originated. He states that "much clinical and bacteriological work still remains to be accomplished before the latest statement of Koch can be either accepted or contradicted."

Preliminary communication of experiments upon the feeding and inoculating of calves with human tuberculous material. W. H. PARK (*Proc. New York Path. Soc.*, n. ser., 1 (1901), No. 5-6, p. 11).—Four calves weighing 150 lbs. were tested with tuberculin and found to be free from tuberculosis. The calves were then fed tuberculous sputum and the same material was used for inoculating the calves by hypodermic injections. The calves were again tested after 2½ months and 3 of the 4 gave a reaction. An autopsy on one of the calves showed a slight enlargement of some of the lymph nodes but no tubercle bacilli were present. The tuberculin reaction is explained by the author as due to the presence of living and dead tubercle bacilli at the point of inoculation. The 3 other calves are reported as in good health and gaining in weight.

Further experiments regarding the immunization of cattle against tuberculosis, J. McFADYEAN (*Jour. Comp. Path. and Ther.*, 15 (1902), No. 1, pp. 60-71, fig. 1).—The present paper contains a report of experiments conducted by the author, during which an attempt was made to demonstrate the effect of repeated injections of tubercle bacilli in calves, with special reference to the possibility of an immunizing effect of such injections. Each of the 4 calves received from 7 to 11 inoculations of virulent tubercle bacilli at intervals of different length. Calf No. 1 received 1½ cc., 2 cc., 2 cc., 5 cc., 5 cc., on January 11, April 1, November 28, January 30, and May 18, respectively. A sixth inoculation with 5 cc. was given on July 31, and a seventh, with 10 cc., on October 24. The size of the doses and the length of time between the doses were approximately the same in all the calves. The cultures which were used in making the inoculations were constantly tested by inoculations of guinea pigs. The calves were inoculated intravenously in all the experiments.

All 4 calves ultimately died of tuberculosis. They resisted the fatal outcome of the disease, however, for an unusually long time, and the author ascribes this strong resistance to partial immunity produced by repeated inoculations. Almost without exception cattle succumb very rapidly to intravenous injections of virulent tubercle bacilli. The bacilli used in these experiments were not of human origin, but were obtained from a natural case of tuberculosis in a dog, and also by passage through a rabbit of cultures obtained from a case in a sheep. Upon making post-mortem examinations of the 4 cases the absence of lesions in the spleen and liver and the constancy of lesions in the kidneys were observed. During the period covered by the experiments the animals were frequently tested with tuberculin, and reacted in an irregular and uncertain manner. At times a good reaction was obtained, while at other times no reaction whatever or only a slight local reaction without rise of temperature developed. As a rule, during these tuberculin tests the maximum temperature was reached between 6 and 9 hours after injection.

Wheezing as a result of retropharyngeal tuberculous adenitis in cattle, C. BESNOT (*Rev. Vet. [Toulouse]*, 27 (1902), No. 6, pp. 365-377, fig. 1).—Notes are given on the symptoms and development of this peculiar affection, and a special report is made on a case in a cow which was finally subjected to emergency slaughter. During life the animal had exhibited symptoms of difficult respiration and at times had been apparently in danger of strangulation. The post-mortem examination revealed a generalized tuberculosis, with the development of a large tumor in the retropharyngeal glands. This tumor pressed upon the larynx so as to cause difficulty in breathing.

A proposal of a new plan for controlling tuberculosis of cattle conservatively, "COLUMELLA" (*Jour. Comp. Med. and Vet. Arch.*, 23 (1902), No. 1, pp. 16-21).—In view of the great expense which would be incurred by the State in paying an indemnity for all tuberculous animals, a plan is suggested in this article whereby all possible service may be secured from tuberculous cattle and no unnecessary loss suffered. It is suggested that certain persons be licensed to purchase tuberculous cows, that these licenses be granted subject to a board appointed for the purpose, and be free, but under certain restrictions exercised by the board. It is recommended that all tuberculous animals bought or sold by such licensed persons be branded or marked in some other way easily recognizable. The milk is to be pasteurized and sold as milk or made into butter. Calves are to be removed from the cows after 3 days and the cows especially inspected from time to time, and when unfit for milk production may be brought to a market condition, if possible, and sold for meat, under certain restrictions. It is suggested that this plan might encourage farmers to eliminate tuberculous cattle from their herds.

The X-ray as an aid to diagnosis of tuberculosis in cattle, J. V. LADNEY (*Jour. Comp. Med. and Vet. Arch.*, 23 (1902), No. 2, pp. 97-104, figs. 4).—The author tested the value of X-rays in the diagnosis of bovine tuberculosis in all its stages. A

number of radiographs were taken, some of which are reproduced in the text. It appears from the author's observations that the presence of even small tubercles in the lungs may be detected by the use of X-rays. The tubercles may be discovered in this way with considerable certainty as soon as calcification takes place. In advanced cases of tuberculosis, in which the clinical symptoms of the disease are not pronounced and in which tuberculin fails to give a reaction, the use of X-rays furnishes a valuable means for detecting the tuberculous foci in the lungs or other organs.

Culture and biology of the tubercle bacillus, H. MENZI (*Ztschr. Hyg. u. Infektionskrankh.*, 39 (1902), No. 3, pp. 407-427).—The author undertook experiments to test the validity of results obtained by Dr. W. Hesse in cultivating tubercle bacillus upon an agar medium to which Heyden's nutrient material was added. As a result of numerous experiments it was found that the Hesse agar is a good nutrient medium for pure cultures of tubercle bacilli, being about equal to the blood of cattle. In the author's experiments the virulence of the tubercle bacillus was retained for several months upon a Hesse agar without exhibiting any pronounced increase or attenuation. With the use of this nutrient medium it was found possible to observe an increase in the tubercle bacilli in the sputum in a few days. If, however, the number of bacilli in the sputum was very small, it proved a difficult matter to follow their development upon the Hesse agar and this nutrient medium was found to possess no advantage over direct microscopic investigations for this purpose. The organisms which are associated with tubercle bacilli are somewhat checked in their development by the Hesse agar, but not sufficiently to allow small colonies of tubercle bacilli to be readily distinguished. The author argues, therefore, that we have no generally applicable method for isolating tubercle bacilli except that of inoculation of experimental animals.

Studies on the action of urea and ammonium carbonate on cultures of tubercle bacillus in bouillon, RAPPIN (*Compt. Rend. Soc. Biol. Paris*, 54 (1902), No. 10, pp. 318-320).—In this paper the results previously obtained by the author are confirmed. It was found that urea in the proportion of 0.003 or 0.005 gm. to 1 gm. per 100 gm. of bouillon exercised a restraining influence upon the development of the tubercle bacillus. This effect of the urea was destroyed by the addition of glucose in the proportion of 5 parts in 100 of bouillon. Similar results were obtained by the use of ammonium carbonate, the latter substance checking the development of tubercle bacillus, even more than did urea. An antiseptic effect was observed when used in the proportion of 0.001 gm. to 100 gm. of bouillon.

The resisting power of buffaloes against experimental tuberculosis, M. PRETTNER (*Centbl. Bakt. u. Par., 1. Abt.*, 31 (1902), No. 14, Orig., pp. 681-686).—A number of experiments were conducted for the purpose of testing the resisting power of these animals to tuberculosis. During these experiments it was found that buffaloes were remarkably refractory to inoculation with tuberculosis material in general, and that they showed complete immunity against inoculation with artificial cultures. Pure cultures acted as if they were attenuated when inoculated into buffaloes. It is stated that among 5,000 buffaloes slaughtered for meat which were inspected by the author, no case of tuberculosis was observed.

The effect of tubercle bacilli introduced in the trachea upon the lungs of rabbits, K. WATANABE (*Beitr. Path. Anat. u. Allg. Path.*, 31 (1902), No. 2, pp. 367-382, figs. 7).—The author's experiments consisted in making intratracheal injections of tubercle bacilli in rabbits and studying, by means of microscopic preparations, the alterations which the bacilli caused in the lungs at varying periods of time. It was found that the tubercle bacilli first attacked the epithelial elements of the minute bronchi and alveoli. In these situations swelling and separation of epithelial cells are occasioned. Simultaneously a serous exudation occurs and an accumulation of polynuclear leucocytes. The first stage of infection is, therefore, a sort of catarrhal

inflammation. Secondly proliferation of the tissue may occur, accompanied with an accumulation of mononuclear leucocytes while the polynuclear leucocytes decrease in number. The giant cells were found to arise by fusion of the other cells.

Histogenesis of hematogenous tuberculosis in the liver of rabbits, J. MILLER (*Beitr. Path. Anat. u. Allg. Path.*, 31 (1902), No. 2, pp. 347-366, pl. 1).—The author gives a brief critical review of the literature relating to the histogenesis of tubercles in different organs of various animals. The experiments reported in this article were made upon rabbits. Direct injections of virulent tubercle bacilli were made into the veins of the liver and the affected rabbits were killed at various lengths of time after inoculation in order to make possible a careful study of the tubercles in the liver. As a result of these experiments it was found that after a hematogenous infection the development of the tubercle in the liver of rabbits begins with an intravascular and perivascular inflammation with polynuclear leucocytes. The first alteration of the fixed tissue cells of the liver in rabbits consists in a swelling and separation of the endothelial cells of the capillaries. These endothelial cells form the epithelioid and giant cells of the tubercle. It was found that a typical tubercle might arise without any observable mitosis. Giant cells were found to arise by fusion of the separated capillary endothelial cells. In the development of the tubercle the liver cells took no active part. The fate of the tubercle bacilli in the liver was not determined by the author. He was unable, however, to observe any leucocytes containing the bacilli.

Hematological studies on experimental tuberculosis of guinea pigs, H. CLAUDE and A. ZAKY (*Compt. Rend. Soc. Biol. Paris*, 54 (1902), No. 16, pp. 505-507).—The authors conducted an extensive series of experiments on guinea pigs for the purpose of determining the relative variation in the number of different corpuscles in the blood at different stages in the development of tuberculosis and under the influence of various lines of treatment. The guinea pigs were divided into 8 lots, of which 1 lot was untreated, and the other 7 lots received various lines of treatment, including injections of lecithin, with or without the addition of creosote or sulphate of iron. The number of red and white corpuscles of various kinds in the blood at different stages of the disease are presented in tabular form.

The influence of an exclusive meat diet on inoculation of tuberculosis in chickens, K. PREISICH (*Centbl. Bakt. u. Par.*, 1. Abt., 31 (1902), No. 15, Orig., pp. 749-758).—The author conducted 2 series of experiments, one in Paris and one in Budapest. In the first series 9 chickens were used in the experiment, 5 of which were fed exclusively on raw horse meat, receiving daily 150 gm. to 200 gm.; the other chickens were fed grain. The chickens were inoculated with tuberculosis from 23 to 53 days after beginning the meat diet. One chicken which received the meat diet died at about the same time with a control chicken, while 3 meat-fed chickens remained healthy, and 3 grain-fed chickens died of miliary tuberculosis. In the second series of experiments 14 chickens were used, of which 8 were fed exclusively on horse meat and 6 were fed corn. The results of these experiments are presented in a detailed tabular form. The influence of the meat diet noticeably prolonged the life of infected chickens, but was not sufficient to overcome infection in any large percentage of cases.

The contamination of meat of healthy animals with tubercle bacilli through nondisinfected slaughter or inspection instruments, G. DECKER (*Ztschr. Fleisch u. Milchhyg.*, 12 (1902), No. 8, pp. 225-231).—In these experiments the purpose of the author was to determine whether in the practice of meat inspection or during the slaughter of animals healthy meat might become infected by the instruments of the butchers or by the knives used in inspection, and also to discover suitable means of preventing this infection. The results of experiments on the first point were positive. Of 47 pieces of meat and meat products handled in the ordinary manner, it was found that 19, or 40.42 per cent had become contaminated with

virulent tubercle bacilli. An examination was made of 13 meat inspectors' knives, and 10 of these, or 76.59 per cent, were contaminated with the tubercle bacillus. A similar examination was made of 9 butchers' knives, showing that 3 were infected. In experiments to determine the best method of preventing infection by these means it was found that the tubercle bacilli on the knives of meat inspectors and butchers could be readily destroyed by placing these instruments in a 2 per cent solution of soda at a boiling temperature.

Preliminary report on the use of blackleg vaccine in Virginia, E. P. NILES (*Virginia Sta. Bul.* 123, pp. 31-37).—The station has been distributing blackleg vaccine since 1898, and the reports received from stock owners indicate that the losses among cattle before the use of vaccine amounted to 11.07 per cent, while after vaccination the losses average 0.89 per cent. The disease appears to be on the increase in Virginia but it is believed that it could be checked by concerted action.

Irrigation of the organism in experimental infection of tetanus, C. TONZIG (*Pub. Ist. Univ. Padova*, 2 (1902), VI, pp. 11; *extr. from Riforma Med.*, 17 (1901), No. 109).—The author conducted a number of experiments in the treatment of tetanus. It was found that no hope can be entertained for favorable results in the treatment of tetanus by peritoneal irrigation of the affected animal with a physiological salt solution. During these experiments it was shown that the tetanus virus does not operate in the circulation but becomes fixed in the histological elements.

Traumatic tetanus in horses, C. EGGMANN (*Schweiz. Arch. Tierh.*, 44 (1902), No. 1, pp. 26-29).—Detailed notes are given on the treatment of a severe case of tetanus in a horse. During the treatment the horse received 70 cc. of antitetanus serum, 70 cc. carbolic-acid solution subcutaneously, 190 gm. chloral hydrate per rectum, and 1 gm. of morphin in 2 doses. The antitetanus serum did not check the redevelopment of the violent symptoms, nor could these be controlled by the other remedies. The horse died on the third day after the appearance of the disease.

The production of toxoids in cultures of tetanus bacilli, A. BOXOME (*Centbl. Bakt. u. Par.*, 1. Abt., 31 (1902), No. 15, *Orig.*, pp. 777-781).—An attempt was made by the author to determine by culture experiments the changes undergone by the toxin of tetanus bacillus on culture media. It was found that a rapid alteration of the toxin may take place in artificial cultures. The modified toxin is called toxoid. It was found that the filtrate from a culture of *Bacterium coli* exercised a decided influence upon tetanus bacillus and its product, when the latter was exposed to its action for a half hour at a temperature of 80° C., or for a few minutes at a temperature of 100° C. It is believed that the facts thus brought to light may be of importance in producing immunization in animals which are especially susceptible.

Intracerebral injection of antitetanin for the cure of tetanus in the horse, S. VILLAR (*Jour. Comp. Path. and Ther.*, 14 (1901), No. 4, pp. 371, 372).—The author describes 2 cases of tetanus in the horse treated by means of intracerebral injections of antitetanin. The symptoms became more favorable within a few hours after the injection, and recovery took place in both cases within about 3 weeks. In 1 case 3 cc. of pure antitetanin and in the other 8 cc. were administered.

Investigations on the nature of tetanus toxin, H. HAYASHI (*Arch. Exper. Path. u. Pharmacol.*, 47 (1901), No. 1-2, pp. 9-18).—As a result of the author's studies it was found that the toxin isolated from cultures of the tetanus bacillus according to the method of Brieger and Boer shows an evident protein reaction. The toxin, therefore, belongs to this group of chemical bodies. It is partly precipitated in a saturated solution of magnesium sulphate. When precipitated with absolute alcohol no alteration of the physical or toxic properties of the toxin were produced. It was found also that the tetanus bacillus would not grow on a medium which does not contain protein.

Actinobacillosis, J. LIGNIÈRES and J. SPITZ (*Actinobacillose. Buenos Ayres: Coni Bros.*, 1902, pp. 108, pls. 9; *extr. from Rev. Soc. Méd. Argentina*).—The authors have

undertaken an extensive study of the diseases included under the name actinomycosis. During these investigations it was found that a large number of cases were not due to the ordinary streptothrix of actinomycosis, but to a bacillus which produces very similar pathological lesions. The disease is therefore called actinobacillosis on account of its being due to a bacillus which produces radiate structures in affected tissues. The disease has been known in Argentina for a number of years but an especially extensive outbreak occurred during the years 1900 and 1901. Actinobacillosis occurs under a number of forms and may affect different tissues, such as the skin, subcutaneous connective tissue, lymphatic glands, salivary glands, and various parenchymatous tissues. Among the vital organs the lungs, tongue, and pharynx are most often affected. The tegumentary form of the disease occurs most frequently in the region of the pharynx, where large tumors are formed which may ultimately open and discharge a part or all of their contents. As contrasted with the ordinary form of actinomycosis due to streptothrix, this form of the disease affects the lymphatic glands very frequently. It is especially frequent in the glands about the pharynx, including the retropharyngeal and sublingual. When the tongue is affected by actinobacillosis this organ becomes altered so as to present the usual symptoms of wooden tongue. Detailed notes are given on the pathological changes produced by the disease in the pharynx, salivary glands, mammary glands, and internal organs.

Considerable evidence is presented to show that actinobacillosis is infectious and that it spreads rapidly among herds of cattle. It is almost entirely confined to cattle, but may occasionally occur in sheep and other animals. The mortality in some outbreaks of the disease was as high as 52 per cent. The morphological characters and behavior of the organism on the various nutrient media are described in detail. The organism is said to possess only a slight resisting power against physical and chemical agents. It is killed by subjection to a temperature of 100° C. for 1 minute or 52° C. for an hour and a half. It is only slightly resistant to desiccation. A toxin was readily obtained from cultures of the organism, and its injurious action was tested on experimental animals. It was found that the serum of animals which had received a culture of the bacillus or of the toxin acquired remarkable agglutinating powers toward the organism. The agglutinating power manifests itself within 3 or 4 days after subcutaneous inoculation in cattle and horses, and persists for a considerable length of time. The intensity of agglutinating power varies with different animals.

Detailed notes are given on inoculation experiments in various animals. Guinea pigs were susceptible to the bacillus, while rabbits were quite resistant and birds entirely refractory. Dogs, cats, and pigs were destroyed by hypodermic inoculation, while horses and donkeys were very resistant.

Iodid of potash was found to be almost a specific for actinobacillosis. Under prolonged treatment with this remedy the lesions disappeared and a complete recovery took place in a large percentage of cases. Where superficial tumors are found it is recommended that they be opened and that the pus be evacuated. This should be followed by the ordinary treatment. The disease is recurrent and one attack does not confer immunity.

Actinomycosis, J. BARCIA Y TRELLES (*L'Ing. Agr. Gembloux*, 12 (1902), No. 10, pp. 472-486).—A general description and discussion of this disease is presented, giving an account of the distribution, clinical symptoms, nature, bacterial cause, morbid infection, serum diagnosis, prophylaxis, treatment, and immunity.

Observations on vertebral actinomycosis in cows, POES (*Ann. Med. Vet.*, 51 (1902), No. 2, pp. 89-92).—In connection with the numerous cases of tubercular meningitis observed in cattle, the author considers it of importance to report the occurrence of actinomycosis of the membranes of the spinal cord, accompanied with nervous symptoms somewhat resembling those of tubercular meningitis. Upon post-

mortem examination, a tumor is found surrounded by a sort of fibrous membrane. The tumor is of a grayish or brownish color, and after being sectioned is found to contain minute yellow granular colonies of actinomyces.

The unsolved problems of milk fever, J. M. W. KITCHEN (*Jour. Comp. Med. and Vet. Arch.*, 23 (1902), No. 4, pp. 230-234).—The various doubtful problems concerning the etiology of this disease are discussed by the author, in connection with detailed notes on a case in which the iodid of potash treatment was used in connection with other remedies.

An enzootic attack of chorea among cattle, A. D. KNOWLES (*Jour. Comp. Med. and Vet. Arch.*, 23 (1902), No. 1, pp. 37-40).—The author reports the occurrence of symptoms of chorea among cattle after being allowed to fatten upon a 40-acre field which was fenced in during the summer and not grazed until fall. The symptoms appeared for 2 or 3 years in succession, and at times became quite serious, but did not result fatally except in one case where the animal fell into a ditch of water in one of its fits and was thoroughly chilled. The etiology of these outbreaks is not explained. It was possibly due to eating poisonous plants.

Poisoning by feeding on *Sinapis nigra*, F. J. ROUB (*Jour. Comp. Med. and Vet. Arch.*, 23 (1902), No. 4, pp. 242-244).—Notes are given on a case of poisoning from eating this plant during which 11 cows died and 7 others were badly affected. The cows had been allowed to eat large quantities of the mustard and were affected with a rather uniform set of symptoms, including coldness of the extremities, difficult respiration, dullness of the sensorium, and more or less difficult locomotion. Some of the cows staggered and occasionally fell. Seven of the cows were treated with sulphate of soda, in 1½-lb. doses, together with nux vomica and spirits of niter. All of them recovered from the effects of the poison.

Foot-and-mouth disease, with an account of the outbreak in Suffolk during 1901, E. J. CHENEY (*Agr. Students' Gaz.*, n. ser., 10 (1902), No. 5, pp. 135-140).—Notes are given on the symptoms of this disease and its infectiousness for different species of domesticated animals. An account is also presented of a number of outbreaks which occurred in Suffolk during 1901. The probable origin of these outbreaks is discussed with a view to devising means for preventing similar outbreaks in the future.

The ineffectiveness of Baccelli's method for treating foot-and-mouth disease, M. STREBEL (*Schweiz. Arch. Tierh.*, 44 (1902), No. 2, pp. 72-76).—The author gives a critical review of the literature of this subject, from which it appears that many investigators have tested the effect of intravenous injections of corrosive sublimate in treating foot-and-mouth disease, without good results.

Corrosive sublimate, the newest remedy for foot-and-mouth disease, M. STREBEL (*Schweiz. Arch. Tierh.*, 44 (1902), No. 1, pp. 19-26).—The treatment of foot-and-mouth disease by intravenous injections of corrosive sublimate, as recommended by Baccelli, has not given good results in the hands of other investigators. The author conducted a number of experiments in making intravenous injections in animals affected with foot-and-mouth disease, and found that the action ascribed to corrosive sublimate by Baccelli did not take place. In 3 animals a considerable increase of temperature was produced; in 3 others the temperature was unaffected; while in another 3 the temperature was slightly lowered. No curative effect was observed. The treatment was applied from 6 to 8 days after the appearance of the disease.

Pustulous dermatitis of cattle, E. LIÉNAUX (*Ann. Med. Vet.*, 51 (1902), No. 5, pp. 237-245).—A description is given of a malignant form of dermatitis, with the formation of pustules and with fatal result in one case. In this case attempt was made to treat the pustules with antiseptic washes, but without result. The cause of death in this case does not appear very clear, without assuming septicemic infection. The

evidence for such infection, however, was wanting, since all the internal organs were found to be intact.

Contagious pustular dermatitis of sheep, A. H. BERRY (*Jour. Comp. Path. and Ther.*, 14 (1901), No. 4, pp. 307-312).—The nature, symptoms, and pathological lesions of this disease are briefly discussed. Notes are also given by way of differential diagnosis between this disease and foot-and-mouth disease. As treatment the author recommends isolation of affected sheep; a change of pasture where possible to high, well-drained land; the administration of tonics and alteratives, such as a mixture of common salt, iron, and gentian; and local treatment of the pustules with some antiseptics, such as lysol, carbolic acid, or permanganate of potash.

The lesions in sheep pox; their complete similarity from a microscopical and histological standpoint with the lesions of cow pox, variola, syphilis, and cancer, F. J. BOSCH (*Compt. Rend. Soc. Biol. Paris*, 54 (1902), No. 4, pp. 114-116).—The author describes in detail the pathological processes which develop during this disease, in the skin, subcutaneous tissue, lungs, stomach, and liver.

The existence in all lesions of virulent sheep pox and in the blood of animals affected with this disease, of special bodies of a definite structure, and their structural and developmental similarity to the sporozoa, F. J. BOSCH (*Compt. Rend. Soc. Biol. Paris*, 54 (1902), No. 4, pp. 117-119).—The author reports the finding of peculiar bodies in the lesions of sheep pox which bear close resemblance to sporozoa. Sections were made of the diseased tissue, and a number of staining methods were tried with considerable success in differentiating the bodies. A number of forms of this organism were observed and were apparently stages in reproduction by the karyokinetic method.

True epithelioma in the liver in cases of sheep pox, F. J. BOSCH (*Compt. Rend. Soc. Biol. Paris*, 54 (1902), No. 9, pp. 271, 272).—The author describes in detail the general appearance of the liver of sheep affected with pox, and also the pathological histology observed in this organ. The liver may become much enlarged and exhibit symptoms of fatty degeneration, nodular hypertrophy, vascular lesions, and a true cancerous condition or epithelioma of trabecular origin.

Sheep scab, J. SPENCER (*Virginia Sta. Bul.* 124, pp. 39-46, figs. 4).—Brief popular notes on the symptoms, treatment, and method of dipping sheep for this disease.

The stomach worm, J. SPENCER (*Virginia Sta. Bul.* 126, pp. 53-58).—*Strongylus contortus* is reported as causing considerable losses, especially among sheep. Notes are given on the means of infection, symptoms, treatment, and post-mortem appearances of this disease.

Heart water in sheep and goats, D. HUTCHESON (*Agr. Jour. Cape Good Hope*, 20 (1902), No. 11, pp. 633-639).—The symptoms of the disease are described, and an account is given of the agency of ticks in carrying the disease, and of various experiments in the use of bile and blood serum treated in different manners for the purpose of producing immunity to the disease. These notes are based chiefly on the experiments by Dixon and Spreull.

Lungworm disease among members of the deer family in Bohemia, G. ZACFAL (*Ztschr. Tiermed.*, 5 (1901), No. 2-3, pp. 148-159).—For a number of years especially since 1886, epizootics of considerable extent have been observed among different species of deer in various parts of Bohemia. At first the death of the game was supposed to be due to unusual exposure in cold weather and the consequent contraction of pneumonia and other affections of the lungs. Later, however, it was observed that certain species of lungworms are invariably present in outbreaks of the disease and these worms were subsequently shown to be the cause of the disease. Notes are given on the post-mortem findings in a number of cases. It was found that the species of worms which cause the lungworm disease of deer in Bohemia are *Strongylus filaria* and *S. commutatus*. The author calls attention to the importance of

the infestation of other animals by these worms in preventing the lungworm disease among deer. A considerable percentage of the hares which were examined were found to be infested with the same species of worm which caused the lungworm disease in deer, and it is believed that the infestation of hare may be responsible in some degree for the spread of the disease during the year.

A few diseases of the hog, A. T. PETERS (*Missouri State Bd. Agr. Rpt. 1902, pp. 399-405*).—Notes are given on various diseases of the respiratory organs, especially coughing in young pigs and verminous pneumonia; and on diseases of the mouth, intestinal parasites, and paralysis of the hind legs. Where hogs become badly infested with lice it is recommended that they be dipped at frequent intervals. For this purpose the various coal-tar preparations, such as zenoleum and chloronaphtholeum are considered effective.

Swine fever, A. H. BERRY (*Jour. Comp. Path. and Ther., 15 (1902), No. 1, pp. 1-21*).—In this paper the author gives a general account of hog cholera, including its introduction and spread in Great Britain; symptoms of the disease in the peracute, acute, and chronic forms; methods of taking the temperature of diseased pigs; normal and pathological conditions in the alimentary tract which may be mistaken for hog cholera; pathological lesions of the disease; and the mortality in various localities. Attention is called also to the modes of infection, period of incubation, and methods of applying disinfectants so as to prevent undue distribution of the disease.

A preliminary report on glanders, S. B. NELSON (*Washington Sta. Bul. 50, pp. 28, pls. 5*).—The station began experiments with mallein 6 years ago, and in the present bulletin records of 76 animals treated with mallein are brought together. Of this number 36 reacted, while 40 failed to react. In 33 of the cases which reacted external symptoms of glanders were present. Notes are given on the symptoms of all the cases.

A number of experiments were planned to test the effect of repeated inoculation with mallein. In 1 experiment a horse received 1 cc. of mallein at first, the injection being repeated 1 week later, and thereafter at shorter intervals until the injection was given daily, when the amount was increased by 0.25 cc. daily until the daily injection reached 7 cc. The treatment was continued from February 2 to July 15. During the treatment the animal lost in flesh, but gained somewhat after the treatment was discontinued. The animal died in November, and it was found that the lungs were partly filled with pus and the nasal mucous membrane was covered with ulcers. In a second test an animal received 1 cc. of mallein monthly. The animal died after the experiment had been continued for 5 months. The post-mortem examination disclosed the presence of farcy buds and ulcers on the upper portion of the air passages. In the third test a mule received 1 cc. of mallein at the first injection, and injections were repeated at monthly intervals, being doubled each time. This animal also died during the course of the experiment, and post-mortem examination showed abundant evidence of active glanders. In the fourth experiment mallein was injected at weekly intervals, beginning with doses of 1 cc. and being increased 1 cc. each week. The experiment lasted from April until July, when the animal died in a greatly emaciated condition. Glanderous tubercles were found in both lungs. A fifth experiment was conducted for the purpose of testing the subject of infection of glanders. A horse which was shown by mallein test not to have glanders was turned into a corral with 2 glanderous horses on July 17. The animal failed to react to mallein on September 14 and also during October. On December 1 the animal was shot for the purpose of examination, and no evidence of glanders was found. An experiment in direct inoculation was made in which glanderous material was rubbed into the mucous membrane of the nose. This operation was performed on June 17, and on November 28 the animal died, showing the characteristic lesions of glanders. Popular notes are also given on the cause and methods of transmission, symptoms, and eradication of glanders.

Glanders in South Africa, R. C. COCHRANE (*Jour. Comp. Path. and Ther.*, 15 (1902), No. 1, pp. 31-40, figs. 3).—It is stated that during the South African war the number of cases of glanders among horses in South Africa increased greatly. A part of this increase was due to the fact that the nature of the disease was not recognized by the horse owners, and healthy animals were allowed to come in contact with diseased ones. Of 12,540 horses and mules admitted to a hospital for examination, 315, or 2.5 per cent, were found to be affected with glanders. Some of these gave both a local and temperature reaction, while others gave either the temperature reaction alone or simply the local reaction. Detailed notes are given on the history of 11 cases for the purpose of indicating the accuracy of mallein as a test for glanders. Further experiments were made in inoculating donkeys and other animals for the purpose of testing the virulence of glanderous virus.

Clinical notes on African horse sickness, J. T. COLEY (*Jour. Comp. Path. and Ther.*, 14 (1901), No. 4, pp. 373-376, fig. 1).—Notes are given on the symptoms, pathological anatomy, and treatment of this disease. A large number of remedies were tested, but no satisfactory results were obtained except from the intravenous injection of a solution containing 4 grains of iodine and 15 grains of potassic iodide in 1 dram each of glycerin and boiling water.

The veterinary inspection of imported American horses, P. T. HOWARD (*Jour. Comp. Path. and Ther.*, 14 (1901), No. 4, pp. 336-342).—Notes are given on the usual forms of disease which are found in imported horses either as a result of infection during shipment or from previous infection. It is stated that cases of glanders observed among horses imported from America are rare, the total number recorded being 6. For the purpose of preventing the spread of infectious diseases the author recommends careful inspection of all horses when landed and isolation of diseased ones, a more vigorous inspection at the time of embarkation, and disinfection and ventilation of devices used for transporting animals.

Ship pneumonia, E. E. MARTIN (*Jour. Comp. Path. and Ther.*, 14 (1901), No. 4, pp. 343-345).—The form of pneumonia which usually develops among horses on board ships is compared with that which is most frequently observed on land. In case of the land form of pneumonia, there is a specific course of the disease marked by a definite crisis. The appetite is lost, constitutional symptoms are well marked, gangrene is quite exceptional, and there is a good percentage of recoveries. In ship pneumonia, on the other hand, the disease runs an irregular course, sometimes resembling that of septic intoxication, the appetite often remains good, the constitutional symptoms are irregular, gangrene of the lungs is always observed, and recovery is rare. Ship pneumonia is considered a true gangrene of the lungs. It is possible that the large percentage of mortality from ship pneumonia may be due to badly ventilated quarters on board ship.

Combating pneumonia by serum treatment, MIECKLEY (*Arch. Wiss. u. Prakt. Thierh.*, 28 (1902), No. 1-2, pp. 102-109).—A series of experiments was conducted by the author for the purpose of determining the value of disinfection of stables in outbreaks of this disease and of the application of serum treatment. Disinfection of stables was not very successful, and negative results were obtained from inoculation with serum.

Nodular peribronchitis of the horse, of a verminous origin, E. LIÉNAUX (*Ann. Med. Vet.*, 51 (1902), No. 2, pp. 80-88, fig. 1).—A description is given of cases in which nodules were found in the walls of the bronchi. The contents of these nodules were often found to be in process of degeneration of a caseous or calcareous nature. Cases of nodular peribronchitis may readily be distinguished from glanders by the fact that in the former disease the corresponding lymph glands are not affected, while in glanders they are usually swollen and pathologically altered.

Mange in horses, J. SPENCER (*Virginia Sta. Bul.* 125, pp. 47-52, figs. 2).—This disease broke out among horses in Tazewell and Giles counties, Virginia. Notes are given on the symptoms and means of transmission of this disease. A 2 per cent

solution of chloro-naphtholeum was applied to the horses twice a week until the symptoms disappeared.

Malignant mold fungus disease of horses, J. DE HAAN (*Centbl. Bakt. u. Par.*, 1. Abt., 31 (1902), No. 15, Orig., pp. 758-763, figs. 2).—The author described a disease of horses caused by a mold fungus, and which was characterized by lesions of the skin and mucous membranes. The mucous membrane of the mouth, lips, and nose are most susceptible to attacks of the disease. The pathological process gradually spreads to tissue surrounding the primary focus, without regard to the kind of tissue involved. The process extends more rapidly in the mouth cavity than in the skin. Experiments in the administration of iodid of potash indicate that this remedy may have in some cases a beneficial effect. Otherwise the diseased patches should be removed at once by operation.

Wandering bot-fly larvæ, C. LEKNES (*Norsk Vet. Tidsskr.*, 14 (1902), No. 1-2, pp. 39-42).—The author reports in detail observations made on a horse infested with bot-fly larvæ. A number of the larvæ were found under the skin, in which situations they produced abscesses of considerable size. Eleven such abscesses were found in the lumbar region of the animal, and others were observed on other parts of the body.

Tibio-peroneal neurectomy for the relief of spavin lameness, W. E. A. WYMAN (*New York: W. R. Jenkins*, 1902, pp. 30, fig. 1).—The author presents a detailed description of this modification of the operation for the relief of spavin lameness. In all, 91 operations of this sort were performed. Of this number there was a healing of the tibial wound in 65 cases, while the peroneal site healed in 40 cases by first intention; muscular hernia occurred in 8 cases, loss of the hoof in 3 cases, and septic infection in 1 case. Four cases remained lame. There was a complete removal of lameness in 55 cases, while a slight lameness persisted in 18 cases.

Diagnosis of anthrax, O. HOSANG (*Arch. Wiss. u. Prakt. Thierh.*, 28 (1902), No. 3-4, pp. 372-380).—In experiments instituted by the author it was found that when material from animals dead with anthrax was smeared on a cover glass in a thick layer and allowed to dry, the anthrax bacilli retained their virulence for 2 or 3 days. During these experiments it was found that blood and spleen tissue which were taken from mice or guinea pigs 2 days after death and preserved for 3 days at a living temperature, were still capable of producing infection in healthy mice. Blood and spleen tissue taken from guinea pigs 4 days after death and preserved for from 24 to 48 hours were still virulent for the majority of mice on which experiments were made, as shown by the fact that 7 out of 8 inoculated mice died of anthrax. It is believed by the author that this method of placing a thick layer of infected tissue or other material upon a cover glass and allowing it to dry is a valuable one and permits the preservation of the material in a virulent condition for a reasonable length of time.

The pyocyanase of Emmerich and Leow in experimental anthrax, L. TAVERNARI (*Centbl. Bakt. u. Par.*, 1. Abt., 31 (1902), No. 15, Orig., pp. 786-793).—Experiments on guinea pigs and a rabbit indicated the favorable effect of the use of pyocyanase, in that death from experimental anthrax was postponed for considerable time. Pyocyanase, however, appeared not to have the effect of preventing a fatal outcome of the disease. The edematous swellings observed in experimental animals after inoculation were developed to a much less extent when the animals were treated with pyocyanase.

Some observations on the Bacillus anthracoides, F. A. BAINBRIDGE (*Jour. Path. and Bact.*, 8 (1902), No. 1, pp. 117-120).—The author's observations on this organism were made on material obtained from Chinese horsehair, which had already been subjected to a boiling temperature long enough to destroy all except spore-bearing organisms. The anthrax bacillus was also found associated with *B. anthracoides*. The latter organism is described as a straight, short, thick rod, which usually forms chains of 8 or 10 bacilli, is motile, stains with aniline dyes, and does not

decolorize by Gram's method. Spore formation takes place after 18 hours' growth, at a temperature of 37° C. The organism may be cultivated on all ordinary media and growth takes place best at a temperature of 37° C. The bacilli are destroyed by exposure to a temperature of 72° C. for 10 minutes, and the spores were killed by being maintained at 100° C. for 5 minutes. Mice when inoculated with this bacillus invariably died in less than 48 hours. The spleen was found enlarged. Guinea pigs inoculated with 1 cc. of a culture of the organism developed an inflammatory nodule at the point of inoculation, or in some cases appeared to be infected. The organism in question resembles closely the anthrax bacillus, but differs from it, however, in its motility and its very limited pathogenic powers.

Anthrax in dogs, LÜPKE (*Deut. Tierärztl. Wchnschr.*, 9 (1901), No. 48, pp. 485-489).—In the author's opinion the usual text-book statements concerning the prevalence and seriousness of anthrax in dogs is inadequate. The matter is frequently treated as if anthrax was an exceedingly rare disease in dogs. Attention is called to the frequency of the occurrence of anthrax in dogs and a number of examples are cited where dogs became fatally infected from eating the meat of animals dead of anthrax. The usual symptoms of anthrax in dogs are described in detail.

Rabies, D. E. BAUGHMAN (*Amer. Vet. Rev.*, 26 (1902), No. 2, pp. 115-123).—Attention is called to the recent controversy in which the existence and nature of rabies have been involved. The author gives a critical review of some of the more important literature on the subject, and accepts the view that rabies is a real disease, produced by a virus which may be communicated by means of the bites of dogs and other animals.

Antitoxin in distemper, H. A. STEVENSON (*Jour. Comp. Med. and Vet. Arch.*, 23 (1902), No. 2, p. 116).—In a case of dog distemper, in which all of the usual symptoms were present and in which the ordinary remedies failed to produce the desired result, Mulford's distemper antitoxin was used in doses of moderate size and caused a decided improvement in the condition within 24 hours. After 48 hours the discharge from the nose was checked and a complete recovery took place inside of one week.
